ANALYSIS OF CONTINUOUS FRAMES BY DISTRIBUTING FIXED-END MOMENTS[1]

By Hardy Cross,[2] M. Am. Soc. C. E.

With Discussion by Messrs. C. P. Vetter, L. E. Grinter, S. S. Gorman, A. A. Eremin, Elmer F. Bruhn, A. H. Finlay, R. F. Lyman, R. A. Caughey, Orrin H. Pilkey, I. Oesterblom, Robert A. Black, H. E. Wessman, Edward J. Bednarski, S. N. Mitra, Jens Egede Nielsen, F. E. Richart, William A. Oliver, R. R. Martel, Clyde T. Morris, Francis P. Witmer, T. F. Hickerson, F. H. Constant, W. N. Downey, E. C. Hartmann, Thomas C. Shedd, David M. Wilson, Marshall G. Findley, George E. Large, Sophus Thompson and R. W. Cutler, Alfred Gordon, A. W. Earl, A. Floris, I. M. Nelidov, E. A. MacLean, George M. Dillingham, Donald E. Larson, J. A. Van den Broek, and Hardy Cross.

Synopsis

The purpose of this paper is to explain briefly a method which has been found useful in analyzing frames which are statically indeterminate. The essential idea which the writer wishes to present involves no mathematical relations except the simplest arithmetic. It is true that in order to apply the method it is necessary to determine certain constants mathematically, but the means to be used in determining these constants are not discussed in the paper, nor are they a part of the method. These constants have been derived by so many writers and in so many slightly different ways that there is little occasion to repeat here the whole procedure.

The reactions in beams, bents, and arches which are immovably fixed at their ends have been extensively discussed. They can be found comparatively readily by methods which are more or less standard. The method of analysis herein presented enables one to derive from these the moments, shears, and thrusts required in the design of complicated continuous frames.

DEFINITIONS

For convenience of reference, definitions of three terms will be introduced at once. These terms are "fixed-end moment", "stiffness", and "carry-over factor".

By "fixed-end moment" in a member is meant the moment which would exist at the ends of the member if its ends were fixed against rotation.

"Stiffness", as herein used, is the moment at one end of a member (which is on unyielding supports at both ends) necessary to produce unit rotation of that end when the other end is fixed.

If one end of a member which is on unyielding supports at both ends is rotated while the other end is held fixed the ratio of the moment at the fixed end to the moment producing rotation at the rotating end is herein called the "carry-over factor."

EFFECT OF JOINT ROTATION

Imagine any joint in a structure, the members of which are being deformed by loads, or in some other way, to be first held against rotation and then released. Call the algebraic sum of the fixed-end moments at the joint the "unbalanced fixed-end moment". Before the joint is released this unbalanced fixed-end moment will not usually be zero; after the joint is released, the sum of the end moments at the joint must be zero. The total change in end moments, then, must equal the unbalanced fixed-end moment. This may be stated in another way by saying that the unbalanced fixed-end moment has been "distributed to" the connecting members in some ratio.

When the joint is released all connecting members rotate through the same angle and this rotation at the end is accompanied by a change in end moment. The change in end moments is proportional to the "stiffness" of the members.

Hence, it may be said that when the joint is released the unbalanced fixed-end moment is distributed among the connecting members in proportion to their stiffness.

The rotation of the joint to produce equilibrium induces moments at the other ends of the connecting members. These are equal in each member to the moments distributed at the rotating joint multiplied by the carry-over factor at the rotating end of the member. This follows from the definition of "carry-over factor".

MOMENT DISTRIBUTION

The method of moment distribution is this: (*a*) Imagine all joints in the structure held so that they cannot rotate and compute the moments at the ends of the members for this condition; (*b*) at each joint distribute the unbalanced fixed-end moment among the connecting members in proportion to the constant for each member defined as "stiffness"; (*c*) multiply the moment distributed to each member at a joint by the carry-over factor at that end of the member and set this product at the other end of the member; (*d*) distribute these moments just "carried over"; (*e*) repeat the process until the moments to be carried over are small enough to be neglected; and (*f*) add all moments

—fixed-end moments, distributed moments, moments carried over—at each end of each member to obtain the true moment at the end.

To the mathematically inclined the method will appear as one of solving a series of normal simultaneous equations by successive approximation. From an engineering viewpoint it seems simpler and more useful to think of the solution as if it were a physical occurrence. The beams are loaded or otherwise distorted while the joints are held against rotation; one joint is then allowed to rotate with accompanying distribution of the unbalanced moment at that joint and the resulting moments are carried over to the adjacent joints; then another joint is allowed to rotate while the others are held against rotation; and the process is repeated until all the joints are "eased down" into equilibrium.

BEAM CONSTANTS

This method of analysis is dependent on the solution of three problems in the mechanics of materials. These are the determination of the fixed-end moments, of the stiffness at each end, and of the carry-over factor at each end for each member of the frame under consideration. The determination of these values is not a part of the method of moment distribution and is not discussed in this paper.

The stiffness of a beam of constant section is proportional to the moment of inertia divided by the span length, and the carry-over factor is $-\frac{1}{2}$.

The proof or derivation of these two statements and the derivation of formulas for fixed-end moments is left to the reader. They can be deduced by the use of the calculus; by the theorems of area-moments; from relations stated in *Bulletin 108* of the Engineering Experiment Station of the University of Illinois (the Slope-Deflection *Bulletin*); from the theorem of three moments; by what is known to some as the column analogy method;[3] or by any of the other corollaries of geometry as applied to a bent member. Formulas for fixed-end moments in beams of uniform section may be found in any structural handbook.

SIGNS OF THE BENDING MOMENTS

It has seemed to the writer very important to maintain the usual and familiar conventions for signs of bending moments, since these are the conventions used in design.

For girders the usual convention is used, positive moment being such as sags the beam. For vertical members the same convention is applicable as for girders if the sheet is turned to read from the right as vertical members on a drawing are usually read. The usual conventions for bending moments are, then, applicable to both girders and columns if they are looked at as a drawing is usually lettered and read.

Moments at the top of a column, as the column stands in the structure, should be written above the column and those at the bottom of the column, as the column stands in the structure, should be written below the column when the sheet is in position to read the columns. This is necessary because positive moment at the right end of a beam and at the top of a column both represent tendencies to rotate the connected joint in the counter-clockwise direction.

---

[3] "The Column Analogy," by Hardy Cross, M. Am. Soc. C. E., *Bulletin 215*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

It makes no difference whether girder moments are written above or below the girder. Either arrangement may be convenient. Confusion will be avoided by writing column moments parallel to the column and girder moments parallel to the girders.

When any joint is balanced the total moment to the right and to the left of the support is the same, both in absolute value and in sign. The unbalanced moment is the algebraic difference of the moments on the two sides of the joint.

Limitation of Method

From the fact that the terms, "stiffness" and "carry-over factor", have been defined for beams resting on unyielding supports, it follows that direct application of the method is restricted to those cases where the joints do not move during the process of moment distribution. The method, however, can be applied in an indirect way to cases in which the joints are displaced during the moment distribution, as indicated later.

As the method has been stated, it is restricted only by this condition that the joints are not displaced. If this condition is satisfied it makes no difference whether the members are of constant or of varying section, curved or straight, provided the constants (*a*) fixed-end moments at each end, (*b*) stiffness at each end, and (*c*) carry-over factor at each end, are known or can be determined. Such values can be derived by standard methods and may be tabulated for different types of members and conditions of loading.

It will be found that in most cases accuracy is needed only in the fixed-end moments. It does not ordinarily make very much difference how, within reason, the unbalanced moments are distributed, nor, within reason, how much of the distributed moments are carried over.

In the "Illustration" which follows it has been assumed that the members are straight and of uniform section. The stiffnesses, then, are proportional to the moments of inertia, (I), divided by the lengths, (L), but the relative values given for $\frac{I}{L}$ in this problem might quite as well be the relative stiffness of a series of beams of varying section. In this latter case, however, the carry-over factors for the beams would not be $-\frac{1}{2}$.

Illustration

The illustration given (Fig. 1) is entirely academic. It is not intended to represent any particular type of structure nor any probable condition of loading. It has the advantage for the purpose of this paper that it involves all the conditions that can occur in a frame which is made up of straight members and in which the joints are not displaced.

The loads on the frame are supposed to be as indicated. The relative values of $\frac{I}{L}$ for the different members are indicated in circles.

The fixed-end moments in all members are first written. In this problem they are arbitrarily assumed to be as shown, as follows: at *A*, 0; at *B*, in *B A*, 0, and in *B C*, — 100; at *C*, in *C B*, — 100, in *C F*, + 80, in *C D*, — 200, and in *C G*, — 50; at *F*, + 60; at *G*, — 50; at *D*, in *D C*, — 100, and in *D E*, 0; at *E*, in *E D*, 0, and in the cantilever, — 10.

Before proceeding to a solution of the problem, attention may be called to the arrangement of the computations. The moments in the girders are written parallel to the girders; those in the columns, parallel to the columns.

A

FIG. 1.

The original fixed-end moments are written next to the members in which they occur, the successive moments distributed or carried over being written above or below these, but farther from the member.

The arrangement of the moments in the columns in positions above the columns, when the paper is turned into a position to write these moments, for the top of the columns (at *B*, *F*, and *C*), and in positions below the columns for the bottom of the columns (at *A*, *C*, and *G*), is an essential part of the sign convention adopted.

The moment at *C* in the girder, *B C*, is written above the girder in order to get it out of the way. Otherwise, it makes no difference whether the moments are written above or below the girder.

The signs of the fixed-end moments are determined by observing the direction of flexure at the ends of the members due to the loads. In order to apply to the columns the ordinary conventions for signs of bending moments it is necessary to turn the drawing of the structure.

The reader should realize that the solution is built up step by step. It is always the last figures showing that are to be operated on—distributed or carried over—so that in ordinary framework there is little chance for confusion as to what step should be taken next.

Distribute at each joint the unbalanced moment, as follows:

1.—At A there is no moment.

2.—At B there is an unbalanced moment of -100 on one side of the joint. This moment is distributed to BA and to BC in the ratio, 2 : 4, so that the distributed moment to BA is $\frac{2}{2+4}\,100 = 33.33$ and to BC, $\frac{4}{2+4}\,100 = 66.67$. The signs are written in the only way possible to balance the joint by giving the same total moment (-33.33) both to left and right of the joint.

3.—At C, the unbalanced moments are, in CB, -100, and in CG, -50, giving a total of -150 on the left of the joint; in CF, $+80$, and in CD, -200, giving a total of -120 on the right of the joint. The total unbalanced moment at the joint, which is the difference between the total moment on the left and on the right of the joint, is 30. This is now distributed in the respective proportions, as follows:

To CB,

$$\frac{4}{4+2+5+1}\,30 = 10$$

to CF,

$$\frac{2}{4+2+5+1}\,30 = 5$$

to CD,

$$\frac{5}{4+2+5+1}\,30 = 12.5$$

and, to CG,

$$\frac{1}{4+2+5+1}\,30 = 2.5$$

There is only one way to place the signs of the distributed moments so that the total is the same on both sides of the joint. This is done by reducing the excess negative moment on the left and increasing the negative moment on the right.

4.—At F, the unbalanced moment is $+60$. The hinge has no stiffness. The moment, then, is distributed between the member, FC, and the hinge in the ratio, 2 : 0; all of it goes to the member. The total balanced moment is $+60 - 60 = 0$, as it must be at a free end.

5.—At G, the abutment is infinitely stiff and the unbalanced moment, -50, is distributed between the member, GC, and the abutment in the ratio, $1 : \infty$. The member gets none of it; the end stays fixed.

6.—At D, the unbalanced moment, -100, is distributed to DC and to DE in the ratio of 5 : 3.

7.—At E, the unbalanced moment is -10 in the cantilever. Since the cantilever has no stiffness, this unbalanced moment is distributed between the beam, *E D*, and the cantilever in the ratio, 3 : 0. This means that all of it goes to *E D*.

All joints have now been balanced. Next, carry over from each end of each member one-half the distributed moment just written, reverse the sign, and write it at the other end of the member. Thus, carry over, successively, in *A B*, 0 from *A* to *B* and + 16.67 from *B* to *A*; in *B C*, — 33.34 from *B* to *C* and — 5.0 from *C* to *B*; in *C F*, + 2.5 from *C* to *F* and + 30 from *F* to *C*; in *C G*, 0 from *G* to *C* and — 1.25 from *C* to *G*; in *C D*, + 6.25 from *C* to *D* and — 31.25 from *D* to *C*; and in *D E*, + 18.75 from *D* to *E* and + 5.00 from *E* to *D*.

Distribute the moments just carried over exactly as the original fixed-end moments were distributed. Thus, at *A*, + 16.67 is distributed 0 to *A B* (fixed-ended); at *B*, — 5.0 is distributed as — 1.67 and + 3.32; at *C*, the unbalanced moment is (— 33.34 + 0) — (+ 30.00 — 31.25) = — 32.09 which is distributed as + 2.67, + 10.68, — 5.34, and — 13.35; at *F*, + 2.50 is distributed as — 2.5 to the member; *G* is fixed-ended; at *D*, + 1.25 is distributed as — 0.78 and + 0.47; at *E*, the unbalanced + 18.75 is distributed to the member as — 18.75.

The moments distributed are now carried over as before and then re-distributed; and the process is repeated as often as desired. The procedure should be stopped after each distribution, however, and a check made to see that statics ($\Sigma M = 0$) is satisfied.

When it is felt that the process has gone far enough, all moments at each end of each member are added to give the total moment at the joint. After the moments at the joints have been determined, all other quantities, such as moments and shears, may be obtained by applying the laws of statics.

Convergence of Results

The distribution herein has been carried out with more precision than is ordinarily necessary, in order to show the convergence of the results. To show the rate of convergence, the successive values of the moments at the joints after successive distributions are given in Table 1.

TABLE 1.—Convergence of Results.

Successive values of bending moment at joint		After one distribution (two rows of figures)	After two distributions (four rows of figures)	After three distributions (six rows of figures)	After four distributions (eight rows of figures)	After five distributions (ten rows of figures)	After six distributions (twelve rows of figures)
A	....	0	+ 16.67	+ 17.50	+ 18.39	+ 18.48	+ 18.55

	" *C F*	+ 75.00	+ 99.66	+100.36	+101.32	+101.36	+101.41
	" *C D*	—212.50	—257.10	—258.09	—259.89	—259.88	—259.93
	" *C G*	— 47.50	— 44.83	— 44.55	— 44.36	— 44.31	— 44.28
D	....	— 37.50	— 32.03	— 23.66	— 23.48	— 23.15	— 23.15
E	....	— 10.00	— 10.00	— 10.00	— 10.00	— 10.00	— 10.00
F	....	0	0	0	0	0	0
G	....	— 50.00	— 51.25	— 52.59	— 52.73	— 52.83	— 52.86

For most purposes the computations might as well have been stopped after the second distribution. Had this been done, the solution would have appeared as shown in Fig. 2.

For any practical purpose the computation might in this case have been stopped after the third distribution. In general, two or three distributions are sufficient. This is not true in all instances, but in any case the exactness of the solution at any stage will be indicated by the magnitude of the moments carried over in the members.

VARIATIONS OF THE METHOD

The writer has developed and used at different times several variations of the method shown, but the original method is itself so simple and so easy to remember that he finds himself inclined to discard the variants.

FIG. 2.

One variant is perhaps worth recording. It is rather tedious to carry moments out to the end of a member which is free to rotate and then balance the moment and carry it back again. This may be avoided by releasing the free end once for all and leaving it free. In this case, for beams of constant section, the stiffness of the beam is to be taken three-fourths as great[4] as the relative $\frac{I}{L}$-value would indicate. After the end of the beam is once released, no moments are carried over to it.

---

[4] The moment needed to produce a given rotation at one end of a beam when the other end is free is three-fourths as great as if the other end is fixed.

Correcting for Side-Sway

Single square or trapezoidal frames, portals, L-frames, box culverts, and similar structures act as simple continuous beams if there is no transverse deflection. If they are symmetrical as to form and loading, they will not deflect sidewise and if they are restrained against sidewise movement, they cannot so deflect.

Side-sway of frames due to dissymmetry of the frame is rarely an important factor in design. Correction for side-sway may be made by a method which may be applied also in cases of transverse loading on bents. The method is to consider that the bent does not sway sidewise and analyze it as a series of continuous beams. The total shear in the legs will not now, except by accident, equal the shear which is known to exist. The difference must be a force which prevents side-sway.

Now, assume all joints held against rotation, but the top of the bent moved sidewise. Assume any series of fixed-end moments in the legs such that all legs have the same deflection. In this case for members of uniform section fixed-end moments in columns vary as $\frac{I}{L^2}$. Distribute these fixed-end moments and find the total shear in the legs. The changes in moments due to side-sway will then be to the moments just computed in the same algebraic ratio as the total unbalanced horizontal shear in the legs due to side-sway when the frame is analyzed as a continuous girder, is to the shear just computed.

Multi-Storied Bents

Bents of more than one story, subject to side-sway, either as a result of unbalanced loading or due to horizontal forces, may be solved by this method. It is understood that exact solution of such problems is not commonly of great interest. It is the approximate effect that is desired rather than exact analysis.

To analyze by this method a two-story bent it will be necessary to make two configurations—one for each story. From the assumed shear in each story (producing, of course, shears in the other stories), a set of moment values may be obtained. These may be combined to obtain the true shears, and from the true shears the true moments follow.

General Application of the Method

The method herein indicated of distributing unbalanced moments may be extended to include unbalanced joint forces. As thus extended it has very wide application. Horizontal or vertical reactions may be distributed and carried over and thus a quick estimate made of the effect of many complicating elements in design. The writer has used it in studying such problems as continuous arch series, the effect of the deflection of supporting girders, and other phenomena.

An obvious application of moment distribution occurs in the computation of secondary stresses in trusses. Many other applications will doubtless suggest themselves, but it has been thought best to restrict this paper chiefly to continuous frames in which the joints do not move.

CONCLUSION

The paper has been confined to a method of analysis, because it has seemed wiser to so restrict it. It is not then an oversight that it does not deal with: (1) Methods of constructing curves of maximum moments; (2) methods of constructing curves of maximum shears; (3) the importance of analyses for continuity in the design of concrete girders; (4) flexural stresses in concrete columns; (5) methods of constructing influence lines; (6) the degree to which continuity exists in ordinary steel frames; (7) continuity in welded steel frames; (8) plastic deformation beyond the yield point as an element in interpreting secondary stress computations; (9) the effect of time yield on moments and shears in continuous concrete frames; (10) plastic flow of concrete as a factor in the design of continuous concrete frames; (11) whether in concrete frames it is better to guess at the moments, to take results from studies made by Winkler fifty years ago, or to compute them; (12) the effect of torsion of connecting members; (13) the relative economy of continuous structures; (14) the relative flexibility of continuous structures; (15) the application of methods of continuous frame analysis to the design of flat slabs; (16) probability of loading and reversal of stress as factors in the design of continuous frames; (17) the relation of precision in the determination of shears and moments to precision in the determination of fiber stresses; and a dozen other considerations bearing on the design of continuous frames.

A method of analysis has value if it is ultimately useful to the designer; not otherwise. There are apparently three schools of thought as to the value of analyses of continuous frames. Some say, "Since these problems cannot be solved with exactness because of physical uncertainties, why try to solve them at all?" Others say, "The values of the moments and shears cannot be found exactly; do not try to find them exactly; use a method of analysis which will combine reasonable precision with speed." Still others say, "It is best to be absolutely exact in the analysis and to introduce all elements of judgment after making the analysis."

The writer belongs to the second school; he respects but finds difficulty in understanding the viewpoint of the other two. Those who agree with his viewpoint will find the method herein explained a useful guide to judgment in design.

Members of the last named school of thought should note that the method here presented is absolutely exact if absolute exactness is desired. It is a method of successive approximations; not an approximate method.

DISCUSSION

C. P. VETTER,[5] ASSOC. M. AM. SOC. C. E. (by letter).—The author presents an ingenuous method for determining certain statically indeterminate quantities in continuous frames, one of the main advantages being the absence of any mathematics except the simplest arithmetic.

He illustrates the application of his theory by analyzing a certain hypothetical frame. In a way it is unfortunate that this particular type of structure has been chosen as an example, as the weaknesses of the principle are here so apparent. Had the author chosen, for example, an ordinary continuous girder, they would not have been evident, and it would have been more clearly demonstrated that he has added a new method to those already known for solving one of the most common problems in modern concrete engineering.

Considering Fig. 1, it is at once apparent that the vertical component of the reactions at *F* and *G* cannot be determined by the method outlined in the paper. In consequence, the direct stresses in the members, *F C* and *C G*, are unknown.

Those familiar with the theory of least work will recognize that this is because of the author's neglect of deformations due to direct stresses and shear. While the latter may often be safely ignored, neglect of the former is dangerous in many cases, the given example being one of them.

In his "Conclusions", the author lists up to seventeen different points which have not been dealt with. The writer could add a great many more which have just as much, and more, to do with the subject under discussion, such as the influence of variation in temperature, the yielding of foundations, and the shrinkage or swelling of members if built of concrete.

The writer does not agree with the author's closing remarks concerning the value of a correct analysis of statically indeterminate structures. Stresses in most, although admittedly not as yet in all, such structures can be determined completely and correctly using those assumptions—and only those assumptions —which are also used when analyzing statically determinate, or simple, structures. Short-cuts and approximations are permissible if one is in a hurry and if the error is negligible and approximately known, but the value of an approximation is determined only by the number of assumptions involved; every time a new assumption is made the value of the findings is reduced. If enough new assumptions are added, the answer may be valueless.

The theory of least work and the slope-deflection method have not added any assumptions to those generally used in all engineering, and, therefore, should be preferred wherever possible. Also, an engineer should "hitch his wagon to a star."

L. E. GRINTER,[6] ASSOC. M. AM. SOC. C. E. (by letter).—In presenting this paper, Professor Cross has made generally available a highly valuable method of structural analysis, which has previously been known to relatively few engineers. This method of balancing fixed-end moments was suggested to the writer a number of years ago by Professor Cross. Subsequently, he has found need to develop it to care for the balancing of shears or deflections, of thrusts or joint forces, and of angle changes or joint rotations.

---

[5] Asst. Civ. Engr., Pacific Gas & Elec. Co., San Francisco, Calif.

[6] Prof. of Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

Considered in its entirety, this is clearly a general method of successive corrections. In the form suggested by Professor Cross, one starts with fixed-end moments and the corrections are computed from the effect of allowing the joints to rotate in succession. The method is, therefore, either approximate or exact to any desired degree, depending only on the number of corrections one is willing to compute. It has the advantage over other methods of approximation in that the operator instinctively senses the amount of error involved in discontinuing the computation of the corrections at any given stage of the process, and naturally he continues until the desired degree of precision is reached. It has the further advantages: (1) Of speed, because one wastes no time in obtaining unnecessary precision; (2) of simplicity, because all computations involve only the use of arithmetic; and (3) of ease of remembering, since each step of the process has a definite physical significance.

These statements are borne out by the fact that the method in its simplest form—balancing moments on a continuous beam—is easily digested by junior engineering students and retained to the extent that, guided by a few suggestions, they readily make use of it in the senior year. Any one who has attempted to have senior students make use of the method of three moments, without considerable coaching, will appreciate the distinction.

In this connection, it should be noted that textbooks on strength of materials frequently do not give the three-moment theorem, except for equal spans and simplified loads. By balancing fixed-end moments, the student finds little added difficulty in handling unequal spans, complex loadings, or even a variation of moment of inertia in the several spans. Of course, variation of moment of inertia within a single span can be handled only by the advanced student.

The writer feels that much of the simplicity of this method is dependent upon a complete visualization of the corresponding physical action of the structure. In most methods of analyzing continuous frames, it is customary to allow rotation and translation to take place freely by inserting pins and sliding plates into the structure. Later in the process, continuity is reproduced by the application of forces at the cut sections. By the same reasoning it becomes clear that one may apply any number of restraining forces or moments to a structure as long as these restraints are removed later.

In the simplest case, that of balancing fixed-end moments where joint translation is not involved, the physical action is best described as the application and successive release of restraining moments at the joints. As these moments are released, each joint rotates until it takes its proper slope. When one joint is allowed to rotate, all others are held fixed. Every member meeting at the rotation joint, therefore, acts physically as a beam which is simply supported at the near end, fixed at the far end, and which, at the same time, is undergoing rotation at the near end. The resistance of such a beam to rotation is dependent upon its physical properties, or $\frac{I}{L}$ - value. As Professor Cross points out, this value must be replaced by the moment necessary to produce a unit rotation at the near end, if the beam is not of uniform section. Again, the physical action of such a rotating joint readily clears up the fact that the unbalanced moment will distribute to all members meeting at the joint in direct proportion to their stiffness or resistance to rotation.

The carry-over moment may best be looked upon as another characteristic of the physical action of the structure. When a simple beam of uniform section is rotated through a given angle at one end, the far end rotates through an angle which is one-half as great. To prevent this rotation, or to rotate the far end backward to its original position, clearly requires the application at the far end of one-half the applied moment at the near end. Using the ordinary sign convention of beams, the carry-over factor is accordingly—50% of the balancing moment. For a beam of non-uniform section, or for one not fully restrained at the far end, the imaginary angle change to be corrected at the far end would not be exactly 50% of that at the near end, and the carry-over factor would be different from 50 per cent.

The writer would like to emphasize the fact that it is not necessary to consider the far end of the member as fixed. It might be allowed to rotate freely and the angular change later be taken into consideration, or its restraint may be determined and a moment carried over in proportion to this restraint. The writer makes occasional use of the conception of free rotation in a method of balancing angle changes, and frequent use of the idea of estimating the end restraint in an approximate method of balancing moments. The viewpoint that he wishes to make clear, however, is that one may consider any joint as fixed, free, or partly restrained, at will, at any point in the process. It is only necessary that the recorded data be consistent with the physical action of the structure, that all artificial restraints be finally released, and that all discontinuities be removed.

The writer makes use of the term, "balancing," to indicate the process that Professor Cross prefers to call "distributing." This matter of terminology is of small moment, except that for clearness it has seemed desirable to reserve the term, "distributing," to explain the process of dividing a known moment in one member among the other members meeting at a joint. "Balancing" is used where an externally applied moment is divided among all members meeting at a joint. When so defined, "distributing" is a process to be applied when "running out" moments through a continuous frame of which only a single span is loaded. This method was mentioned in the preceding paragraph as an approximate method of balancing moments, where the carry-over moment is determined from the restraint at the far end of the member.

It is to be expected that among several investigators starting with the same conception as to balancing of fixed-end moments, each should finally develop a different system for accomplishing this purpose. The writer's convention of signs and method of recording the results are sufficiently different from those used by Professor Cross to justify their presentation.

The sign convention used by Professor Cross is that ordinarily given for horizontal beams in the study of strength of materials. This is ideally adapted to the discussion of moments in horizontal beams, but it has always seemed to the writer to be misplaced when applied to column moments. When thus used, some secondary sign convention must be adopted, such as the agreement that all columns will be considered as rotated through an angle of 90° in a clockwise direction. (Professor Cross suggests rotating the sheet instead.) When members meet at various angles, as in secondary stress computations, the convention of signs for strength of materials becomes still more confusing. In order to obviate this difficulty, the writer prefers to adopt the simple sign convention that positive moment at the end of any member tends to rotate the adjacent joint clockwise. This convention automatically cares for the signs of horizontal, vertical, and diagonal members.

In applying this system, it has been found to be a simple matter roughly to sketch the shape of the deflected structure with fixed ends. This process has the double advantage of fixing the signs beyond question and of enhancing the physical significance of the method. Sketches of typical deflected members are shown in Fig. 3. It is worth noting that a member which does not have a point of contraflexure has moments of opposite sign at the two ends. One point of contraflexure is indicated by moments of like sign and two points of contraflexure again by moments of opposite sign. The distinction between none and two points of contraflexure can not be drawn from the signs of the end moments, but is evident from the condition of loading.

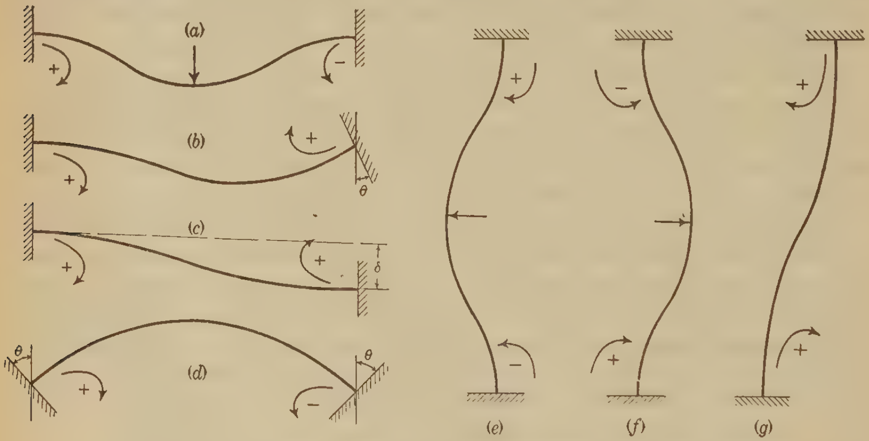

Fig. 3.

When this convention is used, the signs of the balancing moments around any joint are unusually simple. If the resultant unbalanced moment is positive, all balancing moments are negative, and their sum is equal to the total unbalanced moment. Thus, the total moments after balancing around the joint add up algebraically to zero. In comparison, one notices that the algebraic sum of all moments around a joint is not zero when written out according to the sign convention used by Professor Cross.

The carry-over moment, which is 50% of the balancing moment for a member of constant section, is of the same sign as the balancing moment. This fact is evident as the physical action of rotating one end of a member when the far end is restrained or fixed produces one point of contraflexure. (See Fig. 3(*b*).)

This convention of signs accordingly has the following advantages:

1.—Girders, columns, and diagonal members are handled in identically the same manner.

2.—The algebraic sum of all moments around a balanced joint is zero.

3.—All balancing moments at a joint caused by a single balance have like signs. Their sum is equal and opposite to the unbalanced joint moment.

4.—Carry-over moments are of the same sign as the balancing moment.

These advantages may seem somewhat unimportant, but they produce a simplification that reduces the possibility of error to an absolute minimum.

In finally comparing the sign convention used herein with that recommended by Professor Cross, one is naturally influenced in his decision of preference by his previous experience. One's personal system, even though more tedious, is always more satisfactory to him than another with which he is less familiar. It is of interest, however, that both sign conventions are actually used in either system. The signs set up by Professor Cross must be interpreted in terms of clockwise or counter-clockwise rotation in order to check $\Sigma M = 0$ at a joint. Similarly, the sign convention used by the writer must be transferred back into terms of fiber stresses if a moment diagram is to be drawn.

Another simplification which the writer has found advantageous is to complete the carrying over of moments from one joint before balancing the next joint. In this way one eliminates the possibility of neglecting to carry over certain moments. Furthermore, as the carry-over moment is balanced at the same time as the original fixed-end moment, a given number of balances will produce more nearly exact results.

It will further be found advantageous to balance in succession those joints which have the largest unbalanced moment. It is useless to balance a joint early in the process which has merely a slight unbalanced moment, because the carry-over moments from adjacent joints will later entirely disrupt the carefully calculated balance. If one adopts the system of drawing a horizontal line under all columns of moments at a joint each time the joint is balanced, a single glance will serve to point out the joint at any stage of the process which has the largest unbalanced moment.

The most rapid convergence is obtained, therefore, by carefully selecting the proper joint to balance at each step of the process, and then by carrying over the moments before passing on to another joint.

For handling fixed ends and pin ends, the writer prefers to follow the procedure indicated by a study of the physical action of the structure. A fixed end cannot rotate and, therefore, cannot be balanced. The original fixed-end moment plus the carry-over moments, accordingly, add up algebraically to give the final moment. A pin is entirely free to rotate and has zero moment. The fixed-end moments and all carry-over moments, therefore, must be released by allowing free rotation at the pin. In recording the data, this free rotation may be looked upon as produced by the application of equal and opposite moments at the pin.

In order to illustrate the system described herein, the writer has prepared Fig. 4, which is the identical problem worked out by Professor Cross. The balancing is started at Joint *B* where an unbalanced positive moment of 100 exists. This joint was selected because it offered as large an unbalanced moment as any other. Joint *D* might equally well have been chosen as a starting point. Since *BC* is twice as stiff as *BA*, the first correction moments are — 67 in *BC* at *B*, and — 33 in *BA* at *B*. After the balancing moments are recorded, horizontal lines are drawn under these figures to indicate that all moments above these lines are balanced; that is, they add up to zero around the joint. Now, one-half the — 67 at *B* in *BC* is carried over to *C* with the same sign, or — 33. Similarly, one-half the — 33 at *B* in *BA* is carried down to *A* with the same sign, or — 16. The next step is to balance Joint *D* where a large unbalanced moment of — 100 exists. Balancing moments of + 63 in *DC* and + 37 in *DE* are recorded, corresponding to five-eighths and three-eighths, respectively, of the unbalanced moment. Horizontal balance lines are again drawn, and these moments are carried over with one-half their value and like sign to the far ends, *D* and *E*.

The process is thus continued around the frame, the joints being balanced in the following rotation: *B*, *D*, *F*, *E*, *C*, *B*, *F*, and *C*. They might have been balanced with equal satisfaction in some other sequence, but it is not likely that a more rapid convergence will be found. It is well to note here that in returning to balance a joint for a second or third time, one balances only those figures below the last set of horizontal lines.

In Fig. 4 the first recorded figure in each group is the fixed-end moment. The last recorded figure in each group is the final moment in the adjacent member obtained by adding the column of figures. In order to clarify the diagram, column moments are written on the columns, and girder moments are written above the girders.

In justification of this method, it is necessary to show that the results obtained in this case by the balancing of only eight joints are within 4% of those obtained by the system suggested by Professor Cross in thirty balances. Also, after balancing each joint twice by Professor Cross' system, or a total of ten balances, one joint, *D*, still is seen to be 38% in error. A fairer comparison might be obtained by noting that Professor Cross' system gives satisfactory accuracy after balancing each joint three times, or a total of fifteen joints to be balanced. Thus, in this problem, nearly one-half the mechanical labor is saved by the system here suggested. At least a 25% reduction in labor will usually be found in the solution of all continuous frame problems.

The writer wishes to stress particularly the advantage that one sets his standard of accuracy before starting to balance joints. For instance, if whole numbers are used as in Fig. 4, an error arises from the fact that 33 is recorded instead of 33.33, when 100 is to be divided into three equal parts. There is also an error where an uneven number is multiplied by 0.5 to obtain a carry-over moment. When dealing with whole numbers, a maximum error of 2 is a possibility. If the final moments are at least equal to 50, the maximum error is thus limited to about 4 per cent. Where smaller fixed-end moments are found, it may be desirable to use three significant figures. After one becomes familiar with the method, he naturally watches the figures closely and makes the errors balance. An excellent example of this may be seen in Fig. 4. Note that at Joint *A* the writer first carried down less than one-half the balancing moment and the second time he carried down more than one-half. No attempt was made to balance errors at other joints.

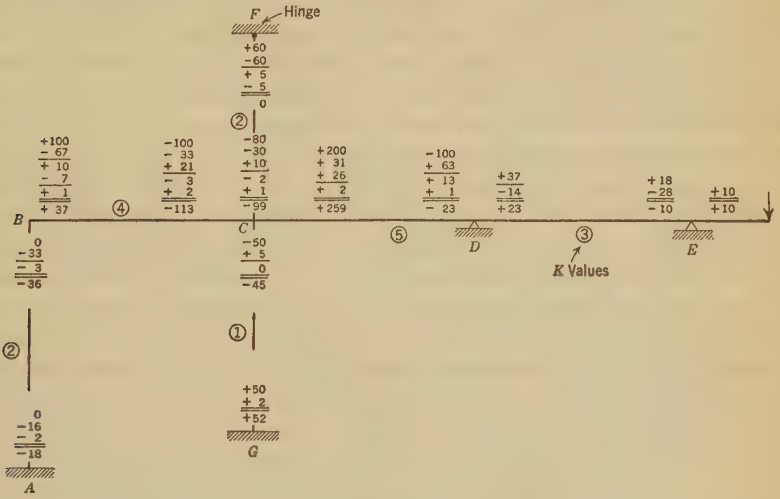

FIG. 4.

If these suggestions are followed, one merely continues to balance joints until the carry-over moments are smaller than unity in the last significant place used. When so reduced, the columns may be added, knowing that the results are within the limits of accuracy represented by a variation of 2 in the last significant figure. Slightly more care will reduce the variation to unity in the last significant figure.

Before closing this part of the discussion on balancing moments, it should be of interest to show that the correction of an error is usually possible without destroying the entire work. For instance, if the operator finds that he has failed to carry over a certain moment, he can carry it over later and then treat it as a single unbalanced moment to be balanced. The results of this balance are to be added algebraically to the first results. Other errors can be handled in a similar manner. It is clear that an error in balancing can be picked up by checking $\Sigma M = 0$ at each joint. An error in the original fixed-end moments or in the carry-over moments can be found by checking a part of the structure for equilibrium with the loads.

The system of balancing moments described herein has been stated to be a special case of the general method of successive corrections, and is directly applicable to all cases where the joints do not translate during the process of balancing. When translation from the balancing of the joints would normally occur, this process gives the moments caused by the original loads and the joint forces necessary to prevent additional translation. If these joint forces are negligible, the moments are nearly exact.

An interesting illustration of such a simplified case is that of secondary stress analysis. Knowing that the deflections of the pin-ended truss and of the riveted truss are essentially alike, one merely calculates the deflections of all panel points caused by the direct stresses; from these deflections one computes the fixed-end moments, and by balancing these moments arrives at the final secondary moments. It should be noted that the fixed-end moments for this case are determined from joint translations, but no additional translations of importance occur during the balancing process. In this same connection, it is interesting to note that the moments caused by a known settlement, horizontal movement, or rotation of a support of a continuous frame may be evaluated in exactly the same way.

A general system of successive corrections for solving all problems involving joint translation can now be set up, based upon the knowledge that the results of the first balancing of moments gives the moments caused by the real loads and the joint restraints. It is only necessary to determine these artificial joint restraints by statics from the calculated moments and the applied loads. All joint restraints are then balanced by equal and opposite forces, and the fixed-end moments caused by this new force system are determined and balanced. This process gives rise to a second set of joint restraints which are removed in the same way. It will be found that the relative importance of each successive set of joint restraints decreases until a set is reached which may be called negligible. Usually, two or three successive corrections will be sufficient for engineering accuracy. The final moments are obtained by adding algebraically the moment sets caused by the several force systems.

It is highly important to study the physical action of the structure, which corresponds to this method of analysis. The first deflected position of the structure does not correspond to the proper deflected position. As each successive force system is allowed to deflect the structure with fixed joints, that structure approaches nearer and nearer its true deflected position. After several successive corrections, it almost exactly coincides with its true deflected position, and the joint restraints are negligible.

The writer has used this method with entire success in the analysis of all continuous frames, including the determination of wind stresses in building frames, open web trusses, continuous arches on elastic piers, and more unusual academic problems. The method has a valuable application to continuous arch systems, in which the idea of balancing joint forces applies directly to the elimination of the troublesome unbalanced thrust at the pier tops.

The method simplifies itself when applied to a single-story bent or culvert in that the restraining force system is merely a single horizontal force applied to the top of the bent. Successive restraining forces are found to form a convergent series, geometric in form, which has a definite mathematical sum. From this knowledge, or from the physical action of the structure, one can readily see that there is a direct proportion between the true moments caused by a given lateral force and the first balanced set of moments caused by this force. This ratio is the same as that between the applied lateral force and the difference between this lateral force and the first joint restraint. Professor Cross arrives at this conclusion in a somewhat different manner.

When discussing multi-storied bents, Professor Cross suggests producing a unit shear successively in each story and determining the effect on adjacent stories in terms of both moment and shear. Then, by combining these effects, the proper shears may be obtained in all stories, and by combining the moment sets in the same proportion, the true final moments are obtained. When the writer first put this method into practical application, it was thought that it would be necessary to make use of simultaneous equations for combining shears. Later, however, he showed that the same result could be obtained more easily and just as accurately by the summation of a simple series of terms for each story. The development of such a series is again best visualized from the physical action of the structure. A shearing distortion in one story gives rise to shearing distortions in other stories. From the ratio of these shears a set of carry-over factors for shear is determined. The proper shears are then applied in all stories and the carry-over shears recorded. These carry-over shears are balanced, and the process is continued until they become negligible, as in balancing moments. From the physical viewpoint, one is successively distorting one story after another until they all take their final deflected position. Finally, by summing each series of terms, the shears necessary to be applied to all stories to produce the proper final shears are known, and the moment sets are combined in the same proportion.

Although this method is convenient and entirely satisfactory, the writer is now finding the general method of successive corrections, just described, to be more useful in most cases. Its main advantage is that it lends itself directly to an approximate solution as one may neglect joint restraints to give any desired degree of approximation, thereby allowing a saving of labor. It also offers an opportunity to the experienced analyst to take advantage of his knowledge of deflections to reduce materially the amount of work required. For instance, the writer seldom finds it necessary to balance more than one set of joint restraints. The method of balancing shears suggested by Professor Cross is more valuable for cases in which the effects of several force systems are to be evaluated. When the carry-over factors for balancing shears are once determined, the moments caused by several force systems may be obtained with relatively little additional labor.

This paper constitutes an outstanding contribution to the field of structural analysis. Without question the method of balancing fixed-end moments and the other closely related methods of analysis are destined largely to supplant the old classic methods dependent upon the solution of simultaneous equations. The writer is not alone in his belief that Professor Cross may be regarded as the leader in a new school of thought in the field of structural analysis.

S. S. GORMAN,[7] ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a clear exposition of a simple and practical solution for many complicated problems. The method presented is very simply and easily applied and is just what its author claims it to be—a method of successive approximations, giving reasonable precision speedily. The writer has applied it to a number of analyses and has found it to be very useful, but he realizes that it must accompany sound judgment in its application.

This discussion will be confined to the method of distribution at a joint similar to *B,* in Fig. 5. While the author's description has been very general, possibly a further elaboration on such a joint will save others from the confusion experienced by the writer.

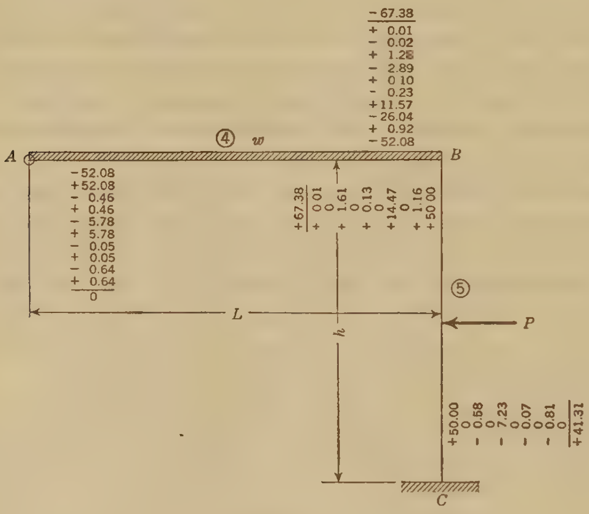

FIG. 5.

Assume an ⅃-frame as shown (Fig. 5), in which, $p = 20\,000$ lb.; $w = 1\,000$ lb. per ft.; $L = 25$ ft.; and, $h = 20$ ft. The relative values of $\frac{I}{L}$ for the members are indicated in circles. End *A* is hinged and End *C* is fixed.

After first writing the fixed-end moments for each member, consider Joint *B*. At first, one might believe that the unbalanced moment is — 102.08, and proceed to distribute this moment, ultimately obtaining an answer which would be incorrect. The unbalanced moment is actually — 2.08, and is distributed between the members, *A B* and *B C,* as on the left side of the joint, and imaginary members of zero stiffness on the right side of the joint, giving the moments as shown in Fig. 5. This procedure is continued, as outlined by the author, always balancing the left-side moments against zero for the right-side moments, until the final moments are obtained.

---

[7] Cons. Structural Engr., San Francisco, Calif.

A similar condition is present in the author's illustration at the joint, *C*, Fig. 1, if the members, *C D* and *C F*, are without load and are considered of zero stiffness. In this case the left-side moments (— 150) would be distributed so as to balance with zero on the right side of *C* (*B C* would get + 120 and *C G* would get + 30).

As the author has pointed out the selection of signs is most important, and as the moments are balanced at a joint algebraically, it is absolutely essential to a proper solution of any problem that the signs are properly selected; this is fundamental. Simplification of analysis is highly commendable, but it must not be spoiled by careless application.

The writer wishes to express his gratitude to the author for his splendid presentation, which eliminates formerly cumbersome methods of analysis of statically indeterminate frames.

A. A. EREMIN,[8] ASSOC. M. AM. SOC. C. E. (by letter).—A number of the analytical and semi-graphical methods of moment distribution in continuous frames with rigid connections have been developed in the last few decades. These methods are generally based on what is commonly known as Mohr's principle,[9] namely "the angular deformations of the elastic line at supports are equal to the reactions of the beam loaded by its moment area divided by *E I*".

This principle applies to beams resting on unyielding supports. However, when a load is applied to continuous frames the joints move from their original positions, due partly to direct stresses in the members, or lateral forces at the frame, and partly to changes in the lengths of the members as the result of variations in temperature, or a combination of all these factors.

The author restricts his analysis to frames in which the joints do not move. If it is required to determine the moments at the joints of a continuous frame under an unsymmetrical static loading the author's method will be the simplest and probably the shortest. However, for distributing moments due to moving loads or for constructing the influence lines for moments at the joints, Strassner's semi-graphical method is more convenient.

In Strassner's method the characteristic points, *J* and *K*, are determined for the unloaded condition and the procedure for determining the moments for each position of the external load is accomplished by simple graphics.

To facilitate the ordinary manipulations in the Strassner method, tables of the necessary quantities for different methods of loading and shapes of beams generally used in practice are prepared.[10]

In the limitations of his method the author omitted to state that the modulus of elasticity of materials was considered to be constant for all members of the frame and also that the lateral rigidity of the members of a continuous frame is sufficient to prevent buckling. The second statement is important to remember in the analysis of steel frames with rigid connections.

[9] "Neuere Methoden zur Statik der Rahmentragwerke," by A. Strassner, Vol. 1, 1921, p. 11.

[10] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 167.

The author defined three schools of designers. There is no justification for the first of these because many experiments on existing reinforced concrete and steel frames with rigid connections have proved that there is a distribution of stresses from one member to adjacent members.

On the other hand, imperfections in workmanship and incomplete knowledge as to the actual elastic properties of structural materials prevent the development of an exact method of determining a real distribution of the stresses in frames.

In order to maintain a reasonably uniform margin of safety for all members in the frame it should be designed for stresses as determined by one of the approximate methods based on the elastic properties of materials. In the formulas for the final stresses in the members of the frame, constants may be introduced to eliminate the errors due to neglecting some minor factors in the development of the method. These constants may be determined by experimental study of the various frames with rigid connections.

ELMER F. BRUHN,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The writer has long been familiar with this method of distributing fixed-end moments and has used it extensively. He strongly recommends it because it has developed for him a much better understanding of the action and relative rigidity of indeterminate structures than is given by the common methods of analysis. These latter, in general, involve the writing of sufficient elastic and static equations, after which the work is entirely an algebraic mechanical process. The structure is entirely forgotten and although the various terms in the equations may represent certain rigidity characteristics or distortional influences, it is no doubt true that this significance often escapes the designer's attention.

Using the author's method one assumes each member of the structure in a definite restrained state and then, realizing that continuity must be preserved and statics satisfied at each joint, the structure is gradually but definitely relieved, joint by joint, from its restrained and unbalanced state and is guided into a state of equilibrium. The structure is at all times the center of thought, a fact that merits emphasis.

In the aeronautic structural field the method of least work seems to be deeply rooted. For analyzing complex continuous structures it gives long and unwieldy equations and has proved to be very unsatisfactory. Of many uses, the writer has found the author's method of particular value in the following three problems:

(1) For making rapid comparative studies of continuous closed frames, a type of structure which is being used more and more in airplane bodies.

(2) For assisting in digesting test results. Government regulations generally require tests to destruction of all major airplane units and new types

---

[11] Engr. of Tests, B/J Aircraft Corporation, Baltimore, Md.

of structures. It is difficult to compute the ultimate strength of a continuous structure accurately. This is due, in part, to the fact that the ordinary elastic formulas apply only for stresses in the materials below the elastic limit. Tests of continuous structures generally show a higher ultimate strength than that computed. This result can be explained as follows: When a continuous structure is loaded some portions of it reach the elastic limit stress first and lose a considerable fraction of their original stiffness or rigidity. The result is that these overstressed portions are relieved of part of their load by the other portions of the structure which still retain their original stiffness. Since it is impossible or impractical to proportion structures for equal stress intensity, this drifting tendency of the internal loads to the portions of higher stiffness has considerable influence upon the ultimate strength, amounting in many cases from 25 to 40% more than the strength computed by the ordinary methods. The author's method has proved valuable in estimating this internal re-adjustment.

(3) For solving extremely complex problems as, for example, the determination of secondary moments due to deflection in a continuous beam with variable moment of inertia and carrying both transverse and axial loads. In airplane structures these moments prove of real importance. To attack such a problem with mathematics is practically impossible.

The question of correcting for joint displacements is less important in airplane work, as, in general, the loads and structures are symmetrical. On the other hand, space frameworks are quite common. This further complicates matters because of torsional forces, but there seems to be no reason why such forces could not be distributed in a similar manner if the torsional characteristics of the members can be determined.

It seems probable that in the aeronautic structural field will be found many problems that will lend themselves to the convenience and advantages of Professor Cross' method.

A. H. Finlay,[12] Assoc. M. Am. Soc. C. E. (by letter).—As the author states, a method of analysis is of value only if it is ultimately useful to the designer. The method of analysis so briefly and yet so fully described in Professor Cross' paper amply fulfills this condition, and structural engineers are fortunate in having it made available to them. Since 1922 Professor Cross has used in his classes the method of distributing unbalanced moments and, since 1924, when he developed the method in its present form, he has taught it to his graduate students with conspicuous success.

The authors of the many papers which have recently been published in connection with this general subject have interested themselves particularly in the analysis of continuous girders and have all approached the problem from more or less conventional directions—directions long since indicated by Clapeyron, Fidler, and others. It is probably sanguine to expect anything inherently new to result from such an approach. To Professor Cross must go the credit for abandoning the paths of his predecessors and for opening up a refreshingly new and eminently useful avenue of approach to the general problem of continuity.

---

[12] Asst. Prof. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

Professor Cross himself states that the mathematically minded may object to solving a set of simultaneous equations by trial, which, of course, is what the successive approximations amount to. Such an objection from the mathematical standpoint is perfectly valid; indeed, it is the sort of objection which a mathematician would be certain to raise. From the standpoint of the designer, however, the trial solution constitutes one of the most important points in favor of the method since, at any time, even after one distribution, the designer is able to form a good idea of the final values of the various moments. The values thus obtained may indicate a complete revision of the elastic properties of the structure. If this is the case he is then at liberty to make the necessary changes, and the only time lost is the negligible time required to make the first distribution. On the other hand, had the equations been set up no idea could have been formed of the final values until the solution had been completed. Only the experienced designer of indeterminate structures will appreciate the importance of this point. Between the analysis of a given structure, which is essentially mathematics, and the design of a required structure, which is essentially art, lie many difficulties.

As the author states the adopted sign convention permits the retention of the usual convention regarding positive and negative moments in the girders. By an ingenious twisting of the sheet this convention is stretched to fit the columns. So far, so good. The writer's criticism is that this sign convention makes it necessary, first, to distinguish between members on the right of a joint and members on the left of the same joint (this distinction when columns are involved is purely arbitrary and may well lead to confusion in complicated structures); second, it requires during the distribution of the unbalanced moment at a joint, that those portions of the unbalanced moment which are distributed to members on one side of a joint be given a different sign from those portions distributed to members on the other side of the same joint. This requires unnecessary thought during the distribution and may well be a contributory source of error. These two characteristics are inevitably associated with any convention based upon retaining that used by the author with regard to positive and negative girder moments. The question arises, is this retention worth while? Professor Cross states that, in his opinion, it is. With due deference the writer feels that it is not and suggests the following: Any moment which tends to rotate any joint clockwise is to be considered positive; the reverse, negative.

As an illustration of the application of this latter method consider Joint *C* in Professor Cross' example (Fig. 1). In the first instance the unbalanced moment will be —30, being the algebraic sum of the fixed-end moments at the joint in accordance with the writer's convention. In other words, the locked joint is tending to turn counter-clockwise and will so turn when released. This unbalanced moment is distributed exactly as in Professor Cross' example with the important exception that all distributed portions have the same sign—

in this case, plus. Consideration will show that, in all cases, the sign given to the distributed portions of the unbalanced moment is opposite to the sign of the unbalanced moment. It is thus apparent that there is no need to consider on which side of a joint a member occurs; and thus an arbitrary distinction is avoided.

If this sign convention is adopted a little consideration will show that the carry-over factor becomes + ½ instead of — ½, as used by Professor Cross. In other words, one-half the distributed moments are carried over to adjacent joints as before, but the signs remain unchanged.

In order to clarify the foregoing, Fig. 6 has been drawn to show the distribution of moments in the frame used by Professor Cross (Fig. 1), in accordance with the writer's sign convention. Selecting the member, *C D,* Fig. 6 shows that the final value of the bending moment at the end, *C,* is + 257.2;

FIG. 6.

that is, the member is tending to turn Joint *C* clockwise. It is evident that tension must exist on the top of the member, *C D,* at Joint *C.* The signs of all other moments in the frame may be similarly translated.

Professor Cross has wisely restricted the paper to the bare description of the method. Those who use his method no doubt have their own particular procedure or technique developed in practice or teaching; indeed, if such is the case it is a healthy sign. The writer, who has used the method both in teaching and in practical design since 1926, has found himself less likely to make errors if, as soon as the moments are distributed at any joint, the correct proportions are at once carried over to adjacent joints before any further distributions are made. Often this procedure is of advantage in so far as the carried-over moments may reduce any unbalance that previously existed at such joints, thereby hastening the convergence.

In practice it will be found quicker, and generally more advantageous, to treat those members having a hinge at one end as the paper suggests, by recognizing the existence of the hinge from the outset. As Professor Cross states, the stiffness of such a member must be modified in keeping with existing restraints, and it must be remembered that no moment can be carried over to a hinged end. It is perhaps hardly necessary to point out that the fixed-end moment for such a member is that obtaining when one end is hinged.

The speed of the method should be at once apparent. Assuming rollers at the support, *D* (Fig. 1), and a pin support at *E*, the frame is eight times statically indeterminate with respect to the external reactions, and yet the solution requires practically no effort.

The application of the principle of distribution to joint forces as well as moments opens up an avenue of great importance in the problem of continuous arches on elastic piers. The further complication introduced by side-sway may be easily overcome, as suggested in the paper. In the writer's opinion side-sway is seldom of importance in continuous viaducts of three spans and may be ignored in all ordinary cases where more than three spans are involved.

Moments induced by temperature changes and settling supports may be handled conveniently by the method. The procedure will be apparent when it is realized that the fixed-end moments from such sources may be readily calculated for any assumed temperature variation and settlements. These moments will result, in general, in unbalanced moments at the joints which may be distributed in the usual way. However, the facility of treating this type of problem should not blind the designer to the probable uncertainties in the results obtained. After all, such factors as temperature variation and settlement of supports by their very nature possess uncertainties which are set far out of the reach of mathematics. The results are merely what the assumptions make them.

One of the outstanding advantages of this method of moment distribution lies in its ease of application to cases of variable moment of inertia within each span—a condition imposed by economic as well as esthetic considerations. Such variation introduces tremendous complications into most so-called standard methods of analysis. In applying the method of moment distribution to such a problem, three factors are changed: (1) The fixed-end moments; (2) the stiffness of the individual spans; and (3) the carry-over factors. Once these quantities have been evaluated, the problem is solved exactly as before. All three of these factors may be tabulated by means of influence lines and graphs and the results made available to designers at a glance. In most cases extraordinarily close results may be obtained by approximating the changes in the various factors outlined.

The writer feels that structural engineers at large will give Professor Cross' paper the attention it deserves. Among those who realize that engineers are now only on the fringe of the general problem of continuity and who welcome each new advance, his work will find enthusiastic support such as may even overcome the inertia of things as they are.

R. F. Lyman,[13] Assoc. M. Am. Soc. C. E. (by letter).—In the practical application of the principles of mechanics to the analysis of a rigid frame, the designer is confronted with several problems, some of which are quite often difficult to solve. Among these may be mentioned the following:

(1) The relative stiffness of the various members of the frame, which, in a design problem, must necessarily be estimated in advance.
(2) The value of the connections, whether fixed, hinged, or partly restrained, as, for example, the end condition at the juncture of column and footing.
(3) The extent to which unbalanced loading should be considered as a factor in the design.
(4) The determination of the moments, shears, and direct stresses in the members of the frame.

In reinforced concrete design Problem (1) is further complicated by the varying moment of inertia of some or all of the individual members.

The method described by Professor Cross provides a solution of Problem (4) that is simple enough to be used, within practical limits of time and effort, in the design of the more complicated types of frames. The writer prefers graphical methods where they can be used, but he has not found such methods feasible for any but the simplest types of frames.

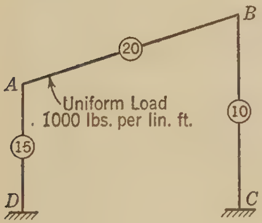

Fig. 7.

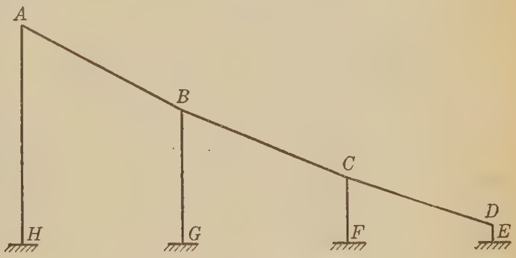

Fig. 8.

The writer believes that the subject of side-sway due to dissymmetry or transverse loading is of considerable importance. For example, in the frame shown in Fig. 7 the correction of the moment at *A* was found to amount to about 23 per cent. In the analysis of the frame shown in Fig. 8, which is typical of grand stand and stadium construction, it was found that the moment at *D* was very much affected by the correction for side-sway, due to dissymmetry, when the deck was uniformly loaded. Furthermore, the moments at other points are considerably affected by this correction when the span, *C D*, alone is loaded.

The author's method of correcting for side-sway is a little difficult to understand. It could, with profit, be explained more fully, and a numerical example given.

---

[13] Asst. Engr., H. J. Brunnier, San Francisco, Calif.

R. A. Caughey,[14] M. Am. Soc. C. E. (by letter).—This paper, in the writer's opinion, covers very important ground. As time goes on, and as people become more accustomed to using it, the value of the method described will be much more appreciated for use in problems, simple and complex.

One of the advantages of the method is that the application does not require complex mathematics; it requires nothing more than simple arithmetic. Another advantage is found in the time saved as compared with other methods; and still another is the automatic check of results.

The writer has presented to a class of undergraduate students, a problem involving a continuous beam of three spans with as many different moments of inertia and span lengths. After a brief presentation of the Cross method of analysis, supplemented by mimeographed notes, the problem was solved with practically no difficulty. The time involved was much less than the same class would require on the same problem by any other method known to the writer.

Mr. H. B. Gotaas, a graduate student working under the writer's supervision, computed moments in the members of a building frame loaded with vertical loads placed in various positions. Fig. 9 shows the dimensions and sizes of members in the bents of this building frame, which was actually built and used at Iowa State College to compare stress measurements obtained by strain gauges to stresses computed by theoretic methods. On this project, results obtained by the slope deflection method (ordinarily considered the most accurate of theoretic methods), were checked against those obtained by the method of Professor Cross, and it was found that the maximum variation in unit stresses, considering complete sets of stresses for ten loading conditions, was only about 400 lb. per sq. in. It is also interesting to note that the time necessary to compute moments in a bent by slope deflection was about 25 hours for each loading, while that required by the Cross method was 4 hours. It will

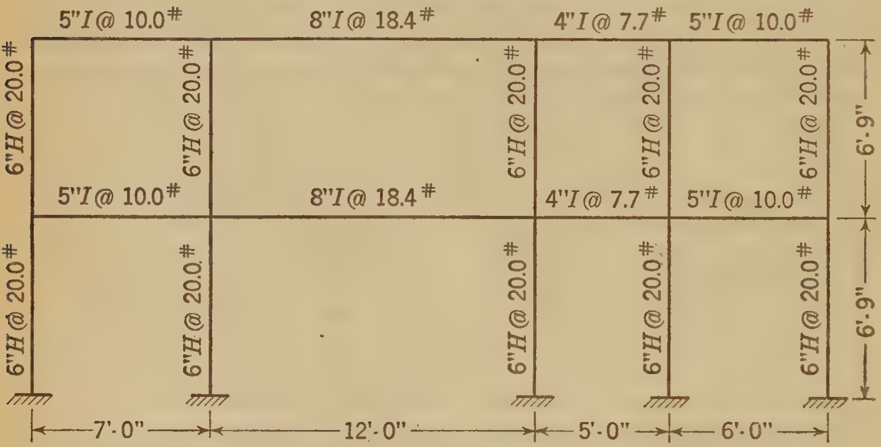

Fig. 9.—Diagram of Building Frame Constructed for Test Purposes at Iowa State College.

---

[14] Prof. of Structural Eng., Iowa State Coll., Ames, Iowa.

be agreed by all that the check on stress values is almost inconceivably accurate and that the time involved is reduced to allowable limits.

It might be well to state that in this comparison no correction was made for horizontal movements of joints. Had the frame been of great height as compared to width, this might have been necessary; but evidently it is not required in ordinary cases.

With concrete structures which are almost always constructed as rigid frames, with the welding of steel structures developing rapidly, and with an increasing desire on the part of designers to obtain stresses more accurately and to use material more economically, the writer prophesies a wide use for this method.

Orrin H. Pilkey,[15] Jun. Am. Soc. C. E. (by letter).—The Cross method of distributing moments is especially valuable in that it keeps intact the picture of the action of the structure. The user does not become lost in a maze of mathematics, rules, or formulas. However, the paper is entirely too brief. Some phases upon which entire chapters could be written with profit, are passed over with a concise statement.

For instance, the discussion of multi-storied bents subject to side-sway is limited to two short paragraphs. The writer feels that this is not sufficient, especially to one unfamiliar with moment distribution. He agrees with the statement that, except for the effect of transverse loads, the joints may be considered fixed in position in practically all rectangular frames. It should be recognized, however, that cases will occur in practice in which it will be important to make certain whether or not the effect of movement in the joints is appreciable. The following example will illustrate in detail a method of making the necessary correction.

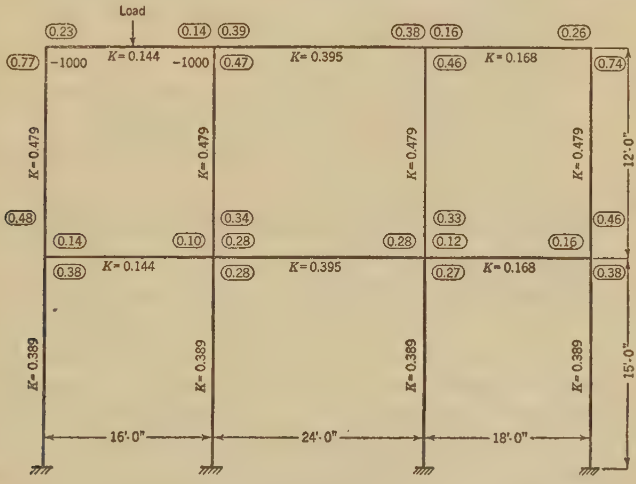

Fig. 10.—Diagram of a Two-Story Bent with a Vertical Unsymmetrical Load.

---

[15] New York, N. Y.

The bent in Fig. 10 presents a rather extreme case of loading, but even in this case the movement of joints is so small that the refinement obtained by correction for it is mostly of academic interest. The percentage of error at some of the joints is certainly great, but the actual magnitude of the error is negligible. It should be noted that it is the magnitude of the error rather than the percentage that is significant. For unsymmetrical loadings encountered in most buildings the movement of joints is so small as to affect the results very little.

Another point, illustrated by Fig. 10, is that the distribution of fixed-end moments is not practicable for analyzing multi-storied buildings subjected to appreciable side-sway, such as would be caused by wind pressure or other transverse loads. It would be more advantageous to distribute joint rotations.

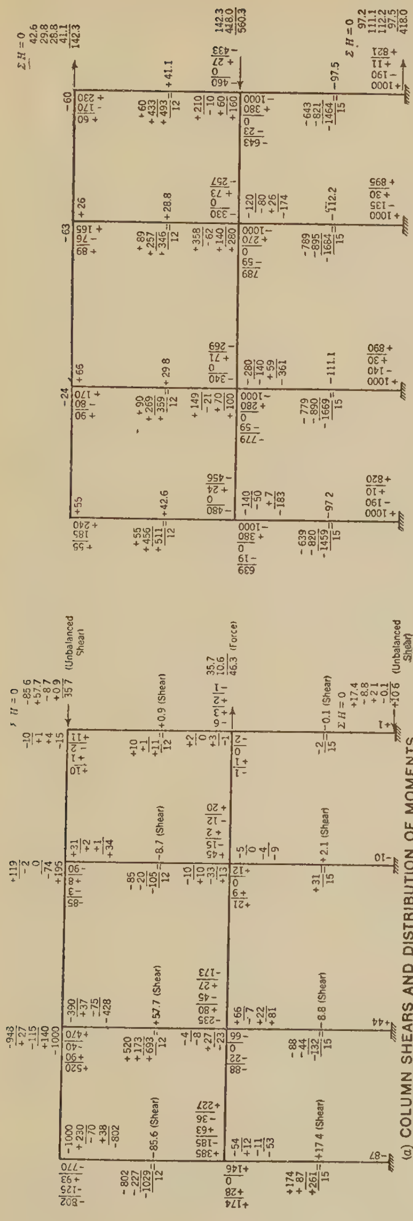
Outline of Steps in Determining Moments Caused by Side-Sway.— Specifically, the method of correcting for side-sway may be conveniently elaborated and described in the following successive steps:

(1) Assume that the joints do not move sidewise and distribute moments;
(2) Find the magnitude of the transverse forces necessary to keep the joints from moving by determining the difference in the shears in the columns;
(3) Find moments in the frame as a result of these forces, by first subjecting each floor, successively, to an assumed load as follows:
  (*a*) Apply a horizontal force to the first-story beams so as to give any desired set of moments in the lower columns, and distribute.
  (*b*) Assume the first floor to be fixed, apply any force to the second floor-beams, and distribute once more.
  (*c*) Write simultaneous equations to find the correct proportion of the moments caused by the assumed forces necessary to hold the joints fixed.
(4) The results are the moments caused by the unbalanced shear and are to be added algebraically to the moments found by assuming the joints held against side-sway.

Example.—In Fig. 10 the load is unsymmetrical and causes the joints to move sidewise. For an exact answer the effect of this movement must be determined separately because, by moment distribution, the joints are assumed to be held against side-sway. Actually, this correction is generally not necessary because the error is negligible. The numerals enclosed in circles are the relative stiffness values of members intersecting at a joint.

The results of Step (1) are shown in Fig. 11 (*a*). In the second-story columns the shears are found to be — 85.6, — 8.7, + 57.7, and + 0.9, respectively, which means that, if the condition, $\Sigma H = 0$, is to be satisfied, the unbalanced shear, — 35.7, must be applied as a horizontal force restraining the bent at that level. Likewise, the unbalanced column shear in the first-story columns is + 17.4 — 8.8 + 2.1 — 0.1 = + 10.6; and for $\Sigma H = 0$, at the first story, the restraining force will be 35.7 + 10.6 = 46.3. This constitutes Step (2).

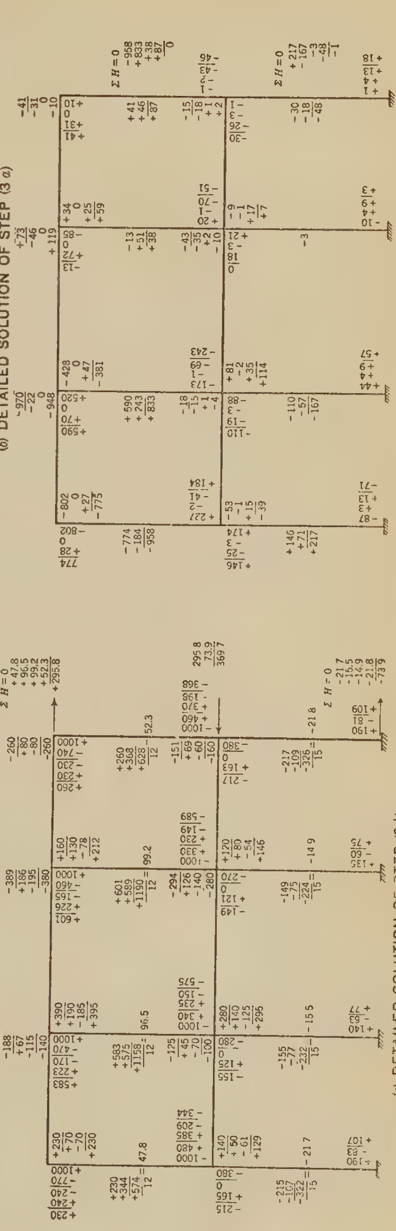
Fig. 11(*b*) illustrates in detail the solution of Step (3(*a*)). If the load is assumed, the moment produced may also be assumed. The first step is to



Σ H = 0
(Unbalanced Shear)
(Shear)
(Force)

(a) COLUMN SHEARS AND DISTRIBUTION OF MOMENTS

(b) DETAILED SOLUTION OF STEP (3 a)



(c) DETAILED SOLUTION OF STEP (3 b)

(d) CORRECT MOMENTS: STEP (4)

FIG. 11.—COMPLETE SOLUTION OF PROBLEM TO FIND EFFECT OF MOVEMENT IN THE JOINTS.

assume moments of + 1 000 and — 1 000 in the first-floor columns and distribute them throughout the frame. Shears are found as before (see Fig. 11(*a*)), and the resultant forces corresponding to the moments are computed. In a similar manner, Fig. 11(*c*) illustrates Step (3(*b*)).

For this example, the equations specified in Step (4) are as follows:

$$+142.3\ C_1 + 295.8\ C_2 = 35.7 \ldots\ldots\ldots\ldots (1)$$

$$+560.3\ C_1 + 369.7\ C_2 = 46.3 \ldots\ldots\ldots\ldots (2)$$

When Equations (1) and (2) are solved simultaneously the values of C_1 and C_2 are found to be 0.00445 and 0.119, respectively. The correct proportion of the moments caused by the assumed loads (see Fig. 11(*b*) and Fig. 11 (*c*)) are then added to the moments found by assuming no side-sway (Fig. 11(*a*)). The final correct results are shown in Fig. 11(*d*). A comparison between Fig. 11(*a*) and Fig. 11(*d*) will show that the error due to ignoring the effect of sidesway in this example is 27, or 3.4 per cent.

I. OESTERBLOM,[16] M. AM. SOC. C. E. (by letter).—In a limited way Professor Cross' method for computing bending moments in elastic frames has been known to the Engineering Profession in the United States. It has been presented in his University lectures and also in mimeographed note form. This presentation has been entirely too limited, however, and the profession should be grateful for its greater distribution as a paper before the Society.

Unfortunately, the task of computing continuous elastic frames is so complicated and time-consuming—although not necessarily time wasting—that the interest of the average engineer has become paralyzed into a state of mild, and sometimes even humorous, interest. The reason for the occasional amusement would be similar to that of a staid old college professor invited to dance the Maxixe with a vivacious Castilian ballerina on the floor of the Café de Paris. Not that the Maxixe is not graceful and the conditions alluring; but oh, how difficult the dance seems to be! The danger, therefore, might be real that this worthy contribution to accurate, and at the same time rapid; design methods might be passed over without a full realization of its economic significance. It is the opinion of those who know the method that it should be given a trial in every prominent designing office in the country.

The difficulty of calculating anything but the most elementary elastic deformations has been considered so great that the problem of computing their compound effects in relation to bending moments has been generally shunned. Even as late as 1930, sixty-six years after Maxwell gave to the world his general equation for elastic deformations, the motto in some of the best engineering offices still is: "Let us assume".

"Let us assume 100 when both theory and experiment show that it ought to be between 45 and 55—or *vice versa*—but let us be sure that the computed stress is not more than 650 or 16 000." The professor prefers a promenade along the boulevard, but with one foot in the gutter. Quite clearly the degree of approximation in the "let us assume" method is absurd in relation to the refinement of permissible stress assumption. To make Professor Cross' method potentially attractive it would seem desirable, therefore, to outline by comparison the real difficulties which one is trying to escape.

---

[16] Civ. Engr., Chicago, Ill.

The fundamental equation derived from Maxwell[17] reads, as follows:

$$\delta_a = \delta_{ao} - X_a \, \delta_{aa} - X_b \, \delta_{ab} - X_c \, \delta_{ac} \, \ldots\ldots + \delta_{at} \ldots\ldots\ldots\ldots \quad (3)$$

Deflections are here represented by δ and the redundants by X. With a δ adjacent to an X, the deflection is for a unity, X. The indices have reference to the frame points, a, b, c, etc., and the temperature change, t. For a double index after δ, the first represents the location of the deflection; and the second, the location of its static or redundant cause. The symbol, δ_{ao}, signifies the deflection at a, with all redundants equal to zero. The equation represents the elementary fact that the deflection at any point is the sum of partial deflections, each attributable to a different cause. This is by the law of superposition, which is substantially true below the elastic limit of stress.

It should be noted further that for each redundant there is a sequence of partial deflections and that, therefore, one may write as many similar equations as there are redundants. Assuming every δ to be known, it would, therefore, be a simple problem of algebra to solve for the redundants.

There are two difficulties, however, to prevent a more common use of the universal method: First, one has to cope with the frequency of numerous redundants, which makes the use of determinants most necessary for the solution of the equations; and, second, each partial deflection, although purely a problem of statics, is difficult to ascertain.

To the average engineer the necessity for using determinants occurs so infrequently that he is very likely to get confused in his plus and minus signs. He is afraid, therefore, of the accuracy of the results and also afraid of the method.

The second objection is even more serious. There are many ways to compute the deflections: (1) By the equation of the elastic line; (2) by Mohr's method of moment areas; (3) by Castigliano's method of least work; (4) by equating the external work with the resilience; and (5) by the use of Maxwell's elastic weights. These methods are more or less similar or comparable and each has its advantages for given frames or elements. The unfortunate fact is that each partial deflection is quite a problem of its own; that there are as many[18] of them as the second power of the number of redundants; and that each is generally complicated through the compounding of several elements in more or less complex relations.

The elementary labor of integrating and summarizing each partial deflection is, therefore, very considerable, and multiplication of work to allow for all the redundants, together with the accumulation of these results into appropriate determinants, makes the task commercially impossible, except for very heavy, important, dangerous structures.

---

[17] This equation in some form occurs in all the textbooks and handbooks of Continental Europe; see, also, "Statically Indeterminate Stresses," by Parcel and Maney, New York, 1926, p. 112.

[18] By the use of Maxwell's law of reciprocal deflections the number of problems due to unity loads may be reduced by one-half.

The formulas for elementary frames are generally well known; some complicated frames have also been analyzed and reduced to a series of formulas,[19] but many of the more complicated frames, or simple frames with a few unusual features, must always be solved as individual problems.

The question then arises: Should not the continuous frame be abandoned for the sake of greater safety and simplicity? Obviously not; there are numerous most necessary frames which are inherently continuous and can be nothing else. They can not be abandoned therefore; neither should they be analyzed, as loosely as they often are, "by the method of assumption".

Here is where Professor Cross' method is certain to render conspicuous service to the profession. Using this method of successive approximations, the writer has checked a heavily loaded three-post reinforced concrete bent in 3 hours and with an error of less than 3 per cent. It was necessary to distribute and "carry over" only three times, whereas a very competent engineer had required several days to analyze it.

Knowing the universal method and its complications one is led to consider such a saving of time almost incredible and must necessarily ask in what manner such a miracle is possible. Professor Cross' method then appears to resolve itself into an interpretation and simplification of the universal method—and none can gainsay that it is both original and graceful. The reasons for simplicity and saving of time are outlined as follows:

> (1) The very annoying product, *EI*—which is scattered all over the calculation sheets of the universal method—has been combined with spans and heights into a "stiffness factor," on the basis of which—for any moment effect—from whatever cause, at any point, a distribution is made in proportion to resultant resisting moments of adjacent elements. This eliminates in one stroke numerous petty notations and calculations of multiple occurrence.
>
> (2) The travel of any moment induced at any point from any external source is then followed through along the lines of the frame by means of the "carry over factor" until such a point is reached that the effect is dissipated to an insignificant magnitude. This means the elimination from the universal method of all those elements of expression, which merely denote an unnecessary refinement of calculation, ordinarily concealed under an innocent looking form, but none the less present as a burden on the calculations.
>
> (3) Finally, there is the author's conventional grouping and summation, which takes the place—after all the "trimmings" have been eliminated—of the basic equations and their determinants.

In the analytical field Professor Cross' method takes a place with the method introduced in the graphical field by George E. Beggs, M. Am. Soc. C. E., of measuring the deflections of elastic models.[20] The two together form a very significant and admirable balance as against the profound theory of Continental Europe, which, excellent and extensively published, has none the less made little impression on the profession in the United States, except in designs of certain types of bridges and dams.

---

[19] See, for instance, Kleinlogel "Rahmenformeln" and "Mehrstielige Rahmen," Berlin, 1925 and 1924.

[20] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208.

Professor Cross himself has confessed to a limitation of his method: It is not apparent how it could be applied, if the supports were truly movable. Perhaps this gap may be eliminated as experience is gained and more thought is given the subject. However, at present, this is of less importance, as most commercial problems are dealing with unyielding supports, and, for those which are not, it would be economically feasible to use the universal method at full length. These are problems that generally involve large quantities of costly construction materials, and sometimes also foundation difficulties, so that the cost of careful analysis is, therefore, not only small by proportion, but also most necessary to safeguard the heavy investment.

ROBERT A. BLACK,[21] ASSOC. M. AM. SOC. C. E. (by letter).—The writer has had occasion to apply the Cross method to the design of simple two-legged bents symmetrically loaded and to continuous beams simply supported, and he knows from experience with what ease, rapidity, and accuracy, indeterminate structures of the type mentioned may be solved. The paper, however, reveals the application of the method to bents of one or more stories subjected to side-sway due either to unsymmetrical or to horizontal loads.

It so happened that the writer was confronted with a problem concerning two-story bents subjected to traction forces and to unsymmetrical loading. The comparative ease and simplicity of the solution afforded by the method described, emphasizes the fact that the subject-matter of the paper offers an invaluable tool for the designer. A brief description of the problem and one phase of its solution follows.

In connection with the extension of a new Outer Drive over the Chicago River and of the development of the air-right territory over the tracks of the Illinois Central Railroad and the Michigan Central Railroad Companies, north of Randolph Street and east of Michigan Avenue, Chicago, the South Park Commissioners are required to build certain viaducts. These are known as the Randolph Street, the Field Boulevard, and the Wacker Drive, Viaducts. They all will be two-level structures having, in general, transverse girders at the column bents and longitudinal floor-beams between bents, and they will be built entirely over railroad-yard tracks. Because of certain sub-surface rights granted the Railroad Companies, it is required that the columns of these viaducts be carried down to Elevation — 19.0 (Chicago City Datum), at which point they will rest on caissons. As the top of the curb of the top deck is at Elevation + 47, the columns will be nearly 65 ft. long. They are limited in size in a direction normal to the center line of track to 2.0 ft., including the concrete encasing. Due to the multiplicity of tracks and their varied alignment, to loading platforms and team tracks, and to limited head-room allowances, the bracing which may be used will be confined entirely to small knee-braces.

The stiffness of these structures will depend almost entirely upon the slender columns and the rigidity of the connections. Therefore, it is important to know the effect of traction and of vertical loading upon bending in the columns and upon the strength of connections. A series of influence lines was considered to be the best means of studying the columns and their connections in these viaducts.

---

[21] Structural Engr., South Park Commrs., Chicago, Ill.

A typical cross-section of the Field Boulevard Viaduct is shown in Fig. 12. The letters refer to floor-beam points on the top deck and the numbers on the structure refer to points at which moments were computed, that is M_1, M_2, etc. The solution for the ordinate to an influence line with the load on the top deck only, may be outlined in six steps as follows, the unit load in this example being placed at Point C:

FIG. 14.—COLUMN SHEARS, H'_{TC} AND H'_{BC}, WITH A LOAD AT POINT C, IN FIG. 15, AND WITH NO SIDEWISE DEFLECTION.

1.—With the unit load at Point C on the top deck, the fixed-end moments at B and F are − 7.734 and − 2.578, respectively (see Fig. 13). Distribute these moments as demonstrated by the author in Fig. 1, using a "carry-over factor" of $-\frac{1}{2}$, and considering no sidewise deflection of the bent. Only the final moments, M'_C, are given in Fig. 13.

2.—After the distribution operations, compute the column shears (see Fig. 14), H'_{TC} and H'_{BC}. (The subscripts refer to the top or bottom story with a unit load at Point C.)

3.—Take the same bent, but without the unit vertical load, and apply any convenient set of fixed-end moments to the top-story columns. The only restriction on these moments is that they shall be proportional to the $\frac{I}{L^2}$ of the columns to insure that the deflections at the tops of the columns will be the same. For the present purpose values of 100, 211, and 100, respectively, were selected and applied as shown in Fig. 15. Distribute these moments as before; sum them up and call the final moments, M''. Repeat Step 3, beginning with the lower-story columns. Call these final moments, M''' as in Fig. 16.

4.—From the moments, M'' and M''', compute the column shears in both stories. These shears are designated H''_T, H''_B and H'''_T, H'''_B, respectively. (See Figs. 17 and 18.)

FIG. 16.—MOMENTS, M''', DUE TO DISTORTION IN THE LOWER STORY.

5.—The total shear in each story is made up of the shear due to the vertical load and that due to the assumed moments causing the side-sway, and this total shear must equal zero to satisfy statics; that is, the total shear is equal to H' plus some fraction of H'' and H'''. Therefore,

$$H'_{TC} + a\,H''_T + b\,H'''_T = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

$$H'_{BC} + a\,H''_B + b\,H'''_B = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

or, using the values from Figs. 14, 17, and 18, Equations (4) and (5) become,

$$-\,0.027 + 42.10\,a - 2.40\,b = 0 \ldots\ldots\ldots\ldots\ldots\ldots(6)$$

$$+\,0.0001 - 0.643\,a + 17.18\,b = 0 \ldots\ldots\ldots\ldots\ldots\ldots(7)$$

Solving Equations (6) and (7) simultaneously, $a = +\,0.000642$ and $b = +\,0.000018$.

The total moments, therefore, at Points 1, 2, 3, etc. (Fig. 12), due to the unit vertical load at C and corrected for side-sway are,

$$M_C = M'_C + a\,M'' + b\,M''' \ldots\ldots\ldots\ldots\ldots\ldots\ldots(8)$$

that is, using values from Figs. 13, 15, and 16, and the previously determined values of a and b,

$$M_1 = -0.942 + 0.00064 \times 90.1 - 0.000018 \times 2.9 = -0.884$$

and so on for all other moments, M_2, M_3, etc.

Sign of a.—By inspection of Fig. 14, it is seen that the resultant shear in the top story (0.027 lb.) acts from right to left. (According to the convention used by Professor Cross the shears as shown in Fig. 14 are acting on the lower portion of each column. In this example, all shears have been shown in this way.) In order to satisfy statics the shears on the outside columns then, should be decreased and the shear on the center column increased. Assume, arbitrarily, that shears acting from left to right are positive and solve Equations (6) and (7). Then, substitute these values of a and b in Equation (8), solving for M_1 and M_{11} (outside column moments). If these moments are decreased numerically from M'_1 and M'_{11}, respectively, then the original assumption for the sign of the shears was correct and will hold for all other positions of the unit load on the top deck. A check on the work is obtained by noting that the sum of the column shears computed from the final moments, M_C, is equal to zero in each story.

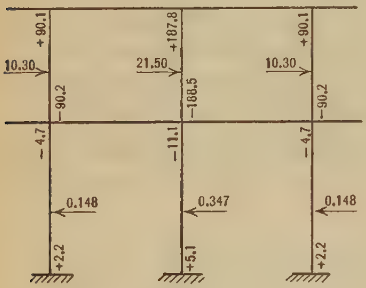

FIG. 17.—SHEARS, H''_T AND H''_B.

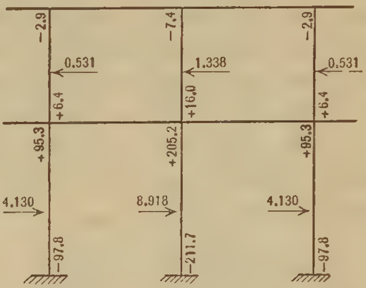

FIG. 18.—SHEARS, H'''_T AND H'''_B.

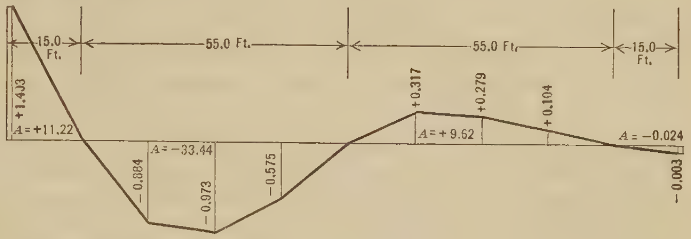
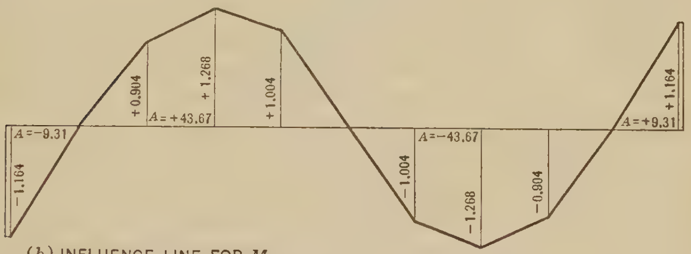
6.—By using Equation (8) to correct all M'_C moments at Points 1, 2, 3, etc., of Fig. 12, the material is derived with which to plot two ordinates (at C and at J) on the influence line for the moment at any one or all of the points shown in Fig. 12. It should be noted that the effect of the load at J on M_1, for example, will be the same as that of the load at C on M_9, the bent being symmetrical, except that the sign of the moment changes when dealing with column moments. (The sign remains unchanged for girder moments.) Examples of influence lines, selected at random, are shown in Fig. 19.

It should be noted, also, that in carrying the problem on for positions of the unit load at other points on either deck, the values of M'' and M''', and H''_T and H''_B, and H'''_T and H'''_B, herein used for Point C, may also be used for the load at all other points.

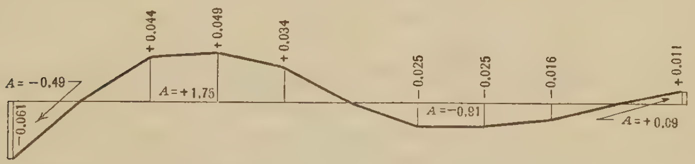
After the load has been run across the top deck, it can be placed on the lower deck and an independent set of influence lines obtained for moments at the same points, 1 to 24, inclusive, shown on Fig. 12. The conclusions and results which may be obtained from these influence lines are obvious and need not be mentioned here.



(a) INFLUENCE LINE FOR M_1



(b) INFLUENCE LINE FOR M_6



(c) INFLUENCE LINE FOR M_{13}

FIG. 19.—INFLUENCE LINES, IN FOOT-POUNDS UNITS, FOR M_1, M_6, AND M_{18}, WHEN THE TOP DECK ONLY IS LOADED.

In this example, tractive forces are acting normal to the bent and hence do not affect the moments herein computed. However, in any case where they are an element to be considered, their effect may be determined by Steps 3 to 6, inclusive, because in this case there are no moments, M', and the shears do not equal zero, but are equal to the known tractive force. This alters Equations (4), (5), and (8). Otherwise, the procedure is the same.

In the example given, the moments of inertia of the various members were obtained from a preliminary design, and while their actual values may change somewhat their relative values should remain about constant. Almost without exception, all computations were made on a 10-in. slide-rule. The method has proved accurate, a great time saver, and a valuable aid to intelligent design.

H. E. WESSMAN,[22] ASSOC. M. AM. SOC. C. E. (by letter).—Professor Cross' method of analyzing continuous frames is the most outstanding contribution made in many years to the field of structural engineering. Although it has for its fundamental basis the geometry of slopes and deflections of elastic members—which is common to all logical methods of analyzing indeterminate structures—it is developed in a much different way. Other methods usually begin by making the structure simple; in other words, by theoretically cutting restrained ends or inserting temporary hinges. End moments are then obtained by solving simultaneous equations which are functions of the angles through which the cut or pinned ends must be rotated to make the structure continuous again. The Cross method, on the other hand, starts by making the structure rigidly fixed at every joint or support and then finding fixed-end moments for any loading condition under consideration. One joint at a time is then released, and the fixed-end moments are modified to secure equilibrium at the released joint. This joint is temporarily fixed again until all other joints have been released and fixed in their new positions. Then, the procedure is repeated again and again, until the desired degree of accuracy is obtained. The process may be easily visualized by thinking of it as a very slow-motion picture of the magnified, physical response of the structure as it gradually adjusts itself to a load condition just created upon it.

The complete mathematical computations which evaluate this adjustment and give final moments and shears are made in so brief a time and in such a simple manner that the method is certain to appeal to the practical-minded engineer. With this tool of analysis at his command, there is no need for the designer to "shy away" from indeterminate structures. There is no excuse for "guessing" moments and shears by means of arbitrary coefficients such as those found in present-day design codes for reinforced concrete, which apply to a limited number of cases.

Curves of Maximum Positive and Negative Moment.—In his concluding remarks, Professor Cross hints of the possibility of applying his method to an almost endless number of specific problems and invites discussion on them. The writer has had opportunity in his design practice and in teaching to compare the application of several methods to some of these problems. He much prefers that of Professor Cross and wishes to illustrate its workability in constructing curves of maximum moments and in analyzing frames subject to lateral displacement. Curves of maximum positive and negative moment have been computed for a four equal-span continuous beam for various ratios of uniform live load to dead load (hereafter called the $\frac{L}{D}$ ratio). In the first case, there is no restraint at the supports from columns or other structural elements. In the second case, corresponding curves are computed for a four-span system having the same span lengths as the first, but in which rigidly connected columns at the supports affect the moments. This case is one in which analysis by previously accepted methods becomes very complex. It is just as easily treated by the author's method, however, as the first case in which there are no restraining columns. A study of the two sets of curves will not only show the effect of column restraint in changing curves of maximum moments for the beams, but will raise some questions about present design codes for reinforced concrete.

FIG. 20.—TYPICAL INFLUENCE LINES FOR MOMENTS AND SHEARS.

It is necessary to know where to place live loads in order to obtain the greatest effect at any point (or section) of the continuous system. Here is where the influence line performs its chief function. It is primarily a guide for the intelligent placing of live load. Fig. 20 shows typical influence lines for moments and shears at various governing points in a four-span continuous system. They are not quantitative; only qualitative. To most engineers familiar with indeterminate structures, sketching the influence line is only a moment's task. In most cases a sketch is sufficient to tell one where to place the loads for maximum effect. For the governing points of the design, that is, points along the middle one-half of the span, Fig. 20 (*a*) and (*c*), and points at the supports, Fig. 20 (*b*), the influence lines for moment show that only full span loads are needed. They change sign (from positive to negative) only at the supports. In reinforced concrete design, these points are the only ones that need to be investigated in most cases.

Note the influence line, Fig. 20 (*d*), however. This is for M at a point in the center span near the support. There is a change in sign within the span and to obtain the maximum positive or negative moment at this point a partial span load must be investigated. This type of influence line is common to all points between the support and the so-called critical point, which, in beams of constant section, is about two-tenths of the span length from the support. To obtain the length of this partial span load, it is necessary to find numerical values for only a short section of the influence line adjacent to the point where it crosses from the positive to the negative side. This is Point x in Fig. 20 (*d*). One unit load may be placed at the three-tenths point in the span and the moments found by the Cross method.

The process is repeated for a unit load at the four-tenths point. From these two load positions, enough of the influence line can usually be determined to obtain the load divide, or the partial length of span over which live load must be placed. It is doubtful, however, whether this is of any practical significance. The part-span load combined with the other full-span loads to give maximum effect calls for a split loading that rarely occurs under actual conditions. In reinforced concrete design, there is certainly no practical necessity to consider these part-span loads for moments. In steel girder design, they may be needed for the longer spans in order to determine cover-plate cut-offs more accurately. It is largely a question of judgment as to the possibility of obtaining the split loadings in service conditions. For continuous steel trusses, however, it is advisable to determine these partial span loadings and their effects in order to obtain maximum chord stresses and provide for possible reversal of stress in the panels near the center piers. Consequently, for the maximum moment curves, illustrated in Fig. 21, only full span loads have been considered. Note how one span at a time is loaded and the results combined to give the final maximum moments for dead load plus live load.

Curves of maximum shear are not given in this discussion, although typical influence lines for shear at various points are shown in Fig. 20 (*e*) and (*f*). To obtain the maximum shear at any point within the span, a part-span load must be used. To get its length it is not necessary to compute any values for any part of the influence line, however, as in the case of moments. This is because the load divide point coincides with the point at which the shear is wanted or is in the same panel if a through girder is being analyzed. For reinforced concrete beams of constant section, there is no practical need to find the maximum shears at any interior point, except the center of the span. From this value and the maximum at the support, stirrup spacing may be determined closely enough. If the beams are haunched, the maximum shear at the quarter-point, or at the point of the haunch, should be found in order to keep the unit shear over the reduced section within specification limits.

Case I.—Four 20-ft. spans are used. (See Table 2.) Each span has the same cross-section and, consequently, the $\frac{I}{L}$ ratio is the same for all. As the ends are freely supported, however, the $\frac{I}{L}$ ratio for the end spans has been decreased by one-fourth, the stiffness of a span with pinned ends being only three-fourths as great as when the ends are fixed. The numbers in circles indicate the relative stiffness of each span. Units are in thousands of foot-pounds.

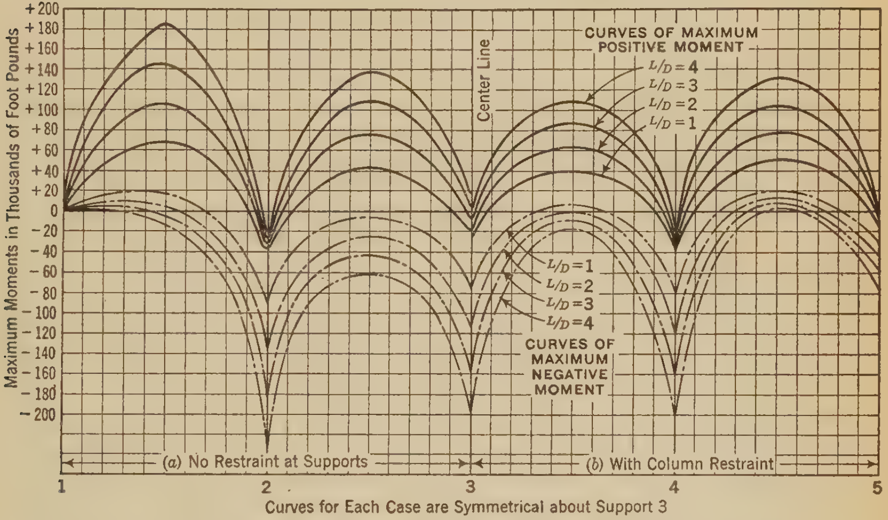

FIG. 21.—CURVES OF MAXIMUM MOMENT.

Moments are found at all supports and in the center of each span, due to a uniform load of 1 000 lb. per ft. over one span at a time. These moments are then combined to give maximum positive and maximum negative moments at each point, due to live load. These two values for each point are then added algebraically to give the moments due to a dead load of 1 000 lb. per ft. over the entire four spans of the continuous system. Live load moments are then combined with dead load moments to obtain the ordinates for the curves of total maximum positive and total maximum negative moments for a ratio, $\frac{L}{D}$, equal to 1. To get curves of moments for any other ratio of $\frac{L}{D}$, the live load moments are first multiplied by the necessary ratio before combining them with those of the dead load. These curves (Fig. 21 (*a*)), are quite easily plotted with no other points than those given, inasmuch as the middle three-fifths (approximately) for each span is a parabola. Curves are shown for $\frac{L}{D}$ ratios of 1, 2, 3, and 4.

Case II.—A three-story reinforced concrete warehouse, 80 by 160 ft. by 42 ft. high, with columns on 20-ft. centers each way, is used as the structure for analysis. (See Table 3.) Sections were obtained (designed) for a $\frac{L}{D}$ ratio of 2.5. Moments were computed for a second-story four-span beam restrained by columns both above and below. Moments of inertia, I, were computed, using the entire concrete section, but ignoring the steel reinforcement. A width of slab equal to one-fourth the span length was used as the T for the beams and was considered in the moment of inertia. From the $\frac{I}{L}$ values, the relative stiffness, shown at the middle of each member, was computed. These same values were used for all ratios of $\frac{L}{D}$, because it is easily possible to make a design for each loading without altering the relative stiffness of each member.

To obtain the curves of maximum positive and negative moment (Fig. 21 (*b*)), the same procedure used for Case I is followed. Maximum column moments are not shown in the final summation, but can easily be obtained by combining the values shown.

Case II is a good example of the form of computations recommended by the author. The method of "Moment Distribution" is admirably adapted to a simple and easily checked arrangement of figures. There is some difference of opinion as to the most desirable sign convention to be used. The writer made a somewhat detailed study of this question, comparing different conventions, and concluded that the one used by the author was to be preferred. It not only harmonizes with the usual practice of defining positive and negative moment in a beam, but, in complicated frames, there seems to be no chance of an error in sign remaining undetected when moments are distributed and the equilibrium of each joint is checked. The important factor, however, is that the method is just as workable, regardless of what sign convention is dictated by personal preference.

Results of Computations.—This discussion is submitted to show primarily the application of the author's method of analysis to a specific problem. It would not be complete, however, unless some pertinent conclusions about the particular problem investigated were included.

The correct values for the maximum moments at critical points are compared with the values obtained, using the conventional moment coefficients found in the design codes for reinforced concrete. (See Table 4.) The coefficients in Article 107 of the report of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete (1924)[23] are used for Table 4 (*a*) and the coefficients in Article 110 (*a*) and (*b*) are used for Case II, Table 4 (*b*). The length of span used in Table 4 (*a*) for code values is the full length, that is, 20 ft. In Table 4 (*b*), in which columns restrain the beams, code values are computed for a clear span of 18.5 ft. Therefore, in order to make a fair comparison, the correct moments at the face of the columns have been computed and tabulated. That explains the difference in values at the supports shown in Table 4 (*b*) and in Case II. The computations, Case II, are for the center line of the support.

TABLE 4.—COMPARISON OF CORRECT MAXIMUM MOMENTS WITH THOSE DETERMINED BY THE USE OF CONVENTIONAL MOMENT COEFFICIENTS.

$\frac{L}{D} = 4$	Correct *M*.........	0	+184.9	—235.6	+140.0	—202.6	— 41.2	+ 32.7	—170.3	—160.9	+110.7	—147.7
	Code *M*............	0	+200.0	—200.0	+166.6	—166.6	—142.5	+142.5	—142.5		+107.0	—142.5
	Error, percentage.	0	+ 8.2	— 15.1	+ 19.0	— 17.8	+246.0	+ 7.4	— 16.5	— 11.4	— 3.3	— 3.5

Figures showing the percentage of error in code moments should interest many designers. For both unrestrained and restrained beams, code coefficients give values too high for positive moment in the centers of the spans and values too low for negative moment at the supports. The difference is enough to warrant a revision in all the coefficients applied to continuous systems with little or no restraint, such as that of Case I. In systems like that of Case II, coefficients for the interior spans are sufficiently accurate for practical purposes. The coefficients for the end spans and particularly the end supports are decidedly in error, however, and should be revised.

---

[23] *Proceedings*, Am. Soc. C. E., October, 1924, Papers and Discussions, p. 1153 *et seq.*

The design codes make no reference whatever to the existence of negative moment at the center of spans. (See Fig. 21.) Even for a $\frac{L}{D}$ ratio as small as unity, negative moment may occur over the full length of interior spans subject to little end restraint. Consequently, reinforcing steel is needed at the top of the beam over its full length. Note the values for a $\frac{L}{D}$ ratio of 4. The maximum negative moment at the center of the second span is 60.8. The maximum positive moment at the same point is 140.0. Most designers will place steel in the bottom but not in the top, disregarding the fact that the top needs 43% of the total used in the bottom. Even for spans subject to column restraint, the negative moment is large enough over the greater part of the interior spans to justify a decided change in current design practice. Some will argue that there is no need for worrying about this because the floor steel in the slab will assist the beam in providing resistance to the tension which may occur on the top side under certain loading conditions. It is true that the floor steel will help somewhat (more in girders than in the beams), but it is quite unscientific to make definite provision for a positive moment and ignore a negative moment which may be half as large.

When the time comes for the next revision of reinforced concrete design codes, the writer hopes that the responsible authorities will omit all values for moment coefficients, thus placing the function of analysis entirely upon the shoulders of the designer. This will not only encourage the engineer to develop more self-reliance and initiative, but it will pay deserved premiums to the man with the technical ability to design structures intelligently. It must be remembered that too many designers will accept a "half-complete" code as the authority for a complete design. "Their's not to question why * * *". However, if the responsible authorities still insist that there must be more rules for the game, then it is advisable to define explicitly those limited cases to which the rules apply. It will impose some check on the designer who is inclined to take too much latitude.

With the author's method, maximum moments and shears for any design subject to any condition of uniform or concentrated loads are so readily computed that there is little need for using arbitrary coefficients in any case. Although the preceding discussion revolves chiefly around equal span systems subject to uniform loads, systems with equal or unequal spans subject to concentrated loads are just as easily treated.

Frames Subject to Lateral Displacement.—The writer also wishes to illustrate the facility of applying the author's method to a problem usually considered quite complex, that is, that of a mill-building bent, with a stepped column subject to a lateral thrust from a traveling crane. The problem is complicated by the variation in moment of inertia of the column due to the different sections used above and below the crane girder seat. (See Fig. 22.) The moments in the columns are wanted, due to the effect of a lateral concentrated load of 6 000 lb. on each column; this is the horizontal thrust of the crane, acting 27 ft. above the base. The moments are first found for the horizontal load acting on one column. Since there is a similar load acting on the other column, the final moments are obtained by combining those due to a single load on opposite hand bents. Vertical loads and wind loads are ignored in this illustration. Moments due to such loads would be computed in a similar manner. For a complete design, they would naturally have to be considered.

FIG. 22.—HALF SKETCH OF A MILL-BUILDING BENT WITH A STEPPED COLUMN.

The base of the column is considered fixed. The ratio of the stiffness of the truss to the stiffness of the column is more than 10. This makes the upper end of the column practically fixed, so that in the following analysis the $\frac{I}{L}$ value for the truss is taken as infinity. The final moments are consequently slightly in error. If the exact moments are wanted, they may be found by using the correct stiffness factor for the truss and releasing Joints P and R (Fig. 23) after the fixed-end moments are found. The correction, however, is too small to have practical significance.

In the first operation, Fig. 23 (A), Column MNP is temporarily supported at N, where the change in column section occurs, and the moments on the resulting two-span continuous beam are found due to the load of 6 000 lb. Reactions at M, N, and P are found; that at N is 5 200 lb. In Fig. 23 (B), the moments due to a force of 5 200 lb. at N, acting in the opposite direction, are found. This simply determines the effect of removing the temporary support. Note that the moments due to this load are not found directly, however. It is easier to find a force which moves N in a horizontal direction only, causing an arbitrary moment in MN of 10 000 ft-lb. This is a fixed-end moment and the corresponding moment in NP is 3 630 ft-lb., found from the equation,

$$M_2 = M_1 \frac{I_2 L_1^2}{I_1 L_2^2} \quad \text{.........................} \quad (9)$$

which is the familiar expression for moments in two members, when one end of each is given the same deflection, while the other end of each remains fixed. Joint N is then released and the moments are adjusted by moment distribution. The shears are then determined and, from these, the arbitrary load is found to be 1 270 lb.; but the actual load is 5 200 lb.; therefore, the final moments and shears in Step B are found by proportion. Then (see Fig. 23), $A + B = C$, a condition which gives the fixed-end moments at M and P, due to the load of 6 000 lb., and with a temporary support at R, to prevent side-sway. The value of this temporary force is 4 500 lb. Therefore, in Fig. 23 (D), the effect of a force of 4 500 lb. at R, acting in the opposite direction, is determined. Thus, $M_M = 27 \times \frac{4\,500}{2} = 60\,800$ ft-lb., and $M_P = 8 \times \frac{4\,500}{2} = 18\,000$ ft-lb. Note in this step that the point of contraflexure in the column for a horizontal load at the top is at the center of gravity of the elastic weights of the column. From the point, P, the distance down to the point of contraflexure is $\left(\frac{1}{6} \times 23 + 5.5\right) \div \frac{7}{6} = 8.0$ ft. The total elastic weight is $\frac{\Sigma L}{E I}$. This location is correct only when there is pure translation of the top and no rotation. The top member, $P R$, must be infinitely stiff to make this possible. A slight correction may be made inasmuch as $P R$ is not infinitely stiff, but the correction is so small that it can be ignored.

In the next step, $C + D = E_R$, which gives the moments due to one of the 6 000-lb. loads. To account for the other load of 6 000 lb. on the other column, the moments shown in E_R are added to opposite-hand moments to obtain the final values in Fig. 23(F).

Fig. 23.—Moments in a Mill-Building Bent Due to Lateral Crane Thrust, in Thousands of Foot-Pound Units.

This problem not only illustrates the application of the Cross method to frames subject to side-sway, but, at the same time, points out some interesting conclusions about mill-building bents of this type.

Moments due to crane thrust demand large increases in column sections. In this particular case, it was found that the area required by the vertical loads had to be increased 100% to care for this moment. If the bottom of the column were pinned instead of fixed, the maximum moment would be about 40% less. Therefore, regardless of whether the bases of the columns are fixed or pinned, this moment is a major factor in design and cannot be overlooked.

Moments such as these are often determined by approximate methods. In one method the top and bottom are considered fixed and side-sway is ignored. A comparison of Fig. 23 (*C*) and Fig. 23 (*F*) will indicate the great error involved in this approximation. In another approximate method pins are assumed to be placed at *M* and *P*, and the column is computed as a simple beam for the lateral load. This would give a design moment of 37 000 ft-lb. under the load, which is 75% in error. An approximate method which is safe in this case is based on considering the column as a cantilever, fixed at the base. That would give a moment of 162 000 ft-lb. which is 9.5% on the safe side. For a wind load, or a concentrated load acting on one side only, this approximate method would waste too much column area. It is rather dangerous to attempt to use approximate methods unless the designer is fully aware of their limitations. It is far better to use the author's method of analysis—the keynote of which is simplicity—and thus obtain accurate values for design purposes.

EDWARD J. BEDNARSKI,[24] ASSOC. M. AM. SOC. C. E. (by letter).—The Cross method appears to be similar to that of deformations developed by Professor A. Ostenfeld[25] in that both methods make use of "fixed-end moments" and "stiffness". Instead of the "carry-over" factor, however, Professor Ostenfeld utilizes the relationship between moments and rotations at the ends of structural members. Instead of successive approximations he uses simple consecutive computations. The results are exact within the limits of primary assumptions on which the method developed by Professor Cross is based. It is of interest, therefore, to compare the actual work required to solve the same problem by both methods.

The writer has computed the problem shown in Fig. 1 by the Ostenfeld method, and finds that the computation and checking require less time than is needed by the Cross method. Besides, there is no confusion whatever regarding the signs of the moments because they are entirely independent of the position of the structural member under consideration.

The Ostenfeld method is not yet widely known in this country. It provides an adequate solution of the stresses in a statically indeterminate structure under unsymmetrical load, and subject to "side-sway". It can also be applied to continuous beams on tall columns as well as to multi-storied bents and multiple arches on high piers. The computation required by this method is outlined herein, as applied to the problem under discussion.

---

[24] Civ. Engr., Sacramento, Calif.

[25] "Deformations Methode," by A. Ostenfeld, Copenhagen, 1926.

The stiffness factors, μ, and the fixed-ended moments, M^0, to be used in the present demonstration are the same as those assumed by Professor Cross (see Fig. 1). The signs of the moments are considered positive in the clockwise direction. To solve the problem by the Ostenfeld method, first determine values of the rotation factors, ζ_{oa}, at the ends of each structural member, by means of the formulas:

$$\zeta_{oa} = \frac{Z_{oa}}{Z_{aa}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(10)}$$

and,

$$\tau_a = \frac{1}{Z_{aa}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(11)}$$

in which,

$$Z_{oa} = -\left[M^0{}_{am} + \frac{2\,\mu_{am}}{1 + 4\,\mu_{am}\,\tau_m}\,(\zeta_{om} - \tau_m\,M^0{}_{ma})\right] - M^0{}_{ai} - M^0{}_{ak} \ldots \text{(12)}$$

and,

$$Z_{aa} = 4\,\mu_{am}\,\frac{1 + 3\,\mu_{am}\,\tau'_m}{1 + 4\,\mu_{am}\,\tau_m} + 4\,\mu_{ai} + 3\,\mu_{ak} \ldots\ldots\ldots\ldots \text{(13)}$$

The subscripts in Equations (10) to (13), inclusive, may be defined briefly as follows:[26]

- $a\,i$ refers to one or more members, $a\,i$, that are connected at Joint a the other end, i, of the members is fixed.
- $a\,k$ refers to one or more members, $a\,k$, that are connected to Joint a; the other end, k, of the members is fixed.
- $o\,a$, as a subscript of the rotation factor, ζ, identifies it as referring to the end, a, of a member at which the moment, M_{am}, is equal to zero; Z_{oa} is the moment necessary at the end, a, of a member, to produce the rotation, ζ_{oa}.
- $a\,a$ appears as a subscript to Z; thus, Z_{aa} is the moment applied at the end, a, of a member, such that it produces a rotation factor, ζ_{aa}, equal to —1.
- $a\,m$, as a subscript of M, identifies it as the moment at Point a in any beam.
- τ_m is the rotation factor at the end, m, of a member, $a\,m$, of such magnitude as to create a moment, M_{am}, equal to 1.

In the example under discussion, the necessary factors for the various beams and columns are found to be:

For Column $B\,A$: $B = a$ and $A = m$ in Equation (12) and Equation (13).

$$Z_{OB} = 0;\; Z_{BB} = 8;\; \zeta = 0; \text{ and } \tau_B = \frac{1}{Z_{BB}} = \frac{1}{8}.$$

For Joint C: $C = a$, $B = m$, $G = k$, and $F = i$, in Equation (12) and Equation (13); hence,

$$Z_{OC} = -100 + \frac{2 \times 4}{1 + 4 \times 4 \times \frac{1}{8}} \times \frac{1}{8} \times 100 - 50 - 110 = -\frac{880}{3}$$

---

[26] See also "Deformations Methode," by A. Ostenfeld, Copenhagen, 1926.

$$Z_{CC} = 4 \times 4 \times \frac{1 + 3 \times 4 \times \frac{1}{2}}{1 + 4 \times 4 \times \frac{1}{8}} + 4 \times 1 + 3 \times 2 = \frac{70}{3}$$

$$\zeta_{CO} = \frac{88}{7}$$

and,

$$\tau_C = \frac{1}{Z_{CC}} = \frac{3}{70}$$

For Joint D: $D = a$ and $C = m$ in Equation (12) and Equation (13); $Z_{OD} = -\frac{1020}{13}$; $Z_{DD} = \frac{230}{13}$; $\zeta_{OD} = -\frac{102}{23}$; and $\tau_D = \frac{13}{230}$.

For Joint E: $E = a$ and $D = m$ in Equation (12) and Equation (13); $Z_{OE} = \frac{3060}{193}$; $Z_{EE} = \frac{2082}{193}$; $\zeta_{OE} = \frac{510}{347}$; and $\tau_E = \frac{193}{2082}$.

The actual rotation factors, ζ_m, are finally determined for each joint in succession by the formula:

$$\zeta_m = \frac{1}{1 + 4\,\mu_{am}\,\tau_m}\left(\zeta_{om} - 2\,\mu_{am}\,\tau_m\,\zeta_a - \tau_m\,M^0{}_{ma}\right) \ldots\ldots\ldots (14)$$

The actual values for the problem in Fig. 1 are thus found to be: $\zeta_E = \frac{2495}{1041}$; $\zeta_D = -\frac{1085}{347}$; $\zeta_C = -\frac{497}{347}$; $\zeta_B = \frac{3228}{694}$; $\zeta_P = \frac{1}{2}\,\zeta_C = \frac{497}{694}$; and $\zeta_A = \zeta_B = 0$.

The final moments are determined by means of the equations:

$$M_{am} = 2\,\mu_{am}\,(2\,\zeta_a + \zeta_m) + M^0{}_{am} \ldots\ldots\ldots\ldots\ldots\ldots (15)$$

and,

$$M_{ma} = 2\,\mu_{am}\,(2\,\zeta_m + \zeta_a) + M^0{}_{ma} \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which, M^0, denotes the original fixed-end moment at the end of the beam indicated. The values of M, thus determined are, respectively,

$$M_{AB} = 18\,\frac{200}{347} = 18.576$$

$$M_{BA} = 2\,M_{AB} = 37.152$$

$$M_{BC}\ \text{(computed independently)} = -\,M_{BA} = -\,37.152$$

$$M_{CB} = 114\,\frac{82}{347} = 114.236$$

$$M_{CF} = 101\,\frac{141}{347} = 101.406$$

$$M_{CD} = -\,259\,\frac{317}{347} = -\,259.913$$

$$M_{CG} = 44\,\frac{94}{347} = 44.271$$

$$M_{DC} = 23\,\frac{49}{347} = 23.141$$

$$M_{DE} \text{ (computed independently as a check)} = -M_{DC} = -23.141$$

$$M_{ED} = \frac{3470}{347} = 10$$

and,

$$M_{F'} = -M_{ED} = -10$$

It should be noted as a check that the sum of all moments around Point C equals zero.

S. N. Mitra,[27] Jun. Am. Soc. C. E. (by letter).—Despite some limitations the method described in this paper is quite unique and satisfactory. In the writer's opinion, however, it has the decided disadvantage that it is not conveniently reducible to a general equation that can be used when the principles themselves have been mastered.

Furthermore, the writer believes that, for less complicated problems than the one the author has illustrated, such as those which occur in practice, other methods of analysis, as, for example, slope deflection and the graphical method of conjugate points, will be found more accurate, and quicker and easier to use.

Jens Egede Nielsen,[28] Assoc. M. Am. Soc. C. E. (by letter).—The large number of papers dealing with moment distribution in continuous beams and rigid frames is proof enough that this question needs a practical solution.

The method, as outlined by Professor Cross, is so easily memorized and so quickly applied that all approximate methods and guesswork profitably can be eliminated without the sacrifice of speed, which often is as essential as economy.

When balancing the moments at a point such as C, Fig. 1, in a system in which the signs are quite arbitrarily considered positive when causing sags downward in horizontal members and toward the right side of vertical members, it is not entirely evident which is the right and which the left side of the joint or, rather, which moments should be added and which should be subtracted in order to determine the unbalanced moment. If, however, it is borne in mind that moments in members which sag clockwise should balance moments in members which sag counter-clockwise, it is easy to visualize which moments should be added and which subtracted. Thus, in Fig. 24, — 200, — 50, and — 100, which members sag counter-clockwise, should be subtracted from — 400, which sags clockwise, giving an unbalanced moment of $-400 - (-200 - 50 - 100) = -50$ to distribute among the four members.

The determination of the fixed-end moments for different loadings can be greatly facilitated by the use of influence lines, such as those given in textbooks, one for concentrated loads and an integrated curve for uniformly distributed loads.

The limitations of the method should be realized at once. Systems in which shears are dominant (wind-bracing bents in tall buildings) and systems in which the longitudinal stresses are dominant (arches, etc.) and, particularly, systems in which moving loads are encountered, the time saving seems problematic, and other methods should be considered.

---

[27] Calcutta, India.

[28] Chicago, Ill.

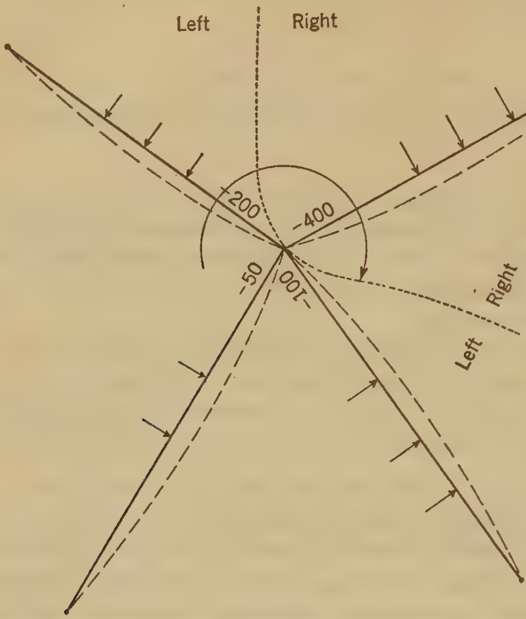

FIG. 24.

The paper is most valuable and should prove helpful to practicing structural engineers.

F. E. RICHART,[29] M. AM. SOC. C. E. (by letter).—The moment-distribution method of analyzing continuous frames originated by Professor Cross is one of the most important developments in this field in many years. The main advantage of the method is its simplicity, through which the designer can attain familiarity with a class of structures generally associated with long algebraic analyses. With this simplicity also comes rapidity of computation, which makes it possible for a structure to be analyzed under many different load conditions in the time previously taken for a single solution. In spite of its advantages, however, it will probably take designers in general a number of years to appreciate the method and to give it the widespread recognition that it deserves.

Because of a disinclination to confuse the reader's conception of the moment-distribution method, the writer hesitates to describe a variation which is nearly as simple in many cases and which leads directly to an exact solution. The scheme is based on an analysis by the slope-deflection method of various typical arrangements of flexural members, for which equations of a standard form may be written.

---

[29] Research Associate Prof., Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.

In Fig. 25, the member, AB, meets the members, BC and BD, in a rigid joint at B. When a couple, M_{AB}, is applied at A (assuming there is no translation of the points, A, B, C, and D), the end, B, is partly restrained. The amount of restraint depends upon the stiffness, as measured by $K = \frac{I}{l}$ for each of the three members, and by the restraints at the points, C and D. In general, the moment, M_{AB}, is given by the equation,

$$M_{AB} = N_1 \, E \, K_1 \, \theta_A \ldots\ldots\ldots\ldots (17)$$

in which, N_1 is a constant, having a value between 3 and 4; E is the modulus of elasticity of the material; K_1 is $\frac{I}{l}$ for the member, AB; and θ_A is the slope of the elastic curve at A, due to the action of the couple.

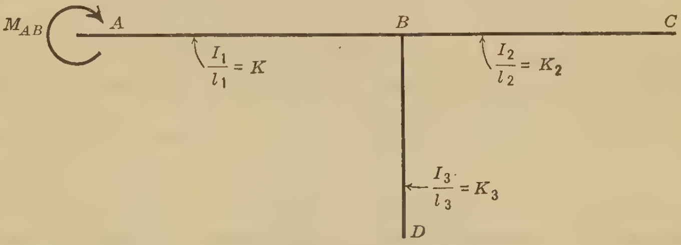

FIG. 25.

The value, N_1, may be written,

$$N_1 = 4 \left(\frac{3 \, K_1 + N_2 \, K_2 + N_3 \, K_3}{4 \, K_1 + N_2 \, K_2 + N_3 \, K_3} \right) \ldots\ldots\ldots\ldots (18)$$

N_2 and N_3 are constants similar to N_1; thus, if there is a hinge at C, $N_2 = 3$; if a fixed end, $N_2 = 4$; if the slopes at B and C are equal and opposite, $N_2 = 2$; and if the slopes are equal and alike, $N_2 = 6$. It will be noted that Equation (18) has terms in numerator and denominator which are alike except for the coefficients of K_1, which are always 3 and 4, respectively.

Another relation between the moments at A and B is as follows:

$$M_{BA} = \frac{M_{AB}}{2} \left(\frac{N_2 \, K_2 + N_3 \, K_3}{N_2 \, K_2 + N_3 \, K_3 + 3 \, K_1} \right) \ldots\ldots\ldots\ldots (19)$$

The moment, M_{BA}, is equal and opposite to the sum of M_{BC} and M_{BD}, and the latter moments are proportional to the respective values of $N_2 K_2$ and $N_3 K_3$.

The application of Equations (17), (18), and (19), to a continuous beam or frame may be started just as in Professor Cross' procedure. For a given loading, the "fixed-beam" moments are found and the unbalanced moment is determined at each joint. In Fig. 26, the values of K for the four spans are denoted by K_1, K_2, K_3, and K_4, and the unbalanced moments at B, C, and D, by U_B, U_C, and U_D. An exact method of distributing these unbalanced moments throughout the beam has been published.[30]

---

[30] "Analysis of Statically Indeterminate Structures by the Slope-Deflection Method," by Wilson, Richart, and Weiss, *Bulletin 108*, Eng. Experiment Station, Univ. of Illinois, 1918, pp. 133 and 137.

Consider the unbalanced moment, U_B, at B. This is distributed between the members, BA and BC, as follows:

$$M_{BA} = U_B \left(\frac{3\ K_1}{3\ K_1 + N_{23}\ K_2}\right) \dots\dots\dots\dots\dots\dots (20)$$

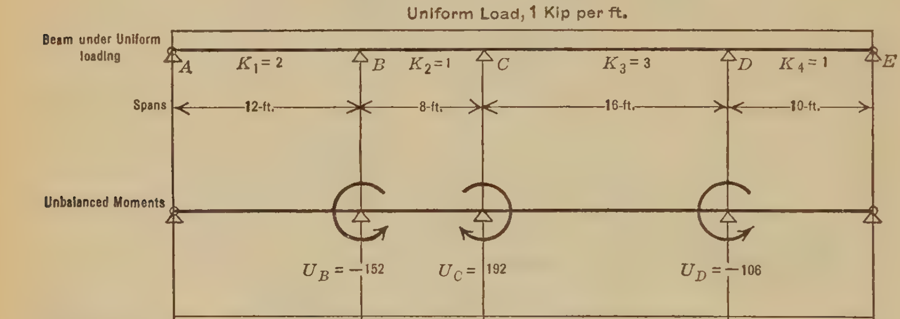
$$M_{BC} = U_B \left(\frac{N_{23}\ K_2}{3\ K_1 + N_{23}\ K_2}\right) \dots\dots\dots\dots\dots\dots (21)$$

$$M_{CB} = \frac{M_{BC}}{2} \left(\frac{N_{34}\ K_3}{N_{34}\ K_3 + 3\ K_2}\right) = -M_{CD} \dots\dots (22)$$

and,

$$M_{DC} = \frac{M_{CD}}{2} \left(\frac{3\ K_4}{3\ K_4 + 3\ K_3}\right) \dots\dots\dots\dots\dots\dots (23)$$

in which, $N_{23} = 4 \left(\frac{3\ K_2 + N_{34}\ K_3}{4\ K_2 + N_{34}\ K_3}\right)$ and $N_{34} = 4 \left(\frac{3\ K_3 + 3\ K_4}{4\ K_3 + 3\ K_4}\right)$.



Fixed Beam Moments with hinges at A and E	0	+ 216	−64	+ 64	−256	+ 256	−150	0
Couple, $U_B = -152$, at B	0	−94.2	−57.8	−22.0	+22.0	+2.2	−2.2	0
Couple, $U_C = 192$ at C	0	−17.5	+17.5	+ 52.4	+139.6	+17.5	−17.5	0
Couple, $U_D = -106$, at D	0	−3.9	+3.9	+11.6	−11.6	−81.0	−25.0	0
Resultant Moment	0	+ 100.4	−100.4	+106.0	−106.0	+194.7	−194.7	0

Note:- Plus sign indicates a clockwise couple acting upon member at a joint; negative sign a counter clockwise couple.

FIG. 26.

Similarly, at C, the unbalanced moment, U_C is distributed, as follows:

$$M_{CB} = U_C \left(\frac{N_{21}\ K_2}{N_{21}\ K_2 + N_{34}\ K_3}\right) \dots\dots\dots\dots\dots\dots (24)$$

$$M_{CD} = U_C \left(\frac{N_{34}\ K_3}{N_{21}\ K_2 + N_{34}\ K_3}\right) \dots\dots\dots\dots\dots\dots (25)$$

$$M_{BC} = \frac{M_{CB}}{2} \left(\frac{3\ K_1}{3\ K_1 + 3\ K_2}\right) = -M_{BA} \dots\dots\dots (26)$$

and,

$$M_{DC} = \frac{M_{CD}}{2} \left(\frac{3\ K_4}{3\ K_4 + 3\ K_3}\right) = -M_{DE} \dots\dots\dots (27)$$

in which, $N_{21} = 4 \left(\frac{3\ K_2 + 3\ K_1}{4\ K_2 + 3\ K_1}\right)$.

At D, the unbalanced moment, U_D, is distributed, as follows:

$$M_{DC} = U_D \left(\frac{N_{32}\,K_3}{N_{32}\,K_3 + 3\,K_4}\right) \dots\dots\dots\dots\dots\dots (28)$$

and,

$$M_{DE} = U_D \left(\frac{3\,K_4}{N_{32}\,K_3 + 3\,K_4}\right) \dots\dots\dots\dots\dots\dots (29)$$

$$M_{CD} = \frac{M_{DC}}{2} \left(\frac{N_{21}\,K_2}{N_{21}\,K_2 + 3\,K_3}\right) = -M_{CB} \dots\dots\dots\dots (30)$$

in which, $N_{32} = 4\left(\frac{3\,K_3 + N_{21}\,K_2}{4\,K_3 + N_{21}\,K_2}\right)$.

The first of the two subscripts used with N indicates the span nearest the origin of the moment being distributed.

Equations (17) to (30), inclusive, are given in full for further reference, but their significance can be expressed in a few words. An unbalanced moment, U, is distributed among the members meeting at the joint in proportion to their respective values of NK. This distribution is final. The value of the term, N, lies between 3 and 4 for the examples given, and the terms of the fraction have a typical form that is easily remembered. The moment at the adjacent joint is less than one-half the moment at the joint where the unbalanced moment is applied. These three types of equations are similar to the operations in Professor Cross' distribution and "carry-over" of moments, but the equations are applied only once to determine an exact final distribution of moments. However, it is necessary to distribute each unbalanced moment in turn, so that the final moments are the algebraic sum of the original "fixed-end" moments and the moments due to the three unbalanced couples.

As a numerical example, consider the four-span beam of Fig. 26 under a uniform load. With the ends, A and E, hinged, it is convenient to apply moments at B and D on the first and fourth spans, which apply to the case having one end hinged and the other fixed. Such "fixed-end" moments are three-halves as great as for the case in which both ends are fixed. The unbalanced moments at B, C, and D, are found to be -152, $+192$, and -106 units, and values of K are assumed at 2, 1, 3, and 1, respectively, for the four spans. The unbalanced moments are applied as couples producing a rotation in the direction indicated by the unbalance.

The values of the constants, N, are found to be $N_{21} = 3.6$; $N_{23} = 3.7$; $N_{32} = 3.2$; and $N_{34} = 3.2$. Using the convention as to signs followed in *Bulletin 108* previously referred to (a clockwise moment or attacking couple at the end of a member is considered positive), the moments at the ends of each span are given in Fig. 26 for the original fixed-end condition at B, C, and D, and for the successive application of the unbalanced moments at these three points. The algebraic sum gives the end moments in each span resulting from the original loading. It is a simple matter to sketch in the positive moments and to calculate shears and reactions by the methods of statics.

While familiarity with a method is likely to prejudice one in favor of it, the writer is inclined to grant that the method of Professor Cross is the simpler of the two to apply. However, both are much less cumbersome than the majority of methods of frame analysis usually encountered in the literature of the subject. It is to be kept in mind that the simplicity of both methods is due in part to the fact that they apply to the type of structure in which there is no displacement of joints or supports.

No originality is claimed by the writer for the idea of distributing the unbalanced moments, but the method of distributing such a moment throughout a frame was given a dozen years ago (1918) in *Bulletin 108*. The writer's method is quite similar to that[31] of H. M. Hadley, Assoc. M. Am. Soc. C. E., except that the procedure given herein for distributing the moment of the unbalanced couples is simpler and more easily followed. The equations given herein will apply to any type of beam or open frame, with various degrees of restraint at the ends of members, as well as for closed frames under conditions of symmetry.

WILLIAM A. OLIVER,[32] ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper and its discussion with much interest. There is a general human tendency to think that best which is one's own. This is as true of knowledge as of some more concrete possession. The structural analyst becomes familiar through use with one of the several methods of determining the moments in a statically indeterminate structure—slope and deflection, area moments, or what not. Being familiar with that method he concludes from first study that the new one is complicated and unwieldy. In this he is mistaken.

The writer does not intend to intimate that he wishes to detract from the value of the older methods. He received his first understanding of statically indeterminate structures from a thorough course in slope and deflection. However, being somewhat familiar with both methods, he realizes the immense saving of time that results with the use of Professor Cross' method. The short time required for the solution of a continuous beam by moment distribution and successive approximations, as compared with the time needed to solve the same beam by the equation of three moments, is surprising, and the first method may be just as accurate as the second.

Furthermore, the number of seemingly complex problems which may be successfully attacked by the method seem limitless—haunched beams (that is, beams continuous over supports with the moment of inertia varying within the span), continuous arches on elastic piers, and many others.

The writer believes that Professor Cross has discovered something which will add immeasurably to the field of structural analysis and design.

R. R. MARTEL,[33] M. AM. SOC. C. E. (by letter).—In his concise presentation, Professor Cross has restricted himself to a single, comprehensive, illustrative example. From this, the careful reader can grasp the two principles involved and apply them to other problems of the same general character without resorting to formulas of any kind. This method is a marked advantage over those others which require substitutions in formulas and subsequent algebraic manipulations.

The author's terse statement of the modifications by which the effect of side-sway, resulting from either unbalanced loading, or due to horizontal forces, may be evaluated, has led some of the discussers to illustrate the application of this by examples.

FIG. 27.

One such example for unbalanced loading can also be used (with very little change) to illustrate the method of dealing with horizontal forces. If the bent shown in Fig. 10, is subjected to horizontal forces of 1 000 at each floor, the procedure would be as follows:

(1) Apply any convenient arbitrary moment to the first-story columns of the bent; balance and distribute. Compute the shears in each story and, from these, the horizontal force which will produce the moments obtained after balancing and distributing.

(2) Apply any convenient arbitrary moments to the second-story columns; balance and distribute. Compute the shears in each story and, from these, the horizontal force which will produce the moments obtained after balancing and distributing.

(3) Write simultaneous equations to find the ratios of the forces obtained in Steps (1) and (2) to the given forces.

(4) Multiply the distributed moments obtained in Steps (1) and (2) by the respective ratios found in Step (3). The algebraic sum of these two sets of moments gives the moments desired. Steps (1) and (2) are demonstrated in Figs 11(*b*) and 11(*c*).

The simultaneous equations of Step (3) would be:

$$+142.3\,C_1 + 295.8\,C_2 = +1\,000 \quad \ldots\ldots\ldots\ldots\ldots (31)$$

$$+560.3\,C_1 + 369.7\,C_2 = -1\,000 \quad \ldots\ldots\ldots\ldots\ldots (32)$$

from which the values of C_1 and C_2 are found to be -5.87 and $+6.20$, respectively. The operations called for in Step (4) are shown in Fig. (27).

A crane column subjected to moment due to the eccentricity of the crane girder, furnishes another simple illustration of the application of the general method with side-sway.

Given such a column subjected to a moment of 243 ft-kips at the crane rail, and with end conditions which justify the assumption of perfect fixity, the lower section of the column is 36 ft. long and the upper portion, 14 ft. long; the ratio of moments of inertia of these sections is 5 : 1.

It is required to find the moments at the ends and at the crane rail:

(*a*) Assume an imaginary support, *F*, (Fig. 28(*a*)) at the crane rail and distribute the moment between the two sections of the column. Then "carry over" to the ends of the column.

(*b*) Compute the shears in both portions of the column. The difference between these shears is the value of the force, *F*, exerted by the imaginary support. Removing this support will produce moments in the columns the same as by applying a transverse load at that point to the crane column considered as a fixed-end beam. These moments are most easily determined by a slight variant of the general method of distributing unbalanced moments.

(*a*) (*b*) (*c*)

FIG. 28.

(*c*) Assume arbitrarily a moment, say, 10, in one part of the column, which is temporarily considered direction-fixed (locked) at the crane rail, (Fig.

28(*b*)). The moment in the other section (13.2), is then obtained from the relation,

$$M_1 \frac{l_1^2}{I} = M_2 \frac{l_2^2}{I_2}$$

(*d*) Remove the restraint at the crane rail (unlock), distribute the unbalanced moments, and "carry over" to the column ends.

(*e*) Compute the shears in both sections of the column, and, from these, the force, P, which produces the moments obtained in Step (4).

(*f*) Multiply these moments by $\frac{F}{P}$, the ratio of the force obtained in Step (2), to the force obtained in Step (4).

(*g*) Add these moments to those found in Step (1), giving the final results. (See Fig. 28(*c*).)

Instead of being rigidly fixed at the top, the crane column may be held at two points by the top and bottom chords of a roof truss. This case can also be solved by the use of an imaginary support at the crane rail. However, it is perhaps as simple and more interesting to consider this problem as a continuation of the one previously given, since in this way there will be a span in which the moment of inertia is not constant and its influence on distributing and carrying over will be brought out.

Let the lower 50 ft. of the column be the same as before. There is an additional 7 ft. at the top between the two points of support and its moment of inertia is unity. (See Fig. 29(*a*).)

The value of the moment, M_1, in terms of the moment, M_2, is found from the condition that the deflection of *o*, with reference to a tangent at *s*, is zero, as shown in Fig. 29(*b*); that is, the statical moment of the $\frac{M}{I}$-diagram (Fig. 29(*d*)) about *b* is zero. The resulting equation is:

$$\frac{14}{2} \times \frac{14}{3} M_2 + \frac{38}{5} \times \frac{36}{2} M_1 + (0.72\ M_2 + 0.28\ M_1) \left(\frac{28}{3} \times \frac{14}{2} + \frac{26}{5} \times \frac{36}{2}\right) = 0 \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

from which,

$$M_1 = -0.812\ M_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

Hence, the carry-over factor for this case is -0.812 instead of $-\frac{1}{2}$.

The angle change at *o* produced by a moment, M_2, can now be determined from the area of the $\frac{M}{I}$-diagram. Thus,

$$\theta E = \frac{14}{2} M_2 + \frac{36}{(2 \times 5)} M_1 + (0.72\ M_2 + 0.28\ M_1) \left(\frac{14}{2} + \frac{36}{2 \times 5}\right) \ldots (35)$$

and, $\theta E = 9.28\ M_2$, or,

$$M_2 = 0.108\ \theta E \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

Considering the upper section, Fig. 29(*c*), subjected to a moment, M_3, the angle change at q, is the deflection at r, with reference to a tangent at q, divided by the length, $c\,d$; that is, $\theta\,E = \frac{1}{3} \times \frac{7}{1}\,M_3$, or,

$$M_3 = 0.428\,\theta\,E \dots\dots\dots\dots\dots\dots\dots\dots (37)$$

Hence, for a given angle change, θ, the ratio of M_2 to M_3 is 0.108 to 0.428. This is the ratio used in distributing the unbalanced moment between the two sections of the column. The remaining operations required to obtain the final moments are shown on Fig. 29(*e*).

Because so little additional work is involved, it is of interest to consider the effect of roof truss deflection on the moments in the crane column.

FIG. 29.

Let the column be the same as before and assume that it is subjected to an outward deflection, δ_1 (by the bottom chord of the truss), of 0.125 in. and an inward deflection, δ_2 (by the top chord), of 0.100 in. (see Fig. 30(*a*)).

The moments of inertia of the column will be taken at 2 000 and 10 000 for the portions above and below the crane rail, thus maintaining the 1 : 5 ratio previously used.

It is convenient to consider that the column remains direction-fixed at the lower chord, Fig. 30(*b*), and on this basis to compute the moments resulting from the deflections in the upper and lower portions of the column. The moments thus found on each side of the bottom chord will not be equal. Removing the imaginary restraint, by means of which direction-fixity has been maintained, will produce changes in the moments that may be evaluated by distributing the unbalanced moment and carrying over in the usual way.

FIG. 30.

For the lower portion of the column the statical moment of the $\frac{M}{I}$-diagram about n equals $E\,I\,\delta_1$. The left-hand side of the resulting equation is the same as in Equation (33) and $E\,I_1 = 30\,000\,000 \times 2\,000$ lb-in.^{2} = 417 000 kip-ft.^{2}; $\delta_1 = 0.125$ in. = 0.0104 ft.; M_1 and M_2 are in feet-kips; or,

$$147.2\,M_2 + 181.5\,M_1 = 4\,340 \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

Since this portion of the column is direction-fixed at both ends, θE, in Equation (35), is zero, or,

$$14.64\, M_2 + 6.57\, M_1 = 0 \dots\dots\dots\dots\dots\dots (39)$$

Solving Equations (38) and (39) simultaneously, $M_2 = -16.9$, and $M_1 = +37.7$.

For the upper portion of the column, the moment, M_3, is obtained from the relation,

$$M_3\, l^2 = 3\, E\, I_1\, (\delta_1 + \delta_2) \dots\dots\dots\dots\dots\dots (40)$$

in which, $\delta_1 + \delta_2 = 0.125 + 0.100 = 0.225$ in. $= 0.0187$ ft., or, $M_3 = 477.3$.

The remaining operation of distributing and carrying over are indicated in Fig. 30(*c*). It will be noted that the relative rigidities and the carry-over factor are the same as in the previous problem.

Clyde T. Morris,[34] M. Am. Soc. C. E. (by letter).—The writer has found the Cross method of analyzing continuous frames of inestimable value; but the sign convention used, when applied to a multi-storied multi-paneled bent, is more cumbersome than the following: "Any moment which tends to rotate a joint clockwise is to be considered positive, and the reverse negative".[35] After the solution is completed, it is a simple matter to translate these signs into the usual convention.

Fig. 31.—Moments in a Two-Legged Bent.

---

[34] Professor of Structural Eng., Ohio State Univ., Columbus, Ohio.

[35] This is the convention suggested by L. E. Grinter and A. H. Finlay, Assoc. Members, Am. Soc. C. E., in their discussions of this paper.

The application of the method to the solution of stresses in building frames due to wind load is not explained. Professor Cross indicates that it is possible, and several of the discussers have mentioned the effects of side-sway due to eccentric loads. The method may be extended to lateral forces on a tall building frame with as much ease and accuracy as for vertical loads, in the following steps:

1.—Calculate the moments in the columns due to the lateral forces, considering the joints fixed against rotation, but free to deflect laterally. The sum of the moments at the top and bottom of all the columns of a story is equal to the shear in the story, multiplied by the story height, and, as the deflections of the columns in a story due to the lateral forces are equal, the column moments and shears are proportional to the $\frac{I}{L^2}$ values of the columns. (When all the columns of a story are of equal height the values of I, or $\frac{I}{L}$ may be used in proportioning the moments.)

2.—Distribute the moments at the joints, considering them free to rotate, but not changing their location. (Same process as for vertical loads.)

3.—Carry over the distributed moments using a carry-over factor of $+\frac{1}{2}$ as is done for vertical loads.

4.—Balance the column moments in each story by making their sum equal the shear in the story times the story height. This assumes the joints to be fixed against rotation, but free to deflect laterally as in the first step. This completes a cycle and the designer is now ready to repeat Steps 2, 3, and 4 as many times as the desired accuracy may require.

To illustrate the procedure, the calculations are given in Fig. 31 for a simple two-legged bent with the bottom of the columns fixed. The loads and dimensions are shown on the diagram. The relative magnitudes of the $\frac{I}{L}$ values for the members are indicated by the figures near the middle of the members. The factors resulting from the application of Steps 1, 2, 3, and 4 are indicated by the figures in parenthesis before the factors. Note that Step 4 does not apply to the girders.

TABLE 5.—COMPARISON OF MOMENTS IN A SIMPLE, TWO-LEGGED BENT

Methods	M'_A	M'_B	M_A	M_B
Elastic theory	28.71	27.00	49.72	38.57
Cross method	28.53	26.68	49.84	38.97

The correct figures for the moments, according to the elastic theory, compared to the corresponding moments by the Cross method, are given in Table 5. If greater accuracy is desired another cycle of corrections would require but a few minutes. After the moments in the members are determined, the shears and direct stresses are readily calculated.

In computing the stresses in Fig. 32, it has been assumed that the carry-over terms for the columns of the fifth story were the same for the top and bottom. This introduces a small error at this story, which diminishes as the solution is carried down to the lower stories. This is shown in Table 6 by the diminishing errors in the lower stories.

The labor of calculating these stresses by the Cross method is little more than that required by the usual approximate methods in use, and infinitely less than for any of the other more exact methods.

FRANCIS P. WITMER,[37] M. AM. SOC. C. E. (by letter).—The author has described his method of analysis so clearly that its virtues are obvious. The writer believes that its simple underlying principles and surprisingly easy application make it the most convenient and expeditious method yet brought forward for the practical solution of numerical problems in internal bending stresses. For algebraic solutions it is, of course, not practically applicable as, without numerical values, one could not know when the process had been carried far enough for proper approximation.

The writer would like to comment on the subject of algebraic signs for moments. In 1917 he had occasion to make an investigation of indeterminate bending stresses resulting from eccentric connections in the trusses of an old elevated railroad structure. This led him to develop a method of analysis which has since become familiar as the "slope-deflection method". The necessity was quickly apparent for assuming that all moments in the same rotational direction were positive, regardless of where they were applied or whether they were external moments or internal resisting moments. Any other assumption was practically certain to result in errors and inconsistencies.

---

[36] "Wind Stresses in the Steel Frames of Office Buildings," *Bulletin No. 80*, Univ. of Illinois, Eng. Experiment Station.

[37] Director of Civ. Eng., Univ. of Pennsylvania, Philadelphia, Pa.

For illustration, consider the frame in Fig. 33. Assume that the various members have center bending from force action, as shown by the curved, dotted lines. The usual convention, as adopted by Professor Cross, would naturally lead to the algebraic designations shown for moments in all members except *B C*; but how shall moments in these members be designated? As they are nearly vertical, it may be logical to consider them similarly to the columns, *C D;* but this would be inconsistent with the adjacent members, *A B,* which are certainly analogous, structurally, to the members, *B C*. The adopted convention must not have limitations depending upon the angle of slope of members. Dilemmas such as these will continually occur in computations of this character, unless the convention adopted permits the assumption that all moments in one rotational direction are positive.

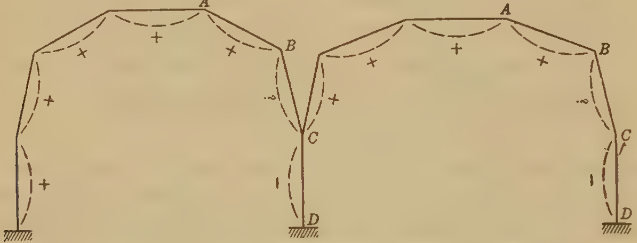

FIG. 33.

Professor Cross has very properly avoided giving proofs for each of the three operations which constitute his method. The writer cannot refrain, however, from a brief statement which he believes will place these relations in a very clear light, for cases in which the moment of inertia is constant throughout the length of each member.

The fundamental expression for the slope-deflection method of analysis, in cases where the straight-line axis joining the ends of a member does not change position, is:

$$M_1 = \frac{2\ E\ I}{l}\ (2\ \theta_1 + \theta_2)\ +\ C \ldots\ldots\ldots\ldots\ldots\ldots (41)$$

in which, C is a constant depending upon the particular loading. All the relations required in Professor Cross' method may be readily derived from Equation (41), as follows:

First.—For a beam fixed at both ends, the end, bending-deflection angles, θ_1 and θ_2, will both be zero, and $M_1 = C$. In other words, the fixed-end moment at either end is simply equal to the constant in the slope-deflection equation which corresponds to the existing loading. Tables of these constants are available in recent books describing this method of analysis.

Second.—Assume a moment applied at one end of a member, the other end being fixed. From the action of this moment alone (remembering that θ_2 at the fixed end is zero), Equation (41) becomes $M_1 = \frac{4\,E\,I\,\theta_1}{l}$. If two or more members meet and are rigidly connected at a point, and a total moment, M, is applied at this point, M will be so divided among the members that the ends of all will deflect through the same angle, θ_1, and these members, therefore, will carry moments proportioned thus:

$$M_1 : M_2 = 4\,E\,\theta_1\,\frac{I_1}{l_1} : 4\,E\,\theta_1\,\frac{I_2}{l_2}$$

or,

$$M_1 : M_2 = \frac{I_1}{l_1} : \frac{I_2}{l_2};\ M_1 : M_3 = \frac{I_1}{l_1} : \frac{I_3}{l_3};\ \text{etc.}$$

This proves the relation used in the second operation.

Third.—Assume, again, a member with a moment, M_1, at one end and a fixed moment, M_2, at the other end. From Equation (41),

$$M_1 = \frac{2\,E\,I}{l}\,(2\,\theta_1 + \theta_2)$$

and,

$$M_2 = \frac{2\,E\,I}{l}\,(\theta_1 + 2\,\theta_2)$$

Since θ_2 at the fixed end is zero, $M_1 = \frac{4\,E\,I\,\theta_1}{l}$, and $M_2 = \frac{2\,E\,I\,\theta_1}{l}$. Hence, $M_2 = \frac{1}{2}\,M_1$, and the "carry-over" factor is $+\,\frac{1}{2}$, as assumed in the third operation (with the proposed modification in the convention as to signs).

These relations are well known, but it seemed to the writer worth while to direct attention to the ease with which all the necessary relations may be established from the single expression, Equation (41).

The author mentions the possibility that an unsymmetrical condition of form or loading may cause the structure to sway, and indicates a process by which correction may be made to allow for this. It appears to the writer that such a condition is really the normal one, and that the case without sway is exceptional. It seems to him important that the process of correction be illustrated by simple numerical examples, in order to increase the availability of Professor Cross' method of analysis.

Consider, first, a frame without any applied horizontal force, but one which is unsymmetrical both in form and loading, as in Fig. 34(*a*). The correct moments and reactions, as computed by the slope deflection method, are shown. Fig. 34(*b*) shows the same frame with moments computed by Professor Cross' method, assuming that no sway occurs. From the moments in the posts, the shear reactions, H_1 and H_2, are computed to be of the values shown. Since these are unequal numerically, equilibrium does not obtain, showing that the structure has sway. The force, H_1, must be increased and the force, H_2, decreased so that they may equal each other, for equilibrium. Furthermore, the numerical sum of these two correcting quantities must be equal to the numerical difference between H_1 and H_2 as first obtained and the two corrections must be proportioned to the values of $\frac{I}{l^3}$ for the respective columns, in order to equalize their sway. By observing these conditions it is found that H_1 must be increased by 17.1 lb. and H_2 must be decreased by 63.3 lb., thus bringing the resulting reactions to agreement at the value, 103.3 lb. This is practically the same as in Fig. 34(*a*).

The moments in the posts must now be corrected to correspond with these corrections in shear. The total correction for the left-hand post will be, $17.1 \times 1\,000 = 17\,100$ in-lb. and that for the right-hand post, $63.3 \times 600 = 37\,980$ in-lb. These total correcting moments must be properly divided between the top and bottom of the posts. If the horizontal girder is infinitely rigid the tops will be perfectly fixed by these correcting moments, and the points of contraflexure produced thereby will be at mid-height, thus dividing the correcting moments equally between top and bottom. With this assumption for the present case, the resulting total moments will be:

(*a*) SLOPE DEFLECTION METHOD (*b*) CROSS METHOD, NEGLECTING SIDE-SWAY

FIG. 34.

Left post:

At the top, 66 100 in-lb.; at the bottom, 37 300 in-lb.

Right post:

At the top, 47 700 in-lb.; at the bottom, 14 300 in-lb.

These are very close to the values in Fig. 34(*a*), as they should be, since the girder is very rigid, as compared with the columns.

If the girder had no rigidity, the points of contraflexure, due to the correcting shears, would be at the top and the moment corrections would be wholly at the bottom. All cases will fall between these two extremes, and the correct proportion must be assumed by consideration of the relative rigidities of the girder and column. Probably, in most cases, the true corrections will not be far from equal at top and bottom, and, undoubtedly, the corrected moments may always be found in this manner, with a reasonably close approximation to the true values.

Consider, next, a frame with an applied horizontal force which will necessitate side-sway, whether or not the frame is symmetrical. Let Fig. 35(*a*) represent such a case, in which there also exists a lack of symmetry in size of columns. The moments and reactions shown on Fig. 35(*a*) are correct as computed by the slope-deflection method. First, divide the horizontal force between the two columns in proportion to their values of $\frac{I}{l^3}$, in order to equalize their sway, obtaining 3 333 lb. at the left and 6 667 lb. at the right column. Next, compute end moments for the columns, assuming them to be fixed top and bottom, following this by distributing unbalanced moments, according to the Cross method. Fig. 35(*b*) shows the resulting moments and forces. It is seen that the horizontal forces are not in equilibrium, showing that there has been sway in addition to that naturally resulting from the applied horizontal force; that is, due to lack of symmetry in the frame. If vertical loads had been applied in an unsymmetrical manner, these also would have contributed to this sway.

(*a*) SLOPE DEFLECTION METHOD

(*b*) CROSS METHOD WITHOUT SIDE-SWAY

(*c*) CROSS METHOD. CORRECTED FOR SIDE-SWAY

FIG. 35.

The amount of unbalanced horizontal force is found to be 458.4 lb. acting toward the left. Each horizontal reaction, therefore, must be increased in proportion to the value of $\frac{I}{l^3}$ of its column, resulting in corrections as follows: 152.8 lb. at the left column; and 305.6 lb. at the right column. Adding these to the horizontal reactions formerly obtained (see Fig. 35(*b*)), will balance the horizontal forces. The total moments for the columns must now be corrected by the following:

Left column .... 152.8 × 1 000 = 152 800 in-lb.
Right column .... 305.6 × 1 000 = 305 600 in-lb.

If the tops are assumed to be fixed by the girder, these moments will be equally divided between top and bottom, and the resulting moments and forces will be as shown in Fig. 35(*c*). These are seen to check very closely with the correct values in Fig. 35(*a*). If the girder is relatively less rigid, the point of contraflexure will rise and the bottom correcting moment will be greater than that at the top, but generally the assumption of equal corrections at top and bottom will probably be sufficiently accurate.

The methods of correction just described may readily be applied to a building of several stories, by the exercise of a little ingenuity, and thus it is probable that the wind moments in a tall building may be computed with sufficient accuracy, and with far less expenditure of time and labor than by any of the methods heretofore available.

T. F. HICKERSON,[38] M. AM. SOC. C. E. (by letter).—The author has presented an ingenious method for determining bending moments in continuous frames, which, simple as it may seem, is in effect an application of the slope deflection method through the medium of successive arithmetical approximations instead of the formal solution of algebraic equations. Although no mathematics beyond arithmetic is used, yet there are many dangerous pitfalls incident to an attempted application of this method by any one who is unversed in the basic principles of continuity of elastic structures.

The method is of most value in analyzing unsymmetrical frameworks (sidesway neglected), such as that given by the author in his Fig. 1, but for less complicated cases—the kind that ordinarily occur in practice—it appears to be too much of a juggling process for general acceptance in a design office.

Believing that the use of coefficients offers the simplest and quickest way of obtaining moments and shears at various sections in continuous beams and frames, the writer has prepared a comprehensive set of tables for this purpose. A simple outline, with a sample table of coefficients, was presented in connection with another paper.[39]

Four cases will now be cited illustrative of typical frameworks and their analyses by two methods: (1) The method of "Tabular Coefficients", proposed by the writer; and (2), the method of "Carry-Over Moments", proposed by the author.

[39] "Continuous Beams Over Three Spans," by I. Oesterblom, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1405.

Case 1.—Symmetrical, Two-Legged Bents.—The following notation[40] applies to this discussion:

l = length of beam, AB.
I_1 = moment of inertia of beam, AB.
S_1 = stiffness of beam, $AB = \frac{I_1}{l}$.
h = length of column, AC (or BD).
S = stiffness of column, AC (or BD).
r = relative column stiffness $= \frac{S}{S_1} = \frac{I}{I_1}\,\frac{l}{h}$.
$M_A = M_{AB}$ = resisting moment at End A of Member AB (or AC).

The moment, C_{AB}, equals that part of M_{AB} which depends only on the loads; if the ends, A and B, are fixed on the same level, $M_{AB} = -C_{AB}$.

Referring to the frame shown in Fig. 36, where the columns are fixed at the bases,

$$M_A = -\frac{1}{2}\left[(C_{AB}+C_{BA})\left(\frac{2r}{1+2r}\right) + (C_{AB}-C_{BA})\left(\frac{r}{6+r}\right)\right]. \quad (42)$$

FIG. 37

For symmetrical loads on AB, say, a uniformly distributed load of w lb. per ft., $C_{AB} = C_{BA} = \frac{1}{12}\,w\,l^2$; and, hence, Equation (42) takes the simple form:

$$M_A = -\frac{1}{6}\,w\,l^2\left(\frac{r}{1+2r}\right) \quad (43)$$

Referring to Fig. 37 where the columns are hinged at the bases,

$$M_A = -\frac{3}{2}\,(C_{AB}+C_{BA})\left(\frac{r}{2+3r}\right) \quad (44)$$

---

[40] This notation is the same as that used in *Bulletin 108*, Univ. of Illinois Eng. Experiment Station.

For a symmetrical loading on $A\,B$, say, a uniform load of w lb. per ft.,

$$M_A = -\frac{1}{4}\,w\,l^2\left(\frac{r}{2+3\,r}\right)\ldots\ldots\ldots\ldots\ldots\ldots(45)$$

Tables may be constructed based on Equations (42) to (45), inclusive, such that the corner moments for any vertical loading and for any condition of relative stiffness may readily be determined. Furthermore, such tables enable one to compare by inspection the difference between the effects of fixed and hinged terminals.

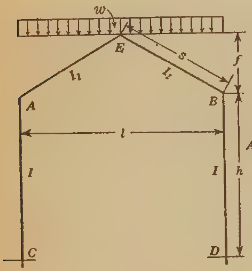

Fig. 38

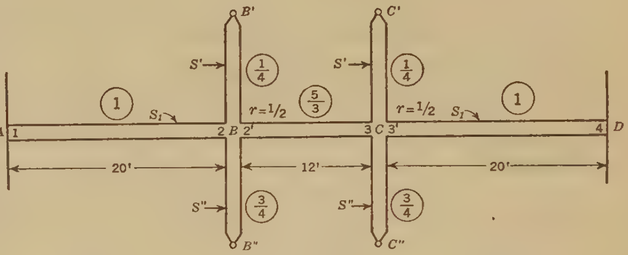

Fig. 39

The author's method as applied to the fixed frame is indicated in Fig. 36. Although the assumed conditions are about the simplest possible ($r = 1$ and a symmetrical load of 1 000 lb. per ft.), the same results are obtained more easily by means of Equation (43), or by means of tabular coefficients prepared from it.

In applying the author's method to the hinged frame of Fig. 37, the writer found it quite tedious to carry moments out to the hinge at Point C and then balance the moment and carry it back again. This procedure was abandoned, and computations were made on the basis of columns three-fourths as stiff, just as if fixed terminals existed at Points C' and D'. This possibility was pointed out by Professor Cross under the caption "Variations of the Method". Again, it may be said that the desired results could be obtained much more readily by applying Equation (45), or from tabular coefficients determined from it.

Case 2.—On Arch Frames.—The frame shown in Fig. 38 is subjected to a uniformly distributed load of w lb. per ft. A table may be used which is based on the formulas derived from the least work theorem; it would give coefficients for determining the corner moments,

$$M_A = \phi\,w\,l^2\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(46)$$

Thus, if $l = 30$ ft., $h = 20$ ft., $f = 6$ ft., $r = \frac{1}{2}$, $\frac{f}{h} = 0.3$, and $w = 1\,000$ lb. per ft., the values of ϕ given by the table (not given herewith) are -0.050 and -0.052 for the hinged and fixed frames, respectively. For the hinged frame, $M_A = -0.050 \times 1\,000 \times (30)^2 = -\,45\,000$ ft-lb.; and for the fixed frame, $M_A = -0.052 \times 1\,000 \times (30)^2 = -\,46\,800$ ft-lb. In Fig. 38, $S = \frac{I}{h}$; $S_1 = \frac{I_1}{S}$; and $r = \frac{S}{S_1} = \frac{I}{I_1}\,\frac{s}{h}$.

If the entire load is concentrated at the central ridge (at Point E, Fig. 38), the foregoing values would be multiplied by $\frac{3}{2}$, or increased by 50% ; and for other symmetrical loadings, the corresponding moments are obtained by merely multiplying the coefficients in the prepared table for this case, by known ratios.

The author's method seems inapplicable to the arched frame; in fact, the slope deflection method itself is hardly adaptable to this case.

Case 3.—Three Continuous Beams.—Fig. 39 shows a symmetrical arrangement of three continuous beams rigidly connected to columns at B and C. Tables of coefficients for determining bending moments at the central section of the middle span can likewise be compiled by adapting Equation (46) to this case, as previously explained elsewhere.[41] All column terminals have been assumed as hinged, but the tables are also adaptable to the case of fixed ends if the computed column stiffness is increased by one-third, that is, if it is multiplied by $\frac{4}{3}$.

Let it be required to find the maximum positive and negative moment at the central section of the middle span, due to a dead load of 1 200 lb. per ft., and a live load of 1 000 lb. per ft. Furthermore, let it be assumed: (1) That the two end spans are each 20 ft., and the middle span is 12 ft.; (2) that the beam terminals are one-half fixed (that is, the terminal moments are one-half the values for absolutely fixed conditions); and (3) that the ratio of average column stiffness to that of the end beam is ½.

Referring to the proper table of coefficients (not given herewith), the following values of ϕ are obtained; -0.017 for first span loaded; $+0.026$ for second span loaded; and -0.017 for third span loaded; from which the following moments are easily computed;

Total maximum negative moment = — 17 440 ft-lb.
Total maximum positive moment = + 6 560 ft-lb.

To solve this problem by means of the author's method is a longer and more tedious process than that of tabular coefficients; so much so, that the writer got no farther than to find the moments (at the supports) due to the live load of 1 000 lb. per ft. on the middle span when the beam terminals are fixed and when they are hinged. The problem is then only about one-third solved, since the moment at the middle of the span must be determined from the equations of statics after the moments at the supports and the reactions are known.

Case 4.—Multiple Spans.—Consider a multiple-span arrangement, as, for example, the five continuous spans shown in Fig. 40(a). The writer has computed shear and moment coefficients upon the following bases: (1) The moment at any interior support and the shear at either side of it are greatest when the two spans adjacent to that support are covered with live and dead load, while the next span to the right and to the left is covered only with dead load; (2) the effect of loads on remote spans; that is, beyond the two spans from the support, in either direction, is neglected; and (3) the span arrangement beyond any support may be removed if a certain fixation factor is substituted therefor.

---

[41] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), Table 12, p. 1407.

In order to find the maximum value of the bending moment, M_2, at the right end of the member, $B\,C$ (Fig. 40(*a*)), two sets of loads will be dealt with: (1) Live and dead load on the two spans, $C\,B$ and $C\,D$, adjacent to the support, C (Fig. 40(*b*)); and (2), dead load on the spans, $B\,A$ and $D\,E$ (Fig. 40(*c*)).

FIG. 40

Referring to a table (not given herewith), with $x = \dfrac{18}{20} = 0.9$:

$$M_2 = [-0.117 + 0.29\,v + 0.010\,t]\,w\,l^2 \ldots\ldots\ldots\ldots\ldots (47)$$

in which, v and t are the fixation factors at the ends, B and D, in Fig. 40(*b*); that is, $v = 1$ and $t = 1$, if both ends are fixed. For this particular span arrangement, $v = 0.65$ and $t = 0.70$, hence, $M_2 = -0.091 \times 2\,200 \times (20)^2 = -80\,080$ ft-lb.

Referring to a table (not given herewith) for the proper coefficient to use in Fig. 40(*c*), the value of 0.019 is obtained; hence, $M_2 = +\,0.019 \times 1\,200 \times (15)^2 = +\,5\,130$ ft-lb. Combining the two values of M_2 thus obtained, the total maximum moment equals $M_2 = -\,80\,080 + 5\,130 = -\,74\,950$ ft-lb.

In applying the author's method to this problem, only those carry-over moments actually needed in evaluating M_2 are indicated in Fig. 40(*a*); and these were determined without much difficulty.

In conclusion, the writer wishes to commend the author for presenting this method, which is valuable to know even if it is tedious to apply.

F. H. CONSTANT,[42] M. AM. SOC. C. E. (by letter).—The treatment of side-sway in multiple-story frames, with intermediate vertical loads and horizontal joint loads (considered either separately or conjointly), may be generalized. For simplicity, a two-story frame bent, with any number of vertical columns, is assumed. The fixed-end moments due to the vertical loads, and the column moments due to the horizontal joint loads (resulting from side-sway and no joint rotation) are first found, and then distributed, carried over, and finally balanced.

As already explained in Professor Cross' paper, the moments thus found will be designated M_0. The M_0-column moments in any story will give rise to shears in those columns the sums of which will not, in general, be equal to the shear known to exist in that story (this latter is the sum of all the horizontal joint loads above the story in question). Let the known true shear in each story be V_1, V_2, etc., and the shear from the M_0-column moments in each story, V_{01}, V_{02}, etc. Finally, let any arbitrary set of column moments (hereafter called shear moments) be introduced in the first story and distributed among the columns of that story in the ratio of their $\frac{I}{h^2}$ values. Distribute, carry over, and finally balance these moments throughout all the members of the frame. Call the moments thus obtained, M_{11}, M_{12}, etc., the first subscript referring to the story in which the arbitrary shear moments are introduced, and the second to the moments in the other stories produced by them, after distribution and balancing.

The column moments, M_{11}, M_{12}, etc., in each story will produce shears in the corresponding stories. These shears will be V_{11}, V_{12}, etc., the subscripts having the same meaning as before. Then, introduce an arbitrary set of shear moments in the second-story columns, distribute, and balance throughout the frame as before. Call these moments M_{21}, M_{22}, etc., and the corresponding shears V_{21}, V_{22}, etc.

Stating this nomenclature more concisely:

M = required correct moment in any member.
V_1 = shear known to exist in the first-story columns.
V_2 = shear known to exist in the second-story columns.
M_0 = distributed and balanced moments, due to the fixed-end moments in the beams, and the shear moments in the columns, produced by the external loading.

---

[42] Prof. of Civ. Eng., Princeton Univ., Princeton, N. J.

V_{01} = shear in the first story, due to the M_0-moments in the first-story columns.
V_{02} = shear in the second story, due to the M_0-moments in the second-story columns.
M_1 = distributed and balanced moments due to an arbitary set of shear moments introduced in the first-story columns.
M_2 = distributed and balanced moments due to an arbitrary set of shear moments introduced in the second-story columns.
V_{11} = shear in first story due to the M_1-moments in the first-story columns.
V_{12} = shear in the second story due to the M_1-moments in the second-story columns.
V_{21} = shear in the first story due to the M_2-moments in the first-story columns.
V_{22} = shear in the second story due to the M_2-moments in the second-story columns.
C_1 and C_2 = constants.

Then,

$$V_1 = V_{01} + C_1\, V_{11} + C_2\, V_{21} \quad \text{(48)}$$

and,

$$V_2 = V_{02} + C_1\, V_{12} + C_2\, V_{22} \quad \text{(49)}$$

Solving for C_1 and C_2,

$$M = M_0 + C_1\, M_1 + C_2\, M_2 \quad \text{(50)}$$

For a one-story bent subjected only to a horizontal force at the top joint, Equation (50) reduces to,

$$M = M_0 \frac{V_1}{V_0} \quad \text{(51)}$$

In a multiple-story building there will be as many independent equations and constants as there are stories. To obtain the M_0-moments due to the external loading it will be necessary to distribute and balance throughout the frame. The moments, M_1, M_2, etc., are only great in and near the story in which the arbitrary moments are introduced. They decrease rapidly and become insignificant one or two stories away, in either direction. Shear moments are distributed between the columns of a story in proportion to their values of $\frac{I}{h^2}$.

The writer prefers the sign convention which designates a moment as positive when the member tends to rotate the joint in a clockwise direction. The shear at the foot of a column, A B, is, then, $V = \frac{M_A + M_B}{h}$, the sign and direction of V being automatically controlled by the signs of the numerical values of M_A and M_B. The work is also greatly expedited by balancing first the joints having the largest unbalanced moments, and carrying over the distributed moments at once, before proceeding to the next joint.

W. N. Downey,[43] Assoc. M. Am. Soc. C. E. (by letter).—The design of a rigid frame by the conventional methods generally in use is unquestionably a tedious and laborious process, because a clear conception of the frame action is obscured by a maze of algebraic manipulations. A method by which the designer can visualize step by step exactly what is happening is of great value. For this reason Professor Cross has made a valuable contribution to the literature on the subject of the statically indeterminate frame.

[43] Care, State Highway Dept., Frankfort, Ky.

The problems introduced in the paper may also be analyzed by successive corrections to the angular turns at the ends of the members. This method, as developed by the writer, has been found to be very rapid. The method of procedure may be stated briefly. All the angular turns, due to the load, are calculated approximately, then corrections are made to these approximate values to obtain more nearly the correct angles. As many corrections may be calculated as is considered necessary for the problem under consideration. From the magnitude of the corrections it can be judged when the computations have been carried far enough. The exactness of the final angles depends only on how many corrections the designer cares to make. The second correction generally gives results exact enough for ordinary design purposes.

Besides being rapid the method of successive corrections has other distinct advantages. It is particularly well suited to the calculation of influence lines for moving loads, which are almost indispensable in bridge design; the effect of horizontal deflection (and, consequently, temperature changes) and of horizontal loads at the joints is taken into consideration in a simple and direct manner. In addition, the method lends itself well to tabular arrangement of the computations, thus minimizing the chance of error in the numerical work. It applies equally as well to beams of variable moments of inertia as to beams of constant section.

Calculations Neglecting the Effect of Horizontal Deflection.—The slope-deflection equations[44] give a convenient way of visualizing the constants required in the approximations for the angles. These equations may be written:

For a beam restrained at both ends:

$$M_{AB} = E\,K_{AB}\left[\beta_{AB}\,\theta_A + \beta'_{AB}\,\theta_B - \beta''_{AB}\,\frac{d}{h_{AB}}\right] \mp C_{AB} \ldots\ldots (52)$$

$$M_{BA} = E\,K_{AB}\left[\beta_{BA}\,\theta_B + \beta'_{BA}\,\theta_A - \beta''_{BA}\,\frac{d}{h_{AB}}\right] \pm C_{BA} \ldots\ldots (53)$$

For a beam restrained at *A* and fixed at *C*:

$$M_{AC} = E\,K_{AC}\left[\beta_{AC}\,\theta_A - \beta''_{AC}\,\frac{d}{h_{AC}}\right] \mp C_{AC} \ldots\ldots\ldots\ldots (54)$$

$$M_{CA} = E\,K_{AC}\left[\beta'_{CA}\,\theta_A - \beta''_{CA}\,\frac{d}{h_{AC}}\right] \pm C_{CA} \ldots\ldots\ldots\ldots (55)$$

For a beam restrained at *A* and hinged at *D*:

$$M_{AD} = E\,K_{AD}\,\beta_{AD}\left[\theta_A - \frac{d}{h_{AD}}\right] \mp H_{AD} \ldots\ldots\ldots\ldots\ldots (56)$$

In Equations (52) to (56), $\beta + \beta' = \beta''$; $\beta'_{AB} = \beta'_{BA}$; and $K = \frac{I}{h}$.

For the case of a beam of constant section: $\beta_{AB} = \beta_{BA} = \beta_{AC} = 4$; $\beta'_{AB} = \beta'_{BA} = \beta'_{CA} = 2$; $\beta''_{AB} = \beta''_{BA} = \beta''_{AC} = \beta''_{CA} = 6$; and, $\beta_{AD} = 3$.

---

[44] *Bulletin 108*, Univ. of Illinois, Eng. Experiment Station.

The values of β and the fixed end moments for beams of varying moment of inertia may be found by any of the standard methods of calculation, or may be readily calculated from the tables[45] given by Strassner, or from the tables[46] given by Walter Ruppel, Assoc. M. Am. Soc. C. E. Both writers cover a wide range of conditions.

Sign Conventions and Notation.—A positive angular change is measured from the original position of the axis in a clockwise direction about the end of the member considered. A positive deflection is measured in the same direction as a positive angular change. An external moment acting in a clockwise direction about the end of a member is positive. An external load acting in a clockwise direction about a joint is negative. The following notation is used:

θ = change in slope of the tangent to the elastic curve at the end of a member, the subscript denotes the joint; θ_A = the change in slope at A.

d = relative displacement of the ends of a member with respect to the original direction of the member.

K = moment of inertia of the member divided by its length.

θ' = change in slope of the tangent to the elastic curve at the end of a member when no horizontal movement is considered, the subscript denotes the joint. θ'_A = the change in slope at A.

β, β', and β'' = constants determined by the elastic properties of the member.

α = angular turn at the joints produced by the deflection, $d = 1$. The subscript denotes the joint. α_A = the rotation at A.

H = horizontal reaction on the frame produced by the deflection, $d = 1$.

ρ = angular turn at the joints produced by $H = -1$. The subscript denotes the joint. ρ_A = the rotation at A.

d_A = deflection of the top of the columns due to a moment, $-X_a$. (The numerical value of $d_A = \rho_A$). Likewise, for d_B, d_C, etc.

X_a = external moment applied at the joint, A. Similarly, for X_b, X_c, etc.

Z_a = angular turn at A due to $X_a = -1$. All other joints held fixed. Similarly, for Z_b Z_c, etc.

X_{ba} = external moment at B, due to a unit angular turn at A, when Joint B is fixed against rotation. Similarly, for X_{ab}, X_{cb}, etc.

$X_{a(d)}$ = external moment about the end, A, of a member, due to the deflection, $d = 1$, when the end, A, is fixed against rotation, and the other end is either fixed or hinged.

Procedure.—The fundamental conception of calculating the angular turns by successive corrections is similar to that of distributing end moments. Consider one joint at a time as elastic and calculate the angular change at this elastic joint, due to the applied external load. Then proceed to the next joint, which is now considered as the only elastic joint, and calculate the angular turn at this joint, due to the angular change at the joint just calculated and the applied external load. In this manner, calculate angular turns at each joint in the structure and obtain the first approximation, $\Delta\, \theta'$.

---

[45] "Neuere Methoden," Vol. I.

[46] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 152.

For instance, consider the joints, A, B, C, and D, in sequence and calculate the first approximations, $\Delta\,\theta'_A$, $\Delta\,\theta'_B$, $\Delta\,\theta'_C$, and $\Delta\,\theta'_D$. To avoid confusion as to whether all effects have been considered, begin at the left joint and calculate to the right, or *vice versa*.

To obtain the corrections, θ'_1, begin with the last calculated $\Delta\,\theta'$ (for instance, $\Delta\,\theta'_D$), and compute the angular turn at C (θ'_{1C}), due to $\Delta\,\theta'_D$. The sum, ($\Delta\,\theta'_C + \theta'_{1C}$), would be a closer approach to the true value of θ'_C. Proceed to Joint B and calculate the angular turn, θ'_{1B}, due to angular change, ($\Delta\,\theta'_C + \theta'_{1C}$). Continue in this manner through the frame. These values constitute the first corrections, θ'_1.

Determine θ'_2 in the same manner as θ'_1, using only those increments of θ, which have not been previously used in going through the frame in this direction. That is, θ'_{2B} is obtained by calculating the angular turn at B due to θ'_{1A}; θ'_{2C} is obtained by computing the angular turn at C due to ($\theta'_{1B} + \theta'_{2B}$), etc.

All other corrections are made in the same way as θ'_2. When, from the magnitude of the corrections, it is seen that the angles are exact enough for the problem considered, sum up the first approximation and the corrections for each angle; that is:

$$\theta' = \Delta\,\theta' + \theta'_1 + \theta'_2 + \dots \qquad (57)$$

Angle θ' is the rotation of the joint due to the effect of the external loads, the effect of horizontal deflection being neglected.

Computations of Constants for Determining Angular Changes.—Referring to Fig. 41, let Z_a equal the angular change at A due to the moment, $X_a = -1$, when all joints except A are considered fixed. Angular changes, Z_b, Z_e, etc., are similarly defined. For any value of X_a other than -1, the angular change at A is equal to $Z_a\,X_a$. For Joint A, Fig. 41:

$$M_{AB} + M_{AD} + M_{AC} = \frac{X'_a}{E} = X_a \qquad (58)$$

Therefore,

$$K_{AB}\,\beta_{AB}\,\theta_A + K_{AD}\,\beta_{AD}\,\theta_A + K_{AC}\,\beta_{AC}\,\theta_A = X_a \qquad (59)$$

When $X_a = -1$,

$$Z_a = \frac{-1}{K_{AB}\,\beta_{AB} + K_{AD}\,\beta_{AD} + K_{AC}\,\beta_{AC}} \qquad (60)$$

The denominator in Equation (60) is the moment at A due to $\theta_A = 1$.

In general:

$$Z_a = \frac{-1}{\Sigma\,K_{A(\ )}\,\beta_{A(\ )}} \qquad (61)$$

in which, the summation is over all the members meeting at Joint A. In a like manner, Z_b, Z_e, etc., are computed.

The Determination of X_{ba}, X_{ab}, X_{be}, X_{eb}, Etc.—The moment at B, due to $\theta_A = 1$, is equal to X_{ba}. All other angles are considered zero. For any other value of θ_A than 1, the moment at $B = \theta_A\,X_{ba}$. The moments, X_{ab}, X_{be}, etc., are similarly defined; thus,

$$X_{ba} = X_{ab} = K_{AB}\,\beta'_{BA} = K_{AB}\,\beta'_{AB} \qquad (62)$$

From the quantities, Z_a, Z_b, etc., and X_{ab}, X_{be}, etc., the angles, θ', may be determined for any external load when the effect of the deflection, d, is neglected.

In using this method for fixed loads, one calculates the fixed-end moments at each joint due to the loads and applies to each joint the algebraic sum of the fixed-end moments at the joint as an external load with proper sign.

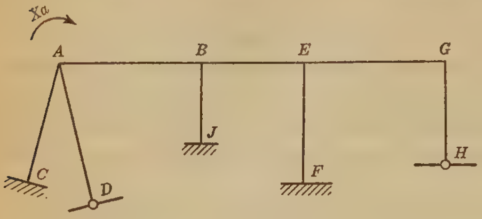

FIG. 41

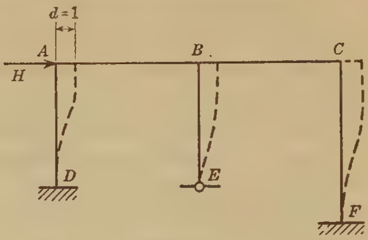

FIG. 42

If there are more than two load conditions to be considered, it is quicker to compute influence values for the moments. In the calculations for influence values, apply $X_a = -1$ (Fig. 41) as the only load on the structure, and compute the corresponding angular changes. Compute angular changes for $X_b = -1$, $X_e = -1$, and $X_g = -1$, respectively. Calculate the moments at the ends of the members for these conditions of loading. The actual moments are in direct proportion to the values of X_a, X_b, X_e, and X_g, due to the actual load. In computing influence lines, the following procedure gives the full solution very quickly. First, compute the angular changes for $X = -1$ for the joint farthest to the left (or right). For instance, in Fig. 41, compute the angular changes for $X_a = -1$. Then, apply $X_b = -1$ as the only load and compute the first approximation, $\Delta\,\theta'_b$. It would be necessary to perform the same operations on this value of $\Delta\,\theta'_b$ that were performed on $\Delta\,\theta'_b$ in the previous computation for $X_a = -1$. Therefore, the angular turns for $X_b = -1$ are equal to the angular turns for $X_a = -1$ multiplied by $\Delta\,\theta'_b$ due to $X_b = -1$, divided by $\Delta\,\theta'_b$ due to $X_a = -1$. In computing θ'_a, only the sum of the corrections from the first computations should be used.

Then, proceed to Joint E and apply Set $X_e = -1$. From Maxwell's theorem, the angular change at E due to a unit moment at A is equal to the angular change at A due to a unit moment at E; likewise, for B and E. Then, the values of θ'_A and θ'_B may be written at once for $X_e = -1$. Since this θ'_B is the final correct value of θ'_B, it is necessary only to make corrections for the joints to the right of B. Compute the angular turn at E due to $X_e = -1$. Compute the angular turn at E due to θ'_B and add the results, which equal $\Delta\,\theta'_e$; calculate $\Delta\,\theta'_g$; and make corrections only to those two angles. Finally, proceed to Joint G.

It is not necessary that the calculations for the load conditions $X_b = -1$; $X_e = -1$; and $X_g = -1$ be carried through as outlined herein, but it is believed that this method of computation requires the least amount of work.

The Effect of Horizontal Movement.—In the preceding discussion, the angles, θ', were obtained for the condition that the frame had no horizontal deflection. It is proposed now to calculate this deflection and corrections to the angles, θ', due to the deflection. The moments acting at the top and bottom of the columns in a frame produce a horizontal thrust, or shear in the columns which causes a deflection, d, and a change in the slope of the tangent to the elastic curve of the members. From Maxwell's law, a moment, —1, at B (see Fig. 42) produces a deflection, d, which is equal to the angular change at B due to a horizontal force, $H = -1$. Instead of applying a unit moment at a joint and computing the deflection, apply a unit deflection, d, and calculate the angular changes, α, at the joints. Knowing these angular changes, α, and knowing $d = 1$ (by assumption), the horizontal thrust, H due to $d = 1$, may be computed. The angular changes, ρ, due to $H = -1$, are then calculated by a simple proportion.

To obtain the angular changes, α, at the joints, due to $d = 1$, first assume the beam, ABC, as infinitely stiff; then, $\theta_A = \theta_B = \theta_C = 0$. For this condition, the moments at the top of the column will be, for $d = 1$ (see Fig. 42):

$$M_{AD} = -\frac{K_{AD}\,\beta''_{AD}}{h_{AD}};\quad M_{BE} = -\frac{K_{BE}\,\beta_{BE}}{h_{BE}};\ \text{and}\ M_{CF} = -\frac{K_{CF}\,\beta''_{CF}}{h_{CF}}.$$

From which,

$$X_{a(d)} = -\frac{K_{AD}\,\beta''_{AD}}{h_{AD}} \quad \ldots\ldots (63)$$

$$X_{b(d)} = -\frac{K_{BE}\,\beta_{BE}}{h_{BE}} \quad \ldots\ldots (64)$$

$$X_{c(d)} = -\frac{K_{CF}\,\beta''_{CF}}{h_{CF}} \quad \ldots\ldots (65)$$

The moments, $X_{a(d)}$, $X_{b(d)}$, and $X_{c(d)}$, are considered as external loads applied at their respective joints. The calculations for the angular changes, α, may be made exactly as in the case of neglecting horizontal deflection, previously described. If the computations for the θ' values have been carried through for influence lines, the more direct way is to proceed, as follows: Since the angular turns have already been found, due to a moment, —1, at each joint, the values of α may be determined by considering that $X_{a(d)}$, $X_{b(d)}$, and $X_{c(d)}$ act one at a time, and adding the effects. Multiply the moment considered acting, by the values of θ' previously obtained when the corresponding joint was loaded with $X = -1$, assuming no horizontal deflection. Repeat this process for all joints and add algebraically. It is obvious that these sums are the angular changes, α, due to $d = 1$. Note that the angles, θ', were calculated for $X = -1$, and the moments about the joints due to $d = 1$ are also negative.

The horizontal shear, $-H$, in the columns is the sum of the moments at the top and bottom of the columns divided by their respective heights. Since $-H$ is the horizontal shear due to $d = 1$, the angular changes, ρ, due to $H = -1$, equals $\frac{\alpha}{-H}$.

Computation of H.—It is best to separate the computations for H into two parts: First, the effect, H', produced by the angular changes, α; and, second, the effect, H'', produced by the deflection, $d = 1$.

For a member restrained at both ends:

$$H' = \frac{K_{AB}\,[\beta_{AB}\;\;\alpha_A + \beta'_{AB}\;\;\alpha_B]}{h_{AB}} + \frac{K_{AB}\,[\beta_{BA}\;\;\alpha_B + \beta'_{BA}\;\;\alpha_A]}{h_{AB}}$$

$$= \frac{K_{AB}\,\beta''_{AB}\;\;\alpha_A}{h_{AB}} + \frac{K_{AB}\,\beta''_{BA}\;\;\alpha_B}{h_{AB}} \quad\ldots\ldots\ldots\ldots (66)$$

$$H'' = -\;\frac{K_{AB}\,\beta''_{AB}}{h^2_{AB}} - \frac{K_{AB}\,\beta''_{BA}}{h^2_{AB}} \quad\ldots\ldots\ldots\ldots (67)$$

and,

$$H = H' + H'' \quad\ldots\ldots\ldots\ldots (68)$$

For a single-story frame, such as that shown in Fig. 42:

$$H' = -\,X_{a(d)}\;\alpha_A - X_{\;(d)}\;\alpha_B - X_{c(d)}\;\alpha_C \quad\ldots\ldots\ldots\ldots (69)$$

in which,

$$-X_{a(d)} = \frac{K_{AD}\,\beta_{AD} + K_{AD}\,\beta'_{DA}}{h_{AD}} = \frac{K_{AD}\,\beta''_{AD}}{h_{AD}} \quad\ldots\ldots\ldots\ldots (70)$$

$$-X_{b(d)} = \frac{K_{BE}\,\beta_{BE}}{h_{BE}} \quad\ldots\ldots\ldots\ldots (71)$$

$$-X_{c(d)} = \frac{K_{CF}\,\beta_{CF} + K_{CF}\,\beta'_{FC}}{h_{CF}} = \frac{K_{CF}\,\beta''_{CF}}{h_{CF}} \quad\ldots\ldots\ldots\ldots (72)$$

and,

$$H'' = +\,\frac{X_{a(d)}}{h_{AD}} + \frac{X_{b(d)}}{h_{BE}} + \frac{X_{c(d)}}{h_{CF}} + \frac{X_{d(d)}}{h_{AD}} + \frac{X_{f(d)}}{h_{CF}} \quad\ldots\ldots\ldots\ldots (73)$$

The values of ρ may next be calculated by solving the formula:

$$\rho = \frac{\alpha}{-H} \quad\ldots\ldots\ldots\ldots (74)$$

that is, $\rho_A = \frac{\alpha_A}{-H}$, $\rho_B = \frac{\alpha_B}{-H}$, $\rho_C = \frac{\alpha_C}{-H}$, etc.

According to the sign system adopted, it will be seen that a negative H or a negative moment around a joint produces a positive deflection; therefore, for $X = -1$, $d = \rho$. For a horizontal load of —1 at the top of columns, $d = \frac{1}{-H}$.

The final values of the angular turns are obtained by adding the effects produced by the assumption that d equals zero, and the angular turns produced by considering the effect of d acting alone. These final angles may be written:

$$\theta = \theta' + \alpha\,d \quad\ldots\ldots\ldots\ldots (75)$$

For instance, for the case of $X_a = -1$: $\theta_A = \theta'_A + \alpha_A\,d_A$; $\theta_B = \theta'_B + \alpha_B\,d_A$; etc. The factor, d_A, signifies the deflection due to $X_a = -1$. The angles are now completely solved and the moments may be calculated by substitution into general slope deflection formulas. The method may be applied to multi-storied frames, secondary stresses, and other problems involving elastic deformations.

Example No. 1.—The writer has chosen the example solved by Professor Cross as an illustration of the method of making the calculations for a fixed condition of loading when the effect of horizontal movement is neglected.

(1).—The fixed-end moments in all the members are first calculated. Since Joint F is considered hinged, the moment at C in CF is computed from the relation: $H_{CF} = C_{CF} + \frac{C_{FC}}{2} = +80 + \frac{60}{2} = +110$, and the moment at $F = 0$.

The values of the external moments, X_b, X_c, etc., acting on the joints are next obtained by adding algebraically the fixed-end moments at the joints. In this connection it is to be noted that the external moment considered as acting around a joint is of the same sign as the fixed-end moment considered as acting on the loaded member. For example, $X_c = C_{CB} + H_{CF} + C_{CD} + C_{CG} = +100 + 110 - 200 + 50 = +60$. Similarly, $X_b = -100$; $X_a = +100$; and, $X_e = C_{ED} +$ cantilever moment $= 0 - 10 = -10$.

(2).—The angular changes at each joint due to a moment, -1, acting at the joint, while all other angles are considered zero, are next computed; thus $Z_c = \frac{-1}{4\,(4 + 5 + 1) + 3 \times 2} = -0.02174$. Similarly, $Z_b = -0.04167$; $Z_a = -0.03125$; and $Z_e = -0.08333$.

(3).—The moment at the fixed end of a member due to a unit rotation at the other end is given by the quantities, X_{cb}, X_{dc}, etc. For example, $X_{cb} = X_{bc} = 2 \times 4 = 8$; $X_{dc} = X_{cd} = 2 \times 5 = 10$; and $X_{ed} = X_{de} = 2 \times 3 = 6$.

(4).—The product, $X_{cb}\,Z_c$, therefore, gives the angular turn at C due to a unit rotation of Joint B. These quantities are computed for carrying over effects of angular turns from right to left, and from left to right. Table 7 gives these values for the author's Fig. 1. All the constants required for the determination of the angular turns have been found, and the computations for the actual rotations may be made.

TABLE 7.—COMPUTATION OF ANGLE CHANGES AT JOINTS INDICATED, CAUSED BY A UNIT ROTATION AT ADJACENT JOINTS

Joint	FOR CARRYING ANGLES TO THE RIGHT		FOR CARRYING ANGLES TO THE LEFT	
	Product $X\,Z$	Value	Product $X\,Z$	Value
B	....	....	$X_{bc}\,Z_b$	-0.3333
C	$X_{cb}\,Z_c$	-0.1739	$X_{cd}\,Z_c$	-0.2174
D	$X_{dc}\,Z_d$	-0.3125	$X_{de}\,Z_d$	-0.1875
E	$X_{ed}\,Z_e$	-0.5	....	....

For the first approximations, $\Delta\,\theta'$, the computations are as follows: At Joint B there is an external moment of -100; hence, $\Delta\,\theta'_B = -100 \times Z_b = -100 \times -0.04167 = +4.167$, which is the value of θ'_B for the moment, -100, at Joint B, when all other joints are held fixed.

At Joint C there is an external moment of $+60$, hence, $\Delta\,\theta'_C = +60 \times Z_c + (\Delta\,\theta'_B)\,(X_{cb}\,Z_c) = +60 \times -0.02174 + 4.167 \times -0.1739 = -2.029$, which is the value of θ'_C for the moment, + 60, at Joint C, when all other joints are held fixed, plus the effect of the angular turn ($\Delta\theta'_B = 4.167$) at Joint B.

The first approximations of θ'_D and θ'_E, computed exactly in the same manner as those for θ'_B, are found to be: $\Delta\,\theta'_D = -2.491$, and $\Delta\,\theta'_E = +2.078$, respectively (see Column (2), Table 8).

TABLE 8.—TOTAL ANGLE CHANGES, EXAMPLE No. 1

Joint	FIRST APPROXIMATION	SUCCESSIVE CORRECTIONS					TOTALS	
	$\Delta\,\theta'$	θ'_1	θ'_2	θ'_3	θ'_4	θ'_5	θ' after two corrections	θ' after five corrections
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
B....	+ 4.1667	+ 0.4675	....	+ 0.01096	....	− 0.00087	+ 4.635	+ 4.644
C....	− 2.029	+ 0.626	− 0.0813	+ 0.0484	− 0.0019	+ 0.00452	− 1.484	− 1.433
D....	− 2.491	− 0.3898	− 0.1703	− 0.0525	− 0.0145	− 0.00628	− 3.051	− 3.124
E....	+ 2.0788	....	+ 0.2800	....	+ 0.0335	....	+ 2.358	+ 2.392

Corrections are made to these approximate quantities to obtain more exact values. The first corrections are made from the joint, E, to the left.

The first correction for the angle, D, is made by computing the angular change at D due to the angle, $\Delta\,\theta'_E = +2.078$; thus, $\theta'_{1D} = \Delta\,\theta'_E\,X_{de}\,Z_d = +2.078 \times -0.1875 = -0.3898$ (Table 8, Column (3)).

The first correction for the angle, C, is made by computing the angular change at C, due to $\Delta\,\theta'_D + \theta'_{1D}$; thus, $\theta'_{1C} = (\Delta\,\theta'_D + \theta'_{1D})\,X_{cd}\,Z = -2.879 \times -0.2174 = +0.626$.

All other corrections are made in the same manner. It is to be noted that they are made only on increments of the angles which have not been previously carried over to the adjacent joint. The total angular change is obtained for any joint by adding the first approximation and the corrections to the angle.

The simplicity of the arrangement of computations shown in Table 8 makes chance of error or failure to consider any term almost negligible. For comparison of results, the moments have been computed for the angles obtained after the second correction and after the fifth correction. The results which are given in Table 9 indicate that for all practical purposes the computations might properly have been stopped with the second correction.

TABLE 9.—COMPARISON OF MOMENTS AFTER TWO AND FIVE CORRECTIONS, RESPECTIVELY

Number of corrections	COMPARISON OF BENDING MOMENTS

Example No. 2.—The real simplicity and value of this method of computation is brought out in the calculations for influence lines for moving loads. The calculations are first carried through for the angles considering that the frame has no horizontal deflection. Then, these angles are corrected for the effect of the deflection. The computations are made for the frame shown in Fig. 43. An external moment, $X = -1$, is considered as the only load on the frame and the angular changes are computed for this condition of loading. The applied moment, $X = -1$, is assumed to act first at Joint A and then at each of the other joints in succession.

The quantities, Z_a, Z_b, etc., and X_{ba}, X_{cb}, etc., and the products, $X_{ba}\, Z_b$, $X_{cb}\, Z_c$, etc., are computed exactly as explained in Example No. 1, and are arranged conveniently in Table 10.

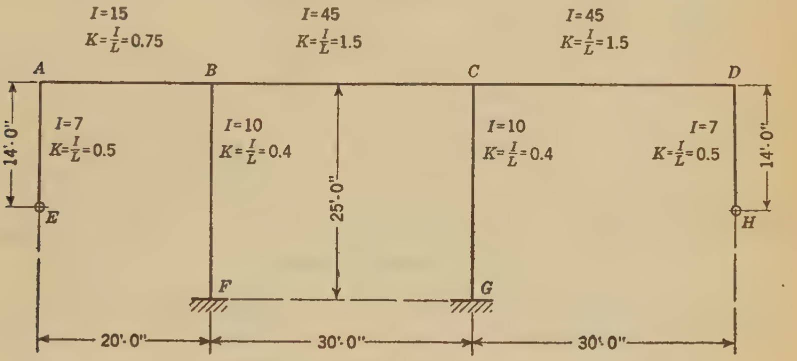

FIG. 43

The computations of the angular turns for $X_a = -1$, etc., are given in Table 11. Explanations of some of the items will serve to make this table clear:

(1).—At A the only load is the moment, -1; hence, for $\Delta\,\theta'_A$, $\Delta\,\theta'_A = -1 \times Z = +0.222$.

(2).—There is no external load at B, and the rotation is caused by the effect of $\Delta\,\theta'_A$; therefore, for $\Delta\,\theta'_B$, $\Delta\,\theta'_B = \Delta\,\theta'_B\, X_{ba}\, Z_b = +0.222 \times -0.1415 = -0.0314$.

(3).—Likewise, the rotation at C is caused by the effect of $\Delta\,\theta'_B$, or $\Delta\,\theta'_C = \Delta\,\theta'_B\, X_{cb}\, Z_c = -0.0314 \times -0.221 = +0.00694$.

(4).—For $\Delta\,\theta'_D$, $\Delta\,\theta'_D = \Delta\,\theta'_C\, X_{dc}\, Z_d = +0.00694 \times -0.4 = -0.00278$. Corrections to these approximate values are made as in Example No. 1.

Computations of the angular turns for $X_b = -1$ are shown in Table 11(*b*). The value of θ'_A was obtained directly by Maxwell's law. The final values of θ'_B, θ'_C, and θ'_D, may be computed from the relation:

$$\theta' = \frac{\Delta\,\theta'_B\ (\text{for } X_b = -1)}{\Delta\,\theta'_B\ (\text{for } X_a = -1)} \times \theta'\ (\text{for } X_a = -1)$$

that is, the angular turns, θ'_B, θ'_C, θ'_D, for $X_b = -1$, are $\left(\frac{+0.0944}{-0.0314} = \right)$ 3.0 times as large as for $X_a = -1$.

Computations of the angular turns, θ'_A and θ'_B, when $X_c = -1$ (see Table 11(*c*)), may be written directly by Maxwell's law. Since they are the final values they require no correction, and computations must be made for θ'_C and θ'_D only, thus, $\Delta\,\theta'_C = -1 \times Z_c + \theta'_B\,X_{cb}\,Z_c = -1 \times -0.0735 - 0.0256 \times -0.221 = +0.07916$, and, $\Delta\,\theta'_D = \Delta\,\theta'_C\,X_{dc}\,Z_d = +0.07916 \times -0.4 = -0.03170$. Corrections are made only to these two angles, and are carried through in the usual manner.

TABLE 10.—COMPUTATION OF ANGLE CHANGES, EXAMPLE NO. 2, CAUSED BY A UNIT ROTATION AT ADJACENT JOINTS

Joint	EXTERNAL MOMENTS, X		ANGLE CHANGE, Z, for $M = -1$	
	Symbol	Computation	Symbol	Computation
A	X_{ab}	$2 \times 0.75 = 1.5$	Z_a	$\dfrac{-1}{3 \times 0.5 + 4 \times 0.75} = -0.222$
B	X_{bc} X_{ba}	$2 \times 1.5 = 3.0$ $2 \times 0.75 = 1.5$	Z_b	$\dfrac{-1}{4\,(0.75 + 1.5 + 0.4)} = -0.0944$
C	$X_{cd} = X_{cb}$	$2 \times 1.5 = 3.0$	Z_c	$\dfrac{-1}{4\,(1.5 + 1.5 + 0.4)} = -0.735$
D	X_{dc}	$2 \times 1.5 = 3.0$	Z_d	$\dfrac{-1}{4 \times 1.5 + 3 \times 0.5} = -0.1333$

ANGLE CHANGES AT THE JOINTS INDICATED, CAUSED BY A UNIT ROTATION AT ADJACENT JOINTS

Joint	FOR CARRYING ANGLES TO THE RIGHT		FOR CARRYING ANGLES TO THE LEFT	
	Product XZ	Value	Product XZ	Value
A	....	....	$X_{ab}\,Z_a$	—0.333
B	$X_{ba}\,Z_b$	—0.1415	$X_{bc}\,Z_b$	—0.283
C	$X_{cb}\,Z_c$	—0.221	$X_{cd}\,Z_c$	—0.221
D	$X_{dc}\,Z_d$	—0.4	....	....

Computations of the angular turns, θ'_A, θ'_B, and θ'_C, for $X_d = -1$, may be written directly (see Table 11(*d*)), as follows: $\theta'_D = -1 \times Z_d + \theta'_C\,X_{dc}\,Z_d = -1 \times -0.1333 - 0.03475 \times -0.4 = +0.1472$. Table 11 gives the values of the rotations when the horizontal deflection is neglected.

To correct for the effect of horizontal deflection a unit deflection is assumed at the top of the columns, and the moments at the top and bottom of the columns are computed on the assumption that the beam, *A B C D*, is infinitely stiff; thus, $X_{a(d)} = X_{d(d)} = \dfrac{-3 \times 0.5}{14} = -0.1071$, and $X_{b(d)} = X_{c(d)} = X_{f(d)} = X_{g(d)} = \dfrac{-6 \times 0.4}{25} = -0.0961$.

The moments at the top of the column are considered as external moments on the joints. They are assumed to act one at a time, and the results are added for the total effect. The effect of $X_{a(d)}$ is obtained by multiplying the angles found for $X_a = -1$ by the value of $X_{a(d)}$; and likewise for all other moments, as shown in Table 12.

d	$+0.8430$	$+0.1929$	$+0.1170$	$+0.5000$	$+38.225$

Computations for H are as follows:

$$H = H' + H''$$

$$H' = -X_{a(d)}\,\alpha_a - X_{b(d)}\,\alpha_b - X_{c(d)}\,\alpha_c - X_{d(d)}\,\alpha_d$$

and,

$$H'' = \frac{X_{a(d)}}{h_{AE}} + \frac{X_{b(d)} + X_{f(d)}}{h_{BF}} + \frac{X_{c(d)} + X_{g(d)}}{h_{CG}} + \frac{X_{d(d)}}{h_{DH}}$$

The operations indicated are listed in Table 13. The angles, ρ, are computed by the formula, $\rho = \dfrac{\alpha}{-H}$, as follows:

$$\rho_A = \frac{\alpha_A}{-H} = \frac{+0.02205}{-(-0.02616)} = +0.843$$

$$\rho_B = \frac{\alpha_B}{-H} = \frac{+0.005048}{-(-0.02616)} = +0.1929$$

$$\rho_C = \frac{\alpha_C}{-H} = \frac{+0.00306}{-(-0.02616)} = +0.1170$$

and,

$$\rho_D = \frac{\alpha_D}{-H} = \frac{+0.013086}{-(-0.02616)} = +0.500$$

The values, ρ, in addition to being the angular turns at the joints due to $H = -1$, are also the deflections at the top of the columns due to $X = -1$ at the various joints; for instance: For $X_a = -1$, $d_A = \rho_A$; for $X_b = -1$, $d_B = \rho_B$; etc.

The angular turns at the joints, including the effect of the horizontal deflection, are computed from the equation: $\theta' = \theta' + \alpha\,d$. For instance, for $X_a = -1$: $\theta_A = \theta'_A + \alpha_A\,d_A$; $\theta_B = \theta'_B + \alpha_B\,d_A$; etc.

The final angular turns and deflections for the various load conditions are shown in Table 14.

The moments are computed by substitution into the general slope-deflection equations. From these values the effect of any load on the frame may be evaluated.

E. C. HARTMANN,[47] JUN. AM. SOC. C. E. (by letter).—The author's method of analyzing continuous frames by distributing fixed-end moments is so simple and direct that there seems to be small reason for suggesting a variation of the system outlined in his paper. However, the writer would like to point out a slightly different system for distributing the fixed-end moments which sometimes may prove useful where the separate effects of a number of loading conditions are to be studied. If it serves no other purpose, this discussion will at least emphasize the flexibility of the Cross method.

The system that the writer has in mind can probably be best illustrated by reference to the case of an ordinary continuous girder. Assume a four-span structure with the points of support lettered, successively, from left to right, A, B, C, D, and E; and assume that it is desired to study the moments caused by a number of different loading conditions. The solution suggested is as follows:

---

[47] Research Engr., Aluminum Co. of America, New Kensington, Pa.

1.—Assume any hypothetical unbalanced negative moment on the left side of Support *B*. Distribute this single unbalanced moment in the manner described in the paper, obtaining the resulting moments at each point of support.

2.—Apply the same hypothetical unbalanced moment at the right side of Support *B*. The resulting moments at each point of support can be determined in this case by inspection from the values obtained in Step 1.

3.—Repeat Steps 1 and 2 for Supports *C* and *D*.

4.—Determine the fixed-end moments for one of the loading conditions to be studied, say, Condition I.

5.—Take one of these fixed-end moments and determine the resulting moment at each point of support by proportion from the values obtained in Step 1, Step 2, or Step 3.

6.—Repeat Step 5 for each of the fixed-end moments for loading Condition I. The final moments at the supports for that loading condition may now be obtained by adding algebraically the results obtained for the several fixed-end moments.

7.—The moments at the supports resulting from other loading conditions may be obtained by repeating Steps 4, 5, and 6.

It is important to note in this example, that, regardless of how many loading conditions are investigated, the number of distributions of unbalanced moments never exceeds three. Having the results of these three distributions on hand, one can tabulate the remainder of the work for easy slide-rule calculation.

THOMAS C. SHEDD,[48] M. AM. SOC. C. E. (by letter).—The writer has had the good fortune to be closely associated with Professor Cross since the fall of 1922 when he first conceived the fundamental idea and began the development of his method of "moment distribution". Some inkling of the extent to which the author has developed this method has been given by several discussions contributed by his former students. More significant, it seems to the writer, is the number of discussers who, presumably unfamiliar with the method prior to the publication of the author's paper, have so quickly grasped the fundamental procedure as to be able to see at once its far-reaching utility, and, in many cases, to present discussions clearly illustrating applications of which the author little more than hinted. In view of the extremely condensed presentation this seems a remarkable tribute to the simplicity and directness of this new tool of analysis.

The development of the method and the manner of its presentation show that the author has strived to eliminate the academic "fiddle-faddle" and unnecessary complexity with which many of the classical methods of statically indeterminate analysis have always been embellished, and to change these from mathematical playthings for academicians to working tools for engineers.

Moment distribution by successive approximations is equally useful whether the engineer needs only a rough approximation or a precise analysis. One who uses the method frequently will be surprised at the number of cases in which an understanding of its fundamental principles enables him to make a mental estimate of indeterminate effects, which is sufficient for his purpose, and at the number of other cases in which a single distribution of the fixed-end moments yields adequate information; and, yet, the same procedure which so quickly gives an approximate answer, with the expenditure of very little additional labor (far less than is required for any kind of answer in other methods), will result in a solution of any desired precision.

---

[48] Associate Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

Appreciation of the power and utility of Professor Cross' method so increases with longer acquaintance that one is tempted to offer a multiplicity of examples of its application. The number of excellent discussions already presented makes this unnecessary, and the writer will content himself with expressing the opinion that "moment distribution" is the most powerful and versatile tool presented for the use of structural engineers in many years. In combination with the author's paper entitled "Column Analogy"[49] this paper will exert an increasingly widespread influence on thinking and design in the structural field. Finally, for the benefit of those who lament that "moment distribution" is not a collection of generalized formulas, the writer would like to quote from Percival Lowell:[50]

> "But worse still for their employed symbols tend to fictitious understanding. Formulæ are the anæsthetics of thought, not its stimulants; * * *.

David M. Wilson,[51] Assoc. M. Am. Soc. C. E. (by letter).—The author has described a method of analysis which is of special interest to one familiar with the slope-deflection method of analyzing statically indeterminate frames. In fact, the steps used in distributing fixed-end moments are based directly on the slope-deflection equation, and as Professor Cross states, the method is, therefore, not approximate, but a method of successive approximations. As the number of approximations is increased, the results approach nearer and nearer those obtained by rigorous application of the slope-deflection method. It should be noted, however, that in the slope-deflection method no account is taken of the change in length of any member due to axial stress. To this extent, both the slope-deflection method and the method of distributing fixed-end moments are approximate.

In the example presented by Professor Cross, joint displacement, due either to horizontal forces or to unsymmetrical vertical loads, has been disregarded. The writer wishes to submit a direct procedure which he believes is a general solution of the problem.

The writer prefers to use the same convention for signs of moments as ordinarily used in the slope-deflection method; that is, clockwise moments at the ends of members are positive and counter-clockwise moments are negative. The general slope deflection equation,

$$M_{AB} = 2EK\,(2\theta_A + \theta_B - 3R) \pm C \quad \dots\dots\dots\dots\dots (76)$$

---

[49] "The Column Analogy," by Hardy Cross, *Bulletin 215*, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill.

[50] "Mars and Its Canals," Preface, p. IX.

[51] Assoc. Prof. of Civil Eng., Univ. of Southern California, Los Angeles, Calif.

expressed in the form,

$$M_{AB} = 2E\left(2\frac{I}{L}\,\theta_A + \frac{I}{L}\,\theta_B - 3\,\frac{I}{L^2}\,d\right) \pm C \ldots\ldots\ldots\ldots (77)$$

suggests four steps for a general solution, as follows:

I (*a*).—Compute the fixed-end moments at the ends of all members.

I (*b*).—Compute and properly distribute the moments at the ends of the columns, due to their deflection, before rotation of the joints is assumed to have taken place.

I (*c*).—Add the moments obtained in Steps I (*a*) and (*b*) and place these values at the ends of members in a line diagram of the frame.

II.—Distribute the unbalanced moment at each joint of the frame so that the sum of the moments at each joint is equal to zero.

III.—"Carry over." In Steps II and III, rotation of the joints is assumed to have taken place.

IV.—Correct the column moments so that the sum of all moments acting on the columns is equal to zero. The distribution of unbalanced column moments is made in the same way as in Step I (*b*), and for the same reason.

The sum of the values found by Steps I, II, and III, for the girders and Steps I, II, III, and IV for the columns is the first approximate value of the moments sought. Better values may be obtained by repeating Steps II and III for the girders and Steps II, III, and IV for the columns, two or more times. Usually, three cycles of operations will give results which are sufficiently accurate for all practical purposes.

The foregoing steps can best be explained by examples selected for the purpose. Steps I (*a*), II, and III have been described by Professor Cross and further explanation of them is not necessary. Three examples are worked out completely, illustrating particularly Steps I (*b*) and IV, and the results, after three cycles of operations, are compared with those obtained by the slope-deflection method (see Table 15).

FIG. 44.

In Step I (*a*), fixed-end moments, in inch-pounds, are $M_{DA} = -133\,333$; $M_{AD} = +266\,666$; and $M_{AB} = M_{BA} = M_{BC} = M_{CB} = 0$. In Step I (*b*), the algebraic sum of all moments acting on the columns must be equal to zero. Therefore,

$$M_{AD} + M_{DA} + M_{BC} + M_{CB} = -1\,200\,000 \ldots\ldots\ldots\ldots (78)$$

Before rotation of the joints is assumed to have taken place, the following moments exist at the ends of the columns, due to their deflection. The deflections, *d* (slope-deflection notation), for Columns *AD* and *BC* are equal:

$$M'_{AD} = M'_{DA} = \frac{-3\,I_{AD}\,d(2E)}{L^2_{AD}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

and,

$$M'_{BC} = M'_{CB} = \frac{-3\;I_{BC}\;d\,(2E)}{L^2_{BC}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

Therefore,

$$\frac{M'_{AD}}{M'_{BC}} = \frac{I_{AD}\;L^2_{BC}}{I_{BC}\;L^2_{AD}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

In this example, $I_{AD} = I_{BC}$ and $L^2_{BC} = L^2_{AD}$. Hence, $M'_{AD} = M'_{DA} = M'_{BC} = M'_{CB}$. Distribute the moment, $-1\,200\,000$ in-lb., to the ends of the columns so that, $M'_{AD} + M'_{DA} + M'_{BC} + M'_{CB} = -1\,200\,000$ in-lb. Then, $M'_{AD} = M'_{DA} = M'_{BC} = M'_{CB} = -300\,000$ in-lb.

In Step I (c) by combining the moments obtained in Steps I (a) and (b) the initial values, in inch-pounds, are as follows: $M'_{DA} = -133\,333 + (-300\,000) = -433\,333$; $M_{AD} = +266\,666 + (-300\,000) = -33\,333$; $M_{AB} = M_{BA} = 0$; and $M_{BC} = M_{CB} = -300\,000$.

Place these values at the ends of the proper members on the line diagram of the frame (Fig. 44).

In Step II, distribute the unbalanced moment at each joint of the frame in proportion to the stiffness of the members.

In Step III, "carry over."

In Step IV, the sum of the column moments is found to be:

$$(-433\,333 + 0 + 9\,550) + (-33\,333 + 19\,100 + 0)$$
$$+ (-300\,000 + 171\,500 + 0) + (-300\,000 + 0 + 85\,700) = -780\,800$$

which does not agree with the value of $-1\,200\,000$ in-lb. found in Step I (b).

Distribute the unbalanced moment, $-1\,200\,000 - (-780\,800) = -419\,200$ in-lb., to the ends of the columns so that $M'_{AD} + M'_{DA} + M'_{BC} + M'_{CB} = -419\,200$ in-lb., in which M'_{AD}, M'_{DA}, etc., are the correction moments at the ends of the columns, due to deflection.

For the same reasons as in Step I(b), $M'_{AD} = M'_{DA} = M'_{BC} = M'_{CB} = \frac{419\,200}{4} = -104\,800$ in-lb. The first approximate values of the moments, in inch-pounds, are: $M_{AD} = -119\,000$; $M_{DA} = -528\,600$; $M_{AB} = 78\,450$; $M_{BA} = 135\,600$; $M_{BC} = -233\,300$; and $M_{CB} = -319\,100$.

Repeat Steps II and III for the girder and Steps II, III, and IV for the columns, until the desired accuracy is obtained.

Example 2.—In this example (Fig. 45), the moments of inertia of all members are assumed equal and the relative stiffnesses are shown in circles, as in Example 1.

In Step I (a), the fixed-end moments for the girder are -40 at A and $+20$ at B; and zero at both ends for each column.

In Step I (b), there are no horizontal forces acting on the columns so that the sum of the column moments is equal to zero, before rotation of the joints is assumed to have taken place. Therefore, no distribution of moments is required at this point.

Steps II and III are carried out as usual.

In Step IV, the sum of the column moments is found not equal to zero, because of the deflection of the frame caused by the unsymmetrical loading; that is, $(0 + 16 + 0) + (0 + 0 + 8) + (0 - 8 + 0) + (0 + 0 - 4) = 12$. Obviously, the unbalanced moment is -12, and this value is distributed to the ends of the columns so that, $M'_{AD} + M'_{DA} + M'_{BC} + M'_{CB} = -12$, as in Example 1, Steps I (b) and IV. The correction moments due to deflection are, for the same reasons, as in Example 1, $M'_{AD} = M'_{DA} = M'_{BC} = M'_{CB} = -3$. The first approximate values of the moments are determined next, and the prescribed cycle of operations is repeated.

FIG. 45.

Example 3.—The frame for this example (Fig. 46), is selected to show how the four steps solve the problem of an unsymmetrical bent. The moments of inertia of all members are assumed equal.

In Step I (*a*), all fixed-end moments are zero.

In Step I (*b*), the algebraic sum of all moments acting on the columns must be equal to zero. Therefore,

$$M_{AD} + M_{DA} + M_{BC} + M_{CB} + R_1 \times 10 + R_2 \times 20 = 0 \ldots\ldots\ldots (82)$$

Furthermore,

$$R_1 + R_2 = 10 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (83)$$

and,

$$M_{BC} + M_{CB} + R_2 \times 20 = 0 \ldots\ldots\ldots\ldots\ldots\ldots (84)$$

Eliminating R_1 and R_2 from Equation (82),

$$M_{AD} + M_{DA} + \tfrac{1}{2}\,(M_{BC} + M_{CB}) = -100 \ldots\ldots\ldots\ldots (85)$$

Before rotation of the joints is assumed to have taken place, the moments in Equations (79), (80), and (81) exist at the ends of the columns, due to their deflection. The deflections, *d*, for Columns *AD* and *BC* are equal.

In this example, $I_{AD} = I_{BC}$ and $L^2_{BC} = 4\,L^2_{AD}$. Hence, by Equation (80), $M'_{AD} = 4\,M'_{BC}$.

Distribute the moment, — 100, to the ends of the columns so that $M'_{AD} + M'_{DA} + \frac{1}{2}(M'_{BC} + M'_{CB}) = -100$. Then, $M'_{BC} = M'_{CB} = \frac{-100}{9} = -11.1111$, and, $M'_{AD} = M'_{DA} = 4 \times -11.1111 = -44.4444$.

In Step I (*c*), since all the fixed-end moments in Step I (*a*) are zero, the values obtained in Step I (*b*) are placed at the ends of the columns on the line diagram of the frame, Fig. 46.

Steps II and III are carried out as usual.

FIG. 46.

In Step IV, the moment relation, as found in Step I (*b*) (see Equation (85)), is not satisfied, since $-22.2222 - 33.3333 + \frac{1}{2}(-7.4074 - 9.2593) = -63.8888$. Distribute the unbalanced moment, $-100 - (-63.8888) = -36.1112$, to the ends of the columns so that, $M'_{AD} + M'_{DA} + \frac{1}{2}(M'_{BC} + M_{CB}) = -36.1112$, in which, M'_{AD}, M'_{DA}, etc., are the correction moments at the ends of the columns, due to deflection.

For the same reasons as in Step I (*b*), $M'_{BC} = M'_{CB} = \frac{-36.1112}{9} = -4.0124$; and, $M'_{AD} = M'_{DA} = 4\, M'_{BC} = -16.0494$.

The first approximate values of the moments are as follows: $M_{AD} = -38.2716$; $M_{DA} = -49.3827$; $M_{AB} = 25.9259$; $M_{BA} = 18.5185$; $M_{BC} = -11.4198$; and $M_{CB} = -13.2717$. Repeat Steps II and III for the girder and Steps II, III, and IV for the columns, until the desired accuracy is obtained.

In the three examples presented, all members are assumed to have uniform cross-section throughout their lengths and, therefore, the "carry-over" factor is $+\frac{1}{2}$. This is by far the most common case. If, however, a member has a variable cross-section between joints, the proper "carry-over" factor can be readily determined by the principle of area moments.

Marshall G. Findley,[52] Assoc. M. Am. Soc. C. E. (by letter).—The Cross method has been tested by the writer for several cases, and the results have been compared with those obtained by other methods, as to speed, convenience, and accuracy. A false impression has been created by the final remarks of Professor Cross concerning the importance of precision in analysis. To correct this, the writer may be allowed to state that while he is a precisionist of the third type, he expects the Cross method to displace all others in at least 90% of all analyses of continuous beams or monolithic frames in his own practice. The writer previously had heard of the Cross method, but only vaguely. After trial, he is now convinced that within certain limits it is an instrument of extreme precision, and a great advance in indeterminate analysis. The writer's previous paper on continuous beam design practice[53] would be considerably revised, if it were to be rewritten so as to include the Cross method.

Professor Cross mentions, in passing, certain methods of dealing with side-sway. It would seem desirable that he deal with these methods at greater length in a separate article, or in his closing discussion.

The ambiguity of the sign-convention for moments in the Cross method is probably best corrected by the clockwise-positive convention, as developed in previous discussions.

The bent to which the method was applied in the paper (see Fig. 1) was evidently chosen to make clear several more or less difficult variations. An ordinary continuous beam of several spans or a monolithic frame, without these variations of arrangement, may be tentatively designed, sections may be selected and revised, and final analyses of great precision may be made, all in the time formerly taken for the tentative first analysis, and with a greater feeling of security concerning freedom from analytic errors. The usual procedure should be to make a number of analyses for the final design, one for dead load and one for each group or span of live loads, and then to use the method of summation to determine all maxima. This procedure has often been impossible on account of time limits when using other methods, but when the Cross method is used, it will be applied to many more situations where it is needed.

George E. Large,[54] Assoc. M. Am. Soc. C. E. (by letter).—The writer believes the profession stands greatly indebted to Professor Cross for his development of the moment distribution method for analyzing continuous frames. A theoretically exact solution of many statically indeterminate structures can now be made with almost no mathematical drudgery. Moreover, the engineer can visualize the action of the structure while the solution is unfolding, and can thus develop a valuable sense of continuity seldom acquired in the use of calculus methods.

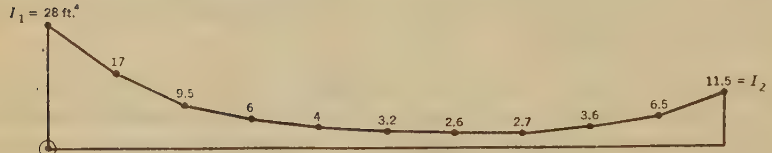
(c) MOMENT DIAGRAM



(d) "I" DIAGRAM

FIG. 47.

The writer has interested himself in a means of applying Professor Cross' method to structures in which the cross-section of a member varies along its length. Previous experience in analyzing and testing some such structures showed that an average value of the moments of inertia of a non-uniform member should not be substituted in the $\frac{I}{L}$ expression for stiffness of uniform members; neither are fixed-end moments and carry-over factors the same. Obviously, there is an infinite number of possible variations of the cross-section of members along their lengths. In comparatively few cases is it possible and feasible to write the equation of moment of inertia variation and perform the necessary integrations to find the required constants. The tables and diagrams prepared by some investigators cannot well cover all the possibilities.

A workable method is presented herein which permits of any conceivable variation of the moment of inertia of a member. It merely requires that the moment of inertia variation be known. Having found the fixed-end moments, and the stiffness and carry-over factors by this method, the solution is completed by moment distribution.

When members are unsymmetrical about the center line of a span there will be different stiffness and carry-over factors for the two ends of a member, and the two fixed-end bending moments due to symmetrically placed loads will have different values. In such cases, finding these six constants presents the chief problem. This general case is illustrated by the following example. When the member and the loading are each symmetrical, the work is shortened greatly.

The General Case: Moment of Inertia Variable; Unsymmetrical Member and Loading.—Fig. 47(a) represents a beam or slab construction of variable section involving complete dissymmetry. The fixed-end moments will be found first, then the carry-over and stiffness factors. To determine the fixed-end moments, let M_1 and M_2 be the unknown fixed-end moments at the large and small ends, respectively. Although ordinarily they will not be equal, it is convenient to assume arbitrary trial values, such as 10 kip-ft. for each, which are utilized to construct the negative parts of the composite moment diagram shown at Fig. 47(c). When the simple-beam bending moment due to the superimposed load is included on the positive side of such a diagram, the algebraic sum of the ordinates at any point gives the net bending moment due to the loading and assumed restraint.

Knowing the moment of inertia variation, as at d, the $\frac{M}{I}$ diagram, Fig. 48, must be constructed to scale, keeping the three parts separate as was done in the moment diagram at c, Fig. 47. The other diagrams need have no exact scale, but should be drawn in correct relation to each other.

The area under each curve of the $\frac{M}{I}$ diagram is found by a summation of the individual trapezoids. In this case, since all are of the same width, the sum of the average ordinates is conveniently taken as the area. (See Table 16.) The moments of the areas about the large end of the member are also found and the three centroids determined.

FIG. 48.—$\frac{M}{I}$ DIAGRAM.

By moment-area principles the algebraic sum of the true $\frac{M}{I}$ areas must equal zero:

$$\frac{9.12}{10} M_1 + \frac{12.27}{10} M_2 = 89.15 \quad \ldots\ldots\ldots\ldots (86)$$

The algebraic sum of the moments of the true $\frac{M}{I}$ areas about the large end of the member must also equal zero:

$$\frac{127.33}{10} M_1 + \frac{240.79}{10} M_2 = 1\,607.8 \quad \ldots\ldots\ldots (87)$$

Solving Equations (86) and (87) simultaneously, the true fixed-end moments (in kip-foot units) are, $M_1 = 27.95$, and $M_2 = 51.95$.

To determine the carry-over factors, consider a member fixed at one end and hinged at the other, as in Fig. 49(*b*). Professor Cross defined a carry-over factor as the ratio of the moment at the fixed end to the moment producing rotation at the rotated end. For members with constant moments of inertia, it is 0.5, but for non-uniform members its values must be calculated. In every case, the rotated end corresponds to the joint just released for moment distribution, while the fixed end is the remote end of the member. Unsymmetrical members have two carry-over factors, depending upon which end is rotated.

$M \propto$	......	......	1 607.83	......	......	127.33	......	......	240.79
Distance of the centroid from the large end, in feet	$\frac{1607.8}{89.15} = 18.00$			$\frac{127.33}{9.12} = 13.97$			$\frac{240.8}{12.27} = 19.62$		

* In computations for fixed-end moments and carry-over factors, the sum of the ordinates is conveniently called the "area" of the diagrams. The actual area is three times the value given.

Continuing the example, and referring to Fig. 49(*b*), the chief problem is to find what fixed-end moment, M_B, is necessary at the small end when the large end is rotated by a moment of 10 kip-ft. If a trial value of $M_B = -10$

is taken, the $\frac{M}{I}$ diagram (Fig. 48) may be sketched immediately from the areas, and the centroids may be found in the fixed-end moment calculations of Table 16. Then, by moment-area principles the algebraic sum of the moments of the true $\frac{M}{I}$ areas about the large end of the member equals zero; thus, $9.12 \times 13.97 - \frac{12.27 \times 19.62}{10} M_B = 0$, and the true $M_B = 5.29$ kip-ft. The carry-over factor from the large end to the small end equals 0.529.

By rotating the small end of the member, as in Fig. 50, and utilizing the same areas, but taking summation of moments about the small end, $12.27 \times 10.38 - \frac{9.12 \times 16.03}{10} M_D = 0$, and $M_D = 8.69$ kip-ft. The carry-over factor from the small end to the large end equals 0.869.

FIG. 50.

Stiffness Factor.—The stiffness of a member is measured by the moment necessary to turn the hinged end of a member through a unit angle when the other end is fixed. When a joint is released in the moment-distribution method, all the ends of the members connecting directly thereto are turned through the same angle. Of the entire moment to be distributed, the part that each member assumes is proportional to its stiffness.

It is proved in mechanics that, for a uniform member, $E\theta_A = \frac{M_A L}{4I}$, or $M_A = \frac{4EI\theta_A}{L}$. (See Fig. 49.)

Since, at any given joint, E and θ_A are constant for all members connecting thereto, the moment upon each will be proportional to its ratio, $\frac{I}{L}$. Accordingly, $\frac{I}{L}$ is used to state the relative stiffnesses of the uniform members of a structure, and is called the stiffness factor.

Since a structure may consist of both uniform and non-uniform members, it is necessary to state the stiffness factors for the non-uniform members in terms of $\frac{I}{L}$ also; thus,

$$S = \frac{k\,I_0}{L} \quad\text{..........................(88)}$$

in which, S is the stiffness factor for a non-uniform member; k is a constant to be determined for each member; and I_0 is the moment of inertia at a particular section of reference.

Furthermore, for non-uniform members,

$$E\,\theta_A = \frac{M_A\,L}{4\,k\,I_0} \quad\text{..........................(89)}$$

Referring again to Fig. 49, one may state concerning the algebraic sum of the positive and true negative areas, by moment-area principles: $E\theta_A = 3\,(9.12 - 0.529 \times 12.27) = \frac{10 \times 30}{k_1 \times 4 \times 28}$, using 3 to state the real area (see Table 16) and the largest moment of inertia, $I_1 = 28$, for reference Finally, $k_1 = 0.34$ and the stiffness factor for the large end $= 0.34\,\frac{I_1}{L}$.

Similarly, for the small end (see Fig. 50): $E\theta_C = 3\,(12.27 - 0.869 \times 9.12) = \frac{10 \times 30}{k_2 \times 4 \times 28}$. Again, using the largest moment of inertia as a reference, $k_2 = 0.205$ and the stiffness factor for the small end $= 0.205\,\frac{I_1}{L}$.

Model Check of Stiffnesses Found.—In order to check the stiffnesses of the two ends of the member as computed herein, a model was made from $\frac{1}{16}$-in. sheet celluloid embodying the exact moment of inertia variation used in the calculations. A bar of a Beggs deformeter gauge was attached to each end of the model, as shown in Fig. 51. One bar was fixed to a drawing-board with screws, while the other was free to rotate about its hinge-pin which had been pressed into the drawing-board. A known torque was applied to the pivoted bar and the displacement of a target was observed with a micrometer microscope. The model was then reversed, and the other end rotated under the same torque.

The average displacements were 248 and 410 micrometer divisions for the rotation of the large and small ends, respectively. This indicates that the actual stiffness of the large end is $\frac{410}{248} = 1.652$ times that of the small end. The corresponding ratio of the *k*'s found in calculating the stiffnesses, is $\frac{0.340}{0.205} = 1.658$. This remarkable correlation also verifies the values of the carry-over factors since the stiffnesses were calculated therefrom.

Sophus Thompson[55] and R. W. Cutler,[56] Juniors, Am. Soc. C. E. (by letter).—In this paper, mention was made of the application of the moment distribution method to the solution of secondary stresses in a truss. The writers have made a study of this phase. For the sake of simplicity and comparison of results, the truss analyzed herein has been chosen from among those treated in current textbooks by the "exact" method.

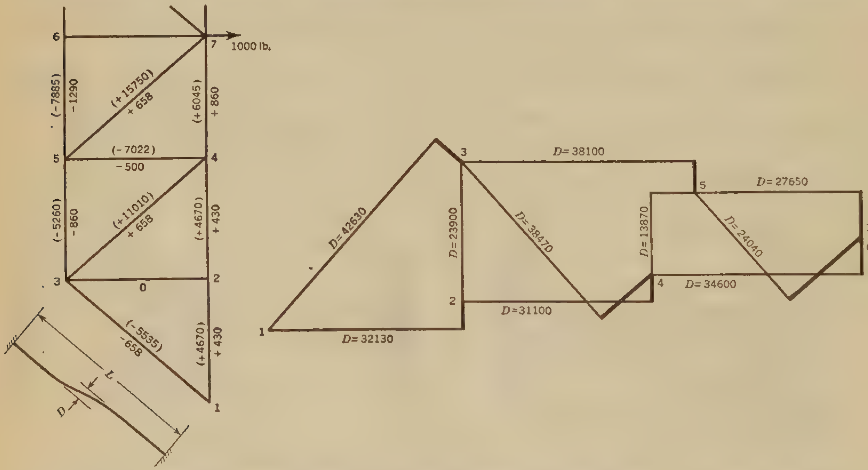

Fig. 52.—Williot Diagram for Analyzing Secondary Stresses by Cross Method.

The method used by the writers requires the construction of the Williot diagram (Fig. 52), from which the value of *D* for each member is obtained, *D* being the displacement, at right angles to the axis of the member, of one end with respect to the other. By cutting each member at the mid-point and

FIG. 53.

treating each half as a cantilever with the deflection, $\frac{1}{2}\,D$, the fixed-end moments are obtained. The value of D as used herein is actually displacement multiplied by E. Then, referring to Fig. 52, $\frac{D}{2} = \frac{P\,(0.5\,L)^3}{3\,I} = \frac{M\,(0.5\,L)^2}{3\,I}$ or $M = \frac{6\,I\,D}{L^2}$.

The determination of the algebraic sign of the fixed-end moments is simplified, first, by the use of the convention which designates as positive any moment tending to rotate a joint in the clockwise direction; and, second, by considering the displacement of the ends of a member relative to each other, as shown on the Williot diagram. For drawing the Williot diagram, Member 6–7 is assumed to stand fast.

Analysis of a Pratt Truss.—Table 17 shows comparisons and percentage differences between moments obtained by the "exact" solution[57] and by the Cross method carried through four, five, and six cycles. It may be noted that it is unnecessary to carry the computations out to as many significant figures as is done in this discussion.

[57] "Modern Framed Structures," Vol. II, by Johnson, Bryan, and Turneaure, p. 440.

Alfred Gordon,[58] Assoc. M. Am. Soc. C. E. (by letter).—The method of analyzing rigid frames, described in this paper, is one of those maddeningly simple solutions, of a baffling problem, that show sheer genius. By a flight of imagination amounting to pure poetry, Professor Cross has made the analysis of indeterminate structures even simpler than that of a simple truss. The flood of discussion his paper has unloosed is proof of its extraordinary verbal economy, nothing having arisen that was not indicated therein.

Although it may be only "dotting the i's and crossing the t's," the writer would point out more exactly the relation between Professor Cross's method and the tables[59] compiled by Walter Ruppel, Assoc. M. Am. Soc. C. E. The slope-deflection equations for any beam subjected to moments at each end may be represented (using Mr. Ruppel's nomenclature), as follows:

$$M_{AB} = \frac{1 - v}{pl\,[1 - (u + v)]}\,\theta_A + \frac{v}{pl\,[1 - (u + v)]}\,\theta_B \quad \ldots\ldots\ldots (90)$$

and,

$$M_{BA} = \frac{1 - u}{ql\,[1 - (u + v)]}\,\theta_B + \frac{u}{ql\,[1 - (u + v)]}\,\theta_A \quad \ldots\ldots\ldots (91)$$

or,

$$M_{AB} = \alpha\,\theta_A + \beta\,\theta_B \quad \ldots\ldots\ldots (92)$$

and,

$$M_{BA} = \gamma\,\theta_B + \delta\,\theta_A \quad \ldots\ldots\ldots (93)$$

in which, p is the area of the $\frac{M}{EI}$ diagram for $M = 1$ at the left support of the beam with unit span, having E and I (minimum) $= 1$; q is the corresponding area for $M = 1$ at the right support, with the same understandings; u is the distance from the left support to the left characteristic point when $l = 1$; and v is the distance from the right support to the right characteristic point when $l = 1$, and α and γ represent the numerators of the moment-distribution factors for the beams, AB and BA, the sum of such θ-coefficients for the members meeting at one point constituting the denominator.

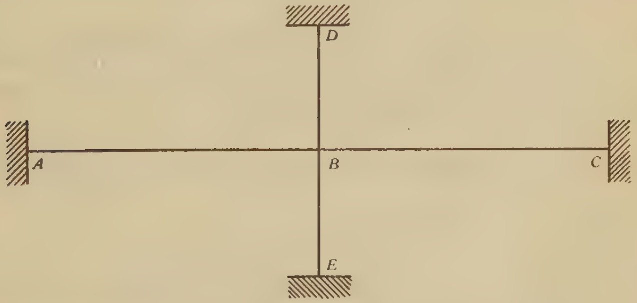

Fig. 54.

---

[58] Engr., Bridge Dept., C. P. Ry., Montreal, Que., Canada.

[59] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 167.

Thus, in Fig. 54, let the equations for the members be,

$$M_{BA} = \gamma\,\theta_B + \delta\,\theta_A \quad \dots\dots (94a)$$

$$M_{BC} = \eta\,\theta_B + \kappa\,\theta_C \quad \dots\dots (94b)$$

$$M_{BD} = \nu\,\theta_B + \epsilon\,\theta_D \quad \dots\dots (94c)$$

$$M_{BE} = \tau\,\theta_B + \psi\,\theta_E \quad \dots\dots (94d)$$

Then, locking the ends remote from their point of juncture, θ_A, θ_C, θ_D, and θ_E are all equal to zero and,

$$M_{BA} = \gamma\,\theta_B \quad \dots\dots (95a)$$

$$M_{BC} = \eta\,\theta_B \quad \dots\dots (95b)$$

$$M_{BD} = \nu\,\theta_B \quad \dots\dots (95c)$$

$$M_{BE} = \tau\,\theta_B \quad \dots\dots (95d)$$

and the moment-distribution factors are:

Beam	Moment distribution factor	Beam	Moment distribution factor
$BA =$	$\dfrac{\gamma}{(\gamma + \eta + \nu + \tau)}$;	$BC =$	$\dfrac{\eta}{(\gamma + \eta + \nu + \tau)}$
$BD =$	$\dfrac{\nu}{(\gamma + \eta + \nu + \tau)}$;	$BE =$	$\dfrac{\tau}{(\gamma + \eta + \nu + \tau)}$

Furthermore, when such general equations are combined with the particular equation for a column, PQ, fixed at the base, Q (that is, $M_{pa} = 4\dfrac{EI}{h}\,\theta_p$), care must be taken that the moment of inertia used, is expressed in terms of that used as unity for the entire frame; otherwise, the term, $\dfrac{4\,EI}{h}$, cannot be compared properly with the θ-coefficient of the beam equations, since that coefficient includes the moment of inertia of the beam. For the same reason, if the inertia moments at the centers of various haunched beams are different, the θ-coefficients must be modified accordingly.

Finally, the carry-over factors will be: From A to B, $\dfrac{p\,u}{q\,(1 - v)}$; and, from B to A, $\dfrac{q\,v}{p\,(1 - u)}$.

The writer prefers the convention in signs supported by the majority of the discussers—all clockwise moments positive.

A. W. Earl,[60] M. Am. Soc. C. E. (by letter).—Structures composed of members the cross-section of which varies from point to point along their length are not, fortunately, of very common occurrence, since an accurate analysis entails considerable work. When such structures do occur, the writer believes that the method so clearly and concisely stated by Professor

---

[60] Berkeley, Calif.

Cross, can be used to advantage and he, therefore, submits a development of the expressions for fixed-end moments, stiffness factors, and carry-over factors for members of variable cross-section, hoping they may prove useful.

The following notation will be used:

M_{AB} = moment at left end, A, of Member AB.
M_{BA} = moment at right end, B, of Member AB.
L = length of Member AB.
θ_A = change in slope of the tangent to the elastic curve of the member at A.
θ_B = change in slope of the tangent to the elastic curve of the member at B.
d = deflection of one end of a member with respect to the other end, measured perpendicularly to the original position of the member.
F_A = area of $\frac{M}{I}$ - diagram, due to the end moment, M_{AB}
F_B = area of $\frac{M}{I}$ - diagram, due to the end moment, M_{BA}
$m = \frac{F_A}{M_{AB}\,L}$ = area of $\frac{M}{I}$ - diagram for $M = 1$ and $L = 1$.
$n = \frac{F_B}{M_{BA}\,L}$ = area of $\frac{M}{I}$ - diagram for $M_{BA} = 1$ and $L = 1$.
s = stiffness factor.
u = distance of centroid of Area m, from the left end.
v = distance of centroid of Area n, from the right end.
F = area of $\frac{M}{I}$ - diagram for the applied loading.
$\bar{x}$ = distance of centroid of Area F from the right end.

The two basic propositions of the slope-deflection method may be expressed as follows:[61]

Area of $\frac{M}{EI}$ - diagram between B and A,

$$\theta_B - \theta_A = \int_B^A \frac{M\,dx}{EI} \quad \ldots\ldots\ldots\ldots\ldots\ldots (96)$$

and moment of $\frac{M}{EI}$ - diagram between B and A about B,

$$d - L\,\theta_A = \int_B^A \frac{Mx\,dx}{EI} \quad \ldots\ldots\ldots\ldots\ldots\ldots (97)$$

These expressions may be written,

$$\theta_B - \theta_A = \frac{1}{E}\Big[- M_{AB}\,m\,L + M_{BA}\,n\,L - F\Big] \ldots\ldots\ldots (98)$$

$$d - L\,\theta_A = \frac{1}{E}\Big[- M_{AB}\,m\,(1 - u)\,L^2 + M_{BA}\,n\,v\,L^2 - F\bar{x}\Big] \ldots (99)$$

---

[61] For proof of the underlying propositions and development of the slope-deflection equations see "Analysis of Statically Indeterminate Structures by the Slope Deflection Method," by W. M. Wilson, F. E. Richart, and Camillo Weiss, *Bulletin 108*, Eng. Experiment Station, Univ. of Illinois. The argument and sign convention of this *Bulletin* have been followed.

Solving simultaneously for M_{AB} and M_{BA} and replacing mu with nv, or *vice versa*, as required:

$$M_{AB} = \frac{E}{mL\,(1-u-v)}\left[\theta_A\,(1-v) + \theta_B\,v - \frac{d}{L}\right] - F\,\frac{\bar{x} - Lv}{mL^2\,(1-u-v)} \quad \text{. . (100)}$$

and,

$$M_{BA} = \frac{E}{nL\,(1-u-v)}\left[\theta_A u + \theta_B\,(1-u) - \frac{d}{L}\right] + F\,\frac{L\,(1-u) - \bar{x}}{nL^2\,(1-u-v)} \quad \text{. (101)}$$

Equations (100) and (101) are the equations of slope deflection for a member of varying cross-section.

That $mu = nv$ may be proved, as follows:

$$mu = \frac{F_A\,ul}{M_{AB}\,L} = \frac{\int_0^L \frac{M}{I}\,x\,dx}{M_{AB}\,L} \qquad nu = \frac{F_B\,vL}{M_{BA}\,L} = \frac{\int_0^L \frac{M}{I}\,(L-x)\,dx}{M_{BA}\,L}$$

$$M = \frac{M_{AB}}{L}\,(L-x) \qquad M = \frac{M_{BA}\,x}{L}$$

then, then,

$$mu = \frac{M_{AB}}{L}\,\frac{\int_0^L \frac{(L-x)\,x\,dx}{I}}{M_{AB}\,L} \qquad nv = \frac{M_{BA}}{L}\,\frac{\int_0^L \frac{(L-x)\,x\,dx}{I}}{M_{BA}\,L}$$

$$= \frac{1}{L^2}\int_0^L \frac{(L-x)\,x\,dx}{I} \qquad = \frac{1}{L^2}\int_0^L \frac{(L-x)\,x\,dx}{I}$$

therefore, $mu = nv$

Since, in the case of a member fixed at both ends, resting on unyielding supports, θ_A, θ_B, and $\frac{d}{L}$, each equal zero, the fixing moments at A and B, respectively, may be written equal to the last terms of Equations (100) and (101) as shown by Equations (102) (Table 18).

TABLE 18.—SUMMARY OF FACTORS FOR MOMENT DISTRIBUTION

Item.	End of beam	Fixing moment, M_F. (102)	Stiffness factor, S (103)	Carry-over factor, γ (104)
A.........	Left	$F\,\frac{\bar{x} - Lv}{mL^2\,(1-u-v)}$	$\frac{E\,(1-v)}{mL\,(1-u-v)}$	$\frac{v}{1-v}$
B.........	Right	$F\,\frac{L(1-u) - \bar{x}}{nL^2\,(1-u-v)}$	$\frac{E\,(1-u)}{nL\,(1-u-v)}$	$\frac{u}{1-u}$

The signs as given are correct for downward loading. In general, the sign of the fixing moment at the end of a member is opposite to that of the moment of the applied load about that end, clockwise moments being considered positive.

The stiffness factor is defined as the moment at one end of a member (resting on unyielding supports at both ends), necessary to produce unit rotation at that end when the other end is fixed. Then, the stiffness factor for the end, A, may be found by placing $\theta_A = 1$, $\theta_B = 0$, $F = 0$, and $\frac{d}{L} = 0$ in Equation (100) and the stiffness factor at the end, B, may be found by placing $\theta_B = 1$, $\theta_A = 0$, $F = 0$, and $\frac{d}{L} = 0$, in Equation (101). The results are as shown by Equations (103) (Table 18).

If E is constant, it may be made equal to unity in these equations, since comparative stiffness is all that is required.

The carry-over factor is defined as the ratio of the moment at the fixed end to the moment producing rotation at the rotating end of a member (which is on unyielding supports at both ends), if one end of the member is rotated while the other end remains fixed. Then, the carry-over factor at End A equals the ratio of M_{AB} to M_{BA} when θ_A, $\frac{d}{L}$, and F, are made equal to zero in Equations (100) and (101). Similarly, the carry-over factor at End B is the ratio of M_{BA} to M_{AB} when θ_B, $\frac{d}{L}$, and F, are made equal to zero in the same equations. Thus, they take the form of Equations (104) (Table 18.)

The quantities, m, n, v, u, F, and x having been determined, the fixing moments, stiffness, and carry-over factors are easily calculated and the analysis may proceed as for a structure with members of uniform cross-section. The "bulk" of the labor is in determining the six aforementioned quantities for each member of the structure. A well-ordered tabulation, Simpson's rule for approximate integration, and a calculating machine will be found very helpful.

The valuable tables[62] given by Walter Ruppel, Assoc. M. Am. Soc. C. E., may be used and the work thus greatly shortened. These tables give coefficients, s, t, u, v, p, and q, for use in the solution of continuous beams of variable cross-section by Fidler's method. Simple relationships exist which make them easily applicable to the slope-deflection method, or to the method of distributed moments. The tables cover a large variety of shapes and loadings.

As defined by Mr. Ruppel (using the writer's symbols) the heights, respectively, of the left and right characteristic points when L and W are equal to 1, are:

$$s = \frac{F \bar{x}}{L^3 W m} \quad \text{.......................} (105)$$

and,

$$t = \frac{F (L - \bar{x})}{L^3 W n} \quad \text{.......................} (106)$$

---

[62] "Moments in Restrained and Continuous Beams," *Transactions*, Am. Soc. C. E., Vol. 90 (1927), 155 *et seq.*

Solving simultaneously:

$$F = W\,L^2\,(s\,m + t\,n) \qquad (107)$$

and,

$$\bar{x} = \frac{s\,m\,L}{s\,m + t\,n} \qquad (108)$$

Thus, in terms of the coefficients given in Mr. Ruppel's table, m and n are obtained by dividing p and q, respectively, by the minimum moment of inertia of the member; u and v are obtained directly from the tables and F and $\bar{x}$ by substituting values for s and t in Equations (107) and (108). The tables are strictly accurate for beams of rectangular cross-section, but they may be used with satisfactory accuracy for **T**-beams.

A. Floris,[63] Esq. (by letter).—The method of analyzing statically indeterminate structures by the aid of successive approximations, as proposed by the author, is not quite new.

The most systematic study, relative to the analysis of structures by means of statically indeterminate deformations instead of statically indeterminate forces, was made by the late Professor A. Ostenfeld, including a method of computation by steps for fixed as well as for movable joints.[64] This last method has been mentioned by one of the discussers. The writer would like to add two more methods due to well-known writers.

The method of Professor Akira Miura may be summarized as follows:[65] First, the joints are assumed to be restrained from rotating and the bending moments of the members are determined for this condition. In reality, the joints are not fixed, and it is necessary, therefore, to calculate, for each joint, the moments that resist rotation. These moments are termed "the moments of restraint." Now, if it is assumed that the moments of restraint are acting at the joints in the opposite direction, the corresponding rotations, and, consequently, the bending moments, of the members can be determined. By adding the values found in the first step to those obtained in the second step the final values for the actual conditions in the structure can be calculated. This analysis permits various simplifications in its detailed development and is, according to its author, more simple and practical than the method devised by Professor Ostenfeld.

The reviewer of an American textbook on structural analysis in which Professor Cross' method is given, states that: "The procedure is somewhat similar to that due to Dr. F. Hartmann [Vienna, Austria], in which the joints are locked by eliminating the end slopes of the members."[66] Since reference is not made to the original source the writer could not verify this statement.

The writer wishes merely to put these comments on record without going into detail as to the relative merits of the methods under consideration.

[64] "Die Deformationsmethode," von A. Ostenfeld, Berlin, 1926, pp. 17, 27, and 37.

[65] "Theory of Rigid Frames," by Akira Miura, Tokyo, 1929 (in Japanese). Also, "Die neuzeitliche Entwicklung der Rahmentheorie in Japan", von Akira Miura, *Proceedings*, World Eng. Congress, Tokyo, 1929, Vol. VII, Pt. I, p. 422.

[66] *Concrete and Constructional Engineering* (London), August, 1931, Vol. XXVI, No. 8, p. 468.

I. M. Nelidov,[67] Assoc. M. Am. Soc. C. E. (by letter).—Rigid frames can be classified as structures consisting of a number of members, which is usually less than that required by the theorem of Cauchy,[68] that is, the number of members equals three times the number of joints minus six. As a consequence, equilibrium under the action of a given set of forces is accomplished only after considerable deformation takes place. In this respect, the point of view sometimes expressed that side-sway of the frame is of no importance apparently is in error.

Rigid frames generally fall into two distinct classes: First, those in which a given deflection of the joint at one end of the frame produces a known deflection at the remainder of the joints; and, second, those in which a given deflection of the joint at one end produces unknown deflections at the remainder of the joints.

Frames of the first class are: Two members connected at a joint and simply supported at oppôsite ends; three members meeting at a joint, or portals with parallel and non-parallel legs, saw-roof frames, and closed-ring frames; four members meeting at a joint, or closed rings, such as culverts, bins, etc.; and, finally, more than four members, such as structural building frames.

Portals consisting of four or more members with parallel or non-parallel legs, closed rings, and polygcns, belong in the second class. Arches are included in the polygon classification. It should be noted that any frame may have rigid connections, but strictly rigid frames proper must have them in order not to become moving mechanisms.

All the frames of the first class can be solved with the aid of the method proposed by Professor Cross, by deflecting the structure a unit of distance, finding the resulting moments and shears, multiplying them by a certain coefficient, and equating them to acting forces.

With frames of the second class this procedure cannot be followed exactly because the deformations of the ring are known only when the total number of members is not greater than three. When this number is exceeded, the intermediate members "give" if the end members are undergoing a certain deformation.

To demonstrate the application of the Cross method to the second class of frames, with the number of members greater than three, the writer selected as the simplest case a symmetrical portal frame, consisting of four members and subjected to the action of a horizontal force, $P = 1$ kip, as shown on Fig. 55. Clockwise moments acting on the ends of a member are considered positive; moments in beams to the left of a section, or those which are plotted in a moment diagram, are assumed positive when the curvature of the elastic line is convex downward.

The deflection of the frame under the load can be resolved into two component deflections: First, two equal deflections to the right, measured at the top of the columns; and, second, two equal but opposite deflections, one at the left column toward the right and one at the right column toward the left.

---

[67] Senior Engr., Hydr. Structural Design, State Dept. of Public Works, Sacramento, Calif.

[68] "Redundant Forces in Structural Mechanics," by the late V. L. Kirpitcheff, Prof. Emeritus at Polytechnic Institute at Kiev, 1903 Edition, p. 10.

The top members of the portal above the columns can be replaced with one straight imaginary member connecting the top of the columns. This member should have properties equal to the replaced top of the portal, and its use will simplify the procedure. The properties to be found are: The new carry-over ratio; the new rigidity; and the forces and moments resulting from the deformation of the imaginary member.

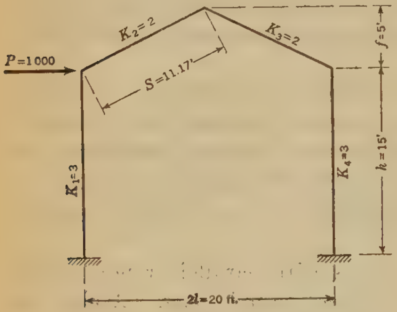

FIG. 55

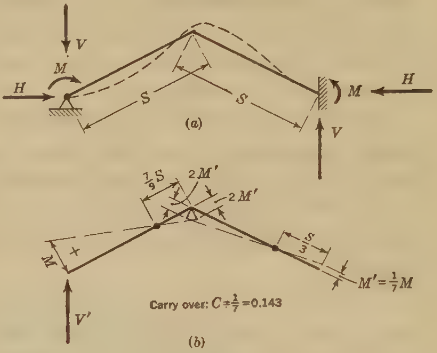

FIG. 56

To determine the carry-over ratio imagine the top portion of the frame hinged at the left end and fixed at the right, as shown on Fig. 56(*a*). From the condition which produces no displacement at the hinge, M' is determined with the aid of the conjugate-beam method: $\Delta L_v = 0$; therefore,

$$\frac{1}{EI}\left[\frac{1}{2}(M+2M')\,s\,\frac{l}{3} - 2\times 2M'\,sl + \frac{1}{2}(2M'+M')\,s\,\frac{5}{3}\,l\right] = 0 \quad ..(109)$$

Wherefrom: $M' = \frac{I}{7}M$, which gives the carry-over ratio, $c_i = -0.1429$, instead of $c = +0.5$ for a straight beam with constant moment of inertia. The moment diagram is shown on Fig. 56(*b*).

The deflection angle at the hinge is:

$$\Delta\phi = \frac{1}{EI}\left[\frac{1}{2}(M+2M')\,s - 2\times 2M's + \frac{1}{2}(2M'+M')\right]$$

$$= \frac{2}{7}\,\frac{Ms}{EI} = \frac{2}{7}\,\frac{M}{Ek} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(110)$$

in which, $k = \frac{I_2}{s_2} = \frac{I_3}{s_3} = 2$. This deflection angle must be equal to that of a straight imaginary beam hinged at the left end and fixed at the right, which is:

$$\Delta\phi_i = \frac{1}{4}\,\frac{M}{Ek_i} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(111)$$

Since $\Delta\phi = \Delta\phi_i$:

$$\frac{2}{7}\,\frac{M}{Ek} = \frac{1}{4}\,\frac{M}{Ek_i} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (112)$$

and $k_i = \frac{7}{8}\,k = \frac{7}{8}\,2 = 1.75.$

After the carry-over ratio and rigidity of the imaginary member are determined, the procedure is as follows.

Step 1.—Deflect the frame toward the right an equal amount, Δ', at both columns, compute the fixed-end moments, release the joints, and balance the moments. Fixed-end moments for columns in this case are:

$$M = -6\,Ek_c\,\frac{\Delta'}{h} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (113)$$

in which, $k_c = \frac{I_1}{l_1} = \frac{I_4}{l_4} = \frac{I}{h} = 3$. Assume an arbitrary value, $M = -10\,000$ ft-lb. Fixed-end moments for the imaginary member in this case are equal to zero. All computations for Step 1 are shown on Fig. 57(*a*).

FIG. 57

Step 2.—Deflect the posts of the frame inward an equal amount, Δ''; compute the fixed-end moments; release the joints; and balance the moments. The fixed-end moments for columns in this case are expressed by:

$$M = \pm 6\,Ek_c\,\frac{\Delta''}{h} \qquad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (114)$$

In this case a value is assumed arbitrarily as $M = \pm 5\,000$ ft-lb. Fixed-end moments in the imaginary member are computed in accordance with Fig. 58(*a*) and Fig. 58(*b*), as follows:

From the condition that $\Delta\phi = 0$, it follows that $M' = -M$; furthermore, $V = 0$ by condition of loading; and, since $M' = M - Hf$, it follows that $M = +\frac{Hf}{2}$. The horizontal shortening of the span, $2l$, is expressed by:

$$\Delta L_h = \frac{1}{EI}\left[2\,Ms\,\frac{1}{2}f - 2 \times \frac{1}{2}Hfs\frac{2}{3}f\right] = -\frac{Hf^2s}{6\,EI} = -\frac{Hf^2}{6\,Ek} \quad \ldots(115)$$

in which, $k = \frac{I}{s} = 2$.

On the other hand: $\frac{\Delta L_h}{2} = \Delta'' = -\frac{M_c h}{6\,Ek_c}$. As $\Delta'' = -\Delta L_h$:

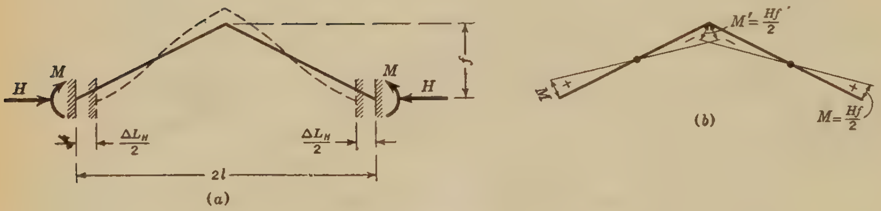
$$\frac{Hf^2}{6\,Ek} = -\frac{2\,M_c h}{6\,Ek_c} \quad \ldots\ldots\ldots\ldots(116)$$

or,

$$H = -\frac{2\,M_c hk}{f\,k_c} \quad \ldots\ldots\ldots\ldots(117)$$

and,

$$M = \frac{Hf}{2} = -\frac{M_c hk}{f^2 k_c} \quad \ldots\ldots\ldots\ldots(118)$$



(*a*) (*b*)

FIG. 58

For the left support, $M_c = -5\,000$ ft-lb.; $h = 15$ ft.; $k = 2$; $f = 5$ ft.; and $k = 3$. Therefore, the fixed-end moment in the imaginary member will be, $M = -\frac{-5\,000 \times 15 \times 2}{5 \times 3} = +10\,000$ ft-lb. The moments are balanced as in Fig. 59(*a*). The next step is to determine the coefficients, C_1 and C_2, by which the moments and shears just found are multiplied, in order to obtain the true moments and shears. When the top of the left column is in equilibrium:

$$C_1\,H_1' + (H_1'' + H)\,C_2 = P \quad \ldots\ldots\ldots\ldots(119)$$

and, when the top of the right column is in equilibrium:

$$C_1\,H_2' - (H_2'' + H)\,C_2 = 0 \quad \ldots\ldots\ldots\ldots(120)$$

In the present case, $H_1' = H_2'$ and $H_1'' = -H_2''$; therefore, $C_1 = \dfrac{P}{2\,H_1'}$ and $C_2 = \dfrac{P}{2\,(H_1'' + H)}$.

Substituting the numerical values: $C_1 = \dfrac{1\,000}{2 \times 667} = 0.75$; and $C_2 = \dfrac{1\,000}{2\,(967 + H)} = \dfrac{500}{967 + H}$, Factor H is the comprehensive force in the imaginary member corresponding to the balanced moments at its ends, as found in Step 2.

(b) MOMENTS AND SHEARS

FIG. 59

From Fig. 58(a), the angle of rotation at the left support is:

$$\Delta\,\phi = \frac{1}{EI}\left(Ms - \frac{1}{2}\,Hfs\right) = \frac{1}{Ek}\left(M - \frac{1}{2}\,Hf\right) \text{ ....(121)}$$

For the adjacent column, $M'' = 2\,E\,k_c\left(2\,\Delta\,\phi_c - 3\,\dfrac{\Delta''}{h}\right)$, and, therefore,

$$\Delta\,\phi_c = \left(M'' + 6\,E\,k_c\,\frac{\Delta''}{h}\right)\frac{1}{4\,Ek} \text{ ....(122)}$$

Substituting $\dfrac{\Delta''}{h} = -\dfrac{M_c}{6\,Ek_c}$,

$$\Delta\,\phi_c = \frac{M'' - M_c}{4\,Ek_c} \text{ ....(123)}$$

From the condition that $\Delta\,\phi = \Delta\,\phi_c$,

$$\frac{1}{Ek}\left(M - \frac{1}{2}\,Hf\right) = \frac{M'' - M_c}{4\,Ek_c} \text{ ....(124)}$$

and as $M'' = -M$,

$$H = \frac{2\,Mk}{f}\left[\frac{1}{k} - \frac{-1^{-u}}{4\,k_c}\right] \text{ ....(125)}$$

in which, u represents the ratio, $\dfrac{M_c}{M}$, for convenience.

The vertical reaction, V, equals zero, as before. Let $M = +8\,000$ ft-lb.; $M_C = -5\,000$ ft-lb.; $k = 2$; $k_C = 3$; and $f = 5$ ft.; then,

$$H = 2 \times 8\,000 \times \tfrac{2}{5}\left[\tfrac{1}{2} - \frac{-1 - \dfrac{-5\,000}{8\,000}}{4 \times 3}\right] = +3\,400 \text{ lb.}$$

and,

$$C_2 = \frac{500}{967 + 3\,400} = 0.1145$$

The actual moments and shears are shown on Fig. 57(a) and Fig. 59(b). By adding these values, the resultant moments and shears are shown in Fig. 60. With all the external moments and forces known, the moment at the top of the portal is found to be:

$$M_C = M_A - Vl + H_1(h+f) - Pf = -5\,744 - 250 \times 10 + 611\,(15+5) - 1\,000 \times 5 = -1\,024 \text{ ft-lb.}$$

Fig. 60

An analytical check[69] gives the following results: $M_A = 5\,744$ ft-lb.; $M_B = 3\,431$ ft-lb.; $M_C = -1\,036$ ft-lb.; $M_D = -1\,590$ ft-lb; and $M_E = -4\,256$ ft-lb.

The foregoing computations show that Professor Cross' method can be applied to both classes of rigid frames.

---

[69] "Rahmenformeln," von A. Kleinlogel, Fifth Edition, p. 295.

E. A. MacLean,[70] Esq. (by letter).—The following example of the Cross method of distributing moments, as applied to a truss, is submitted for determining secondary stresses. In spite of the simplicity of the Cross method, it becomes tedious when applied to a large truss, but the chances of error can be greatly reduced by systematizing the work. The method of laying out the computations, as shown in the example herein, will be found to be very helpful, not only in the computation of the secondary stresses in a truss, but in computing the moments in a multi-story bent or any other complicated structure.

The problem is taken from a standard textbook[71] in which a solution of the secondary stresses is made by one of the older methods. The necessary data are shown in Fig. 61, in which, I = moments of inertia; l = length, in inches; $K = \frac{I}{l}$; c = distance from the neutral axis to the outer fiber; and s = unit stress. In Table 19 the "Percentage of the unbalanced moment going to member" (Item 1), is the ratio of the K of the member to the total of all the K's for that joint. The fixed-end moments are obained from the equation, $\frac{6\,DEK}{l}$, in which, E = modulus of elasticity; and D = the deformation of one end of a member with respect to the other end measured at right angles to the axis of the member. The D's may be obtained from a Williot diagram or by computation. Clockwise rotation of the joint causes positive moments in the members entering the joint. In Table 19, the computations for Joints D and E are omitted because the moments are the same as for Joints B and A, respectively, with opposite signs.

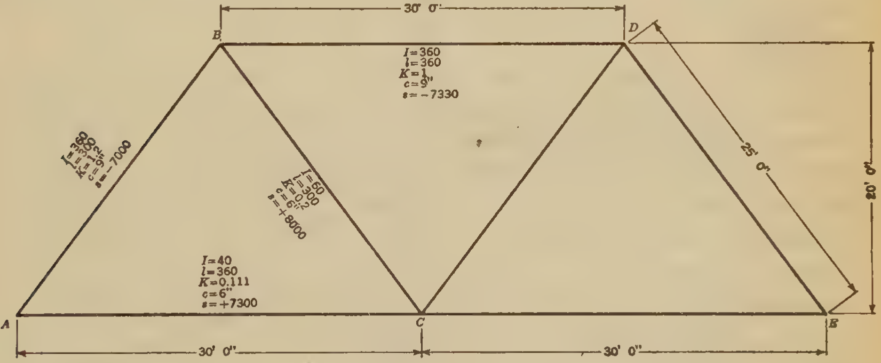

FIG. 61

The fixed-end moments are entered in the table (Item 2), under the proper member and are added across algebraically for each joint, in order to obtain the unbalanced moment. This unbalanced moment is balanced at each joint (Item 3). Each member will get the percentage shown at the top of the table (Item 1). These "balancing" moments are then distributed on the following line, one-half the "balancing" moment at one end of a member being the "distributing" moment at the other end. In making up Table 19 it should be noted that a member (for example, the end-post, *AB*) is identified as *AB* under Joint *A* and as *BA* under Joint *B*. The "distributing" moments (Item 4) are added across to obtain a new unbalanced moment, and one cycle is finished. As the work proceeds, every box in the table is filled, except those with the dotted lines, or better still, diagonal lines. This system eliminates as far as possible the chances of making an error by omitting a part of a step, and it also enables the work to be checked easily. The final moment in the members is obtained by adding each column of moments algebraically (Item 13).

---

[70] Designer, State Highway Comm., Augusta, Me.

[71] "Steel Mill Buildings," by Milo S. Ketchum, M. Am. Soc. C. E., p. 309.

The following secondary stresses were obtained which are, of course, very close to the results shown in the original problem: $BA = -630$; $CA = +1\,780$; $CB = +826$; and $BD = -700$.

In teaching work the writer found that undergraduate as well as graduate students readily grasped the Cross method and obtained a much clearer conception of the action of undeterminate structures as they followed through this method, than is possible by the more or less blind application of formulas. Students are appreciative, of course, of the ease of its application, particularly after using some of the more formal methods. Once the Cross method is grasped, it can be called to mind after only a few minutes' thought without any reference to notes or complicated formulas.

George M. Dillingham,[72] Assoc. M. Am. Soc. C. E. (by letter).—For the analysis of continuous frames subjected to changes in loading, the method developed by Professor Cross is made readily applicable by the following steps:

(1) Determine the structural properties for a given frame; that is, dimensions; conditions of end restraint; the values of I, K, and the "carry-over" factors of the members, etc.

(2) Apply a "trial fixed-end moment" at the end of a member, either positive or negative, and of any convenient magnitude and unit.

(3) Distribute this "trial fixed-end moment" throughout the frame by the author's method, and tabulate the "trial final moment" thus induced for each end of all members.

(4) In like manner apply, in turn, "trial fixed-end moments" at the other end of the member mentioned in Step (2), and at each end of all other members; and tabulate for each application the corresponding "trial final moments."

(5) Determine all the "actual fixed-end moments" induced by following Step (3) for a specific loading.

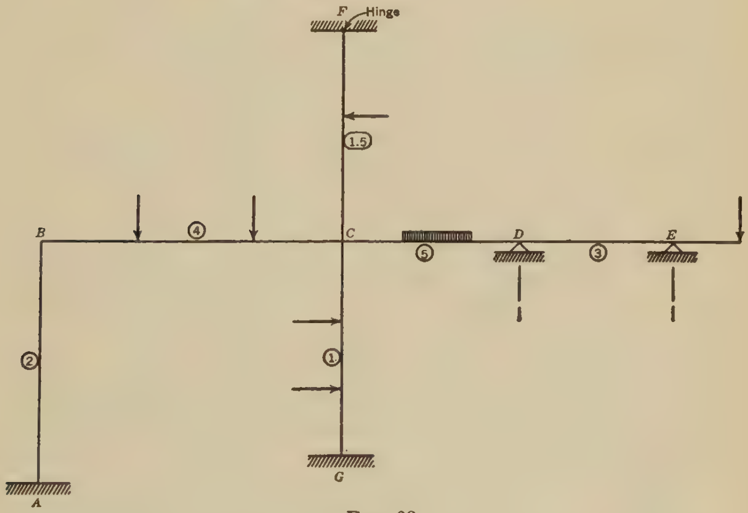

Fig. 62

(6) Determine the "actual final moments" for the given loading by the use of the following proportion:

$$\frac{\text{Actual final moment}}{\text{Actual fixed-end moment}} = \frac{\text{Trial final moment}}{\text{Trial fixed-end moment}}$$

Tabulate the final moments caused by each of the several actual fixed-end moments; add these algebraically for the end of each member, and record the total final moment.

(7) Change the loading, and repeat Steps (5) and (6).

---

[72] Evanston, Ill.

Example.—In demonstration of Steps (1) to (7) the structure shown in Fig. 62 is analyzed herewith. The signs of moments are determined by the convention which designates, as positive, clockwise rotation at a joint due to externally applied forces.

Step (1): For greater ease in distributing the fixed-end moments, the *K* of the member, *CF*, is reduced from 2.0 to 1.5; the fixed-end moment at *F* is eliminated; and the fixed-end moment at *C* in *CF* is changed from −80 to −110 (see Fig. 62). These changes are made possible by the absence of restraint at the hinge, *F*. In all other respects, the data given by the author are used unchanged.

Steps (2), (3), and (4): In Table 20, Items 1 to 19 show the final moment induced at each end of each member by the trial fixed-end moment of −1 000.0, which is applied successively at Joints *B*, *C*, and *D*, as indicated. In preparing Table 20, the trial moment was applied to *AB* at *B*, to *CB* at *C*, and to *CD* at *D*; and the distribution process was carried out in the usual manner for each of these applications. From the results of these three applications, the values of the final moments for the other locations of the trial fixed-end moment were written by inspection.

Step (5): See Step (1).

Step (6): In Table 20, Items 20 to 29 show the final moments induced at each end of each member by the actual fixed-end moments given in Fig. 62.

The similarity of the general procedure described in this example to influence line diagram construction is easily recognized. Having once performed Steps (2), (3), and (4), loading changes may be made as desired, and final moments for each loading determined quickly and with a minimum of effort.

The distribution of Step (3) may be performed either by the method given in the paper under discussion, or by the method (termed the "Exact Method") described by Professor Cross in his paper[73] entitled "Continuity as a Factor in Reinforced Concrete Design."

DONALD E. LARSON,[74] JUN. AM. SOC. C. E. (by letter).—In presenting the method of moment distribution, Professor Cross has barely hinted at the possibilities of the more general method of moment and force distribution which includes the distribution of unbalanced joint forces as well as moments. This general method must be used in analyzing structures in which the joints are subject to linear displacement as well as rotation. A continuous series of arches supported on long slender piers is a structure of this type. Loads applied to the arches produce both rotation and horizontal translation of the joints. For this reason, the processes of moment distribution and force distribution cannot be carried out independently of each other. When the moments at a joint are balanced, the horizontal forces at the ends of the members intersecting at that joint are changed and must be adjusted accordingly. In the same way, the moments at the ends of these members must be adjusted when the horizontal forces at the joint are balanced.

---

[73] *Proceedings*, Am. Concrete Inst., 1929, p. 689.

[74] With Chicago Bridge & Iron Works, Chicago, Ill.

After considerable experimenting, the writer has worked out a fairly convenient procedure for analyzing multiple-span arches by distributing fixed-end horizontal forces and fixed-end moments. The method has several desirable features even if it is complicated to a certain extent by the adjustments previously mentioned. An outline of the procedure follows.

Step 1.—

(*a*) Compute the fixed-end horizontal forces at the ends of each arch, due to loads on the arch.

(*b*) Compute the fixed-end moments at the ends of each arch, resulting from loads on the arch.

Step 2.—

(*a*) Distribute the unbalanced horizontal force at each joint among the connecting members in proportion to their resistance to horizontal deflection. The percentage of the unbalanced force distributed to each member is equal to $\frac{J}{\Sigma J}$, in which, J is the horizontal force required to deflect the near end of the member one unit when applied along the centroidal axis of the member, the far end of the member being fixed.

(*b*) Distribute the unbalanced moment at each joint among the connecting members in proportion to their resistance to rotation. The percentage distributed to each member is equal to $\frac{N}{\Sigma N}$, in which, N is the moment required to rotate the near end of the member one unit when the far end is fixed.

Step 3.—

(*a*) The horizontal force distributed to each member in Step 2 (*a*) is carried over to the opposite end of the member with opposite sign. This is to keep the member in static equilibrium.

(*b*) A certain proportion, r, of the moment distributed to each member in Step 2 (*b*) is carried over to the far end of the member. This "carry-over factor," r, is the same as the one defined by the author. It may be either positive or negative, depending upon the geometric properties of the member.

Step 4.—

(*a*) Compute the horizontal thrust at the end of each member produced by the moments distributed to that member in Step 2 (*b*). These thrusts are equal to the product of this moment by h, in which, h is the horizontal force produced by a unit moment applied to one end of the member.

(*b*) Compute the moments at the ends of each member produced by the horizontal force distributed to that member in Step 2 (*a*). These moments are equal to the product of the force by d, in which, d is the vertical distance from the joint to the elastic center of the member.

Step 5.—

(*a*) The horizontal forces obtained in Step 3 (*a*) and Step 4 (*a*) are added algebraically.

(*b*) The moments obtained in Step 3 (*b*) and Step 4 (*b*) are added in the same manner.

These steps form a complete cycle in the process of moment and force distribution. Step 5 (*a*) gives a new set of horizontal forces at each joint. The resulting unbalanced force is again distributed, as in Step 2 (*a*). Step 5 (*b*) gives a new set of moments at each joint and the unbalanced moment is again distributed as in Step 2 (*b*). The foregoing procedure is then repeated as many times as required to produce results of the desired accuracy.

Formulas for Constants.—The constants defined in Steps 1 to 5, inclusive, may be computed by the relations given in Equations (126) to (134). The derivation of these relations is based upon the assumptions: First, that plane sections remain plane; and, second, that the material obeys Hooke's law. The subscript, *a*, is used to indicate that the constant applies to an arch, and the subscript, *p*, to indicate that the constant applies to a pier.

Constants for arches are expressed by the following equations:

$$d_a = \frac{\sum y \frac{ds}{I}}{\sum \frac{ds}{I}} \dots\dots\dots\dots (126)$$

$$J_a = \frac{1}{\sum y^2 \frac{ds}{I} - d^2_a \sum \frac{ds}{I}} \dots\dots\dots\dots (127)$$

$$N_a = \frac{1}{\sum \frac{ds}{I}} + \frac{L^2}{4 \sum x^2 \frac{ds}{I}} + d^2_a J_a \dots\dots\dots\dots (128)$$

$$r_a = 1 - \frac{L^2}{2 N_a \sum x^2 \frac{ds}{I}} \dots\dots\dots\dots (129)$$

and,

$$h_a = \frac{d_a J_a}{N_a} \dots\dots\dots\dots (130)$$

Constants for piers are:

$$d_p = \frac{\sum y \frac{ds}{I}}{\sum \frac{ds}{I}} \dots\dots\dots\dots (131)$$

$$J_p = \frac{1}{\sum y^2 \frac{ds}{I} - d^2_p \sum \frac{ds}{I}} \dots\dots\dots\dots (132)$$

$$N_p = \frac{1}{\sum \frac{ds}{I}} + d^2_p J_p \dots\dots\dots\dots (133)$$

and,

$$h_p = \frac{d_p J_p}{N_p} \dots\dots\dots\dots (134)$$

The factor, r_p, corresponding to r_a in Equation (129) is not required when piers are fixed at the base. The geometric properties which are needed for computing the arch constants are shown in Fig. 63. The properties used in computing constants for the piers are shown in Fig. 64.

Signs.—The convention of signs adopted by the writer is similar to that introduced by the author; that is, positive moment in the arches corresponds to compression at the extrados; positive moment in the piers corresponds to compression on the left side of the pier; horizontal forces acting inward on the end of the arch are positive; and a force acting to the right on the top of the pier is positive. In balancing moments and horizontal forces at the joint, the pier is considered to be on the same side of the joint as the arch at the left. A positive moment applied to an arch or a pier produces a positive horizontal force; and a positive horizontal force applied to an arch or pier produces a positive moment. The directions of positive moments and forces are indicated by arrows in Fig. 63 and Fig. 64. The constants, except *r*, are always positive when used with the foregoing convention of signs.

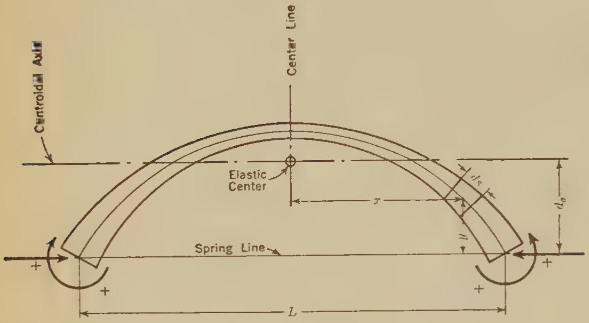

FIG. 63

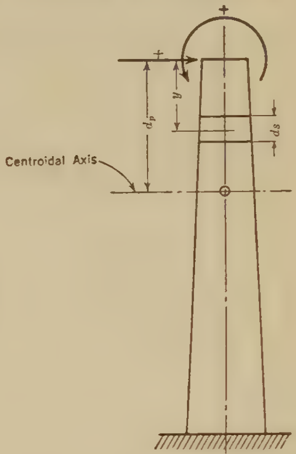

FIG. 64

Illustrative Example.—The analysis of a three-span arch by the method outlined, is illustrated in Fig. 65. For the sake of simplicity, a structure with arches all alike and piers of the same height has been chosen. The ends of the outer arches and the bases of the piers are fixed. The problem is to determine the moments and horizontal forces at the ends of the arches and piers.

Since the only purpose of the problem is to illustrate the method used in distributing the fixed-end moments and forces, the actual dimensions of the arches and piers are not given. The constants required for the analysis are: For arches, $d_a = 39.7$; $J_a = 0.00111$; $N_a = 2.53$; $r_a = +0.491$; and $h_a = 0.0175$; and for piers, $d_p = 47.5$; $J_p = 0.00643$; $N_p = 21.60$; and $h_p = 0.0141$. These constants represent a continuous arch series supported by piers which are relatively long and slender.

FIG. 65.—COMPUTATIONS FOR A CONTINUOUS SERIES OF ARCHES SUPPORTED ON LONG SLENDER PIERS.

The table or form used in distributing the fixed-end horizontal forces and moments really consists of two parts, the one on the left being for horizontal forces and the one on the right for moments. The fixed-end forces and moments due to the load, P, in Span CD, are written in the top line (Steps 1(a) and 1(b)).

The unbalanced horizontal force, 65.5, at Joint C, is distributed as follows: The proportion to each arch $= \frac{J_a}{2\,J_a + J_p} = 0.128$; and the proportion to the pier $= \frac{J_p}{2\,J_a + J_p} = 0.744$. Using these distributing factors, a force of 8.4 goes to each arch and a force of 48.7 to the pier. Arrows have been used instead of plus and minus signs for indicating the direction of the forces.

The unbalanced moment, $-$ 1 440, at Joint C, is distributed in the following manner: The proportion to each arch $= \frac{N_a}{2\,N_a + N_p} = 0.095$; and the proportion to the pier $= \frac{N_p}{2\,N_a + N_p} = 0.810$. From these factors, a moment of 137 goes to each arch and a moment of 1 166 to the pier. The signs are those required to balance the joint.

The remainder of the analysis is carried out as described under Steps 1 to 5 and the steps in Fig. 65 are numbered accordingly in order to facilitate reference to the outline. In distributing forces and moments to the piers, Steps 3 and 5 are not required, as the piers are fixed at the base.

When the distribution has been carried out to the desired degree of accuracy, the forces and moments at the ends of the arches and tops of the piers are obtained by adding the values indicated in Fig. 65. Knowing these, the stresses at any point can be determined by applying the laws of statics.

Value and Limitations of Method.—Three statements can be made as to the value and limitations of the foregoing method:

(1) As outlined it applies only to structures made up entirely of symmetrical arches.

(2) When the piers are relatively long and flexible, a number of distributions are required to obtain accurate results. Such piers are uncommon in the United States. When the method is used for the analysis of a multiple-span arch with the usual sturdy piers, several distributions will be sufficient and accurate results are quickly obtained.

(3) The greatest merit of this method lies in the ease with which the signs of all moments and forces may be visualized. Each step of the analysis has a definite physical meaning and the signs can be written by inspection, thus avoiding the mistakes in signs which are so inevitable in all methods which require the solution of simultaneous equations.

The procedure which has been described may be varied in a number of ways. The intent of the discussion has been to illustrate one way in which the general method of moment and force distribution may be applied to the analysis of multiple-span arches, or similar structures. The steps outlined need not be considered as a "hard- and-fast" set of rules which must always be applied in the exact order described. The idea of using arrows instead of plus and minus signs to indicate the direction of the horizontal forces was suggested to the writer by Professor Cross, and experience has proved this to be a valuable expedient as it decreases the probability of errors in the signs.

J. A. VAN DEN BROEK,[75] ASSOC. M. AM. SOC. C. E. (by letter).—Possibly the greatest single contribution to the theory of stress analysis of redundant structures in a generation is that presented by Professor Cross in this paper. Engineers have long been aware of the fact that the influence of a load on a support, several spans removed from the load, is negligible; yet, they have not found a legitimate way by which to avoid the cumbersome process of writing as many simultaneous equations as there are unknowns before attempting a solution. In a large number of problems commonly encountered, Professor Cross' method overcomes this objection. It appears to have been known and used for a number of years. When the subject was first called to the writer's attention, his immediate reaction was highly favorable. How simple! A veritable Columbus' egg! Upon closer study this first enthusiastic appreciation has grown rather than diminished.

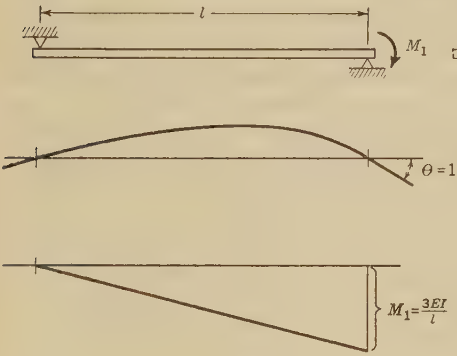

FIG. 66

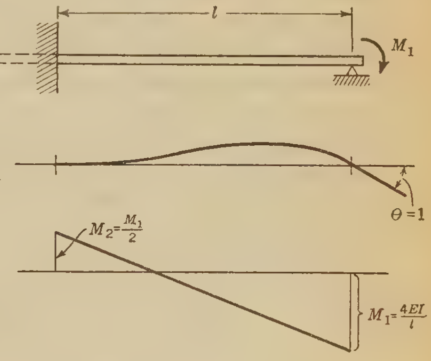

FIG. 67

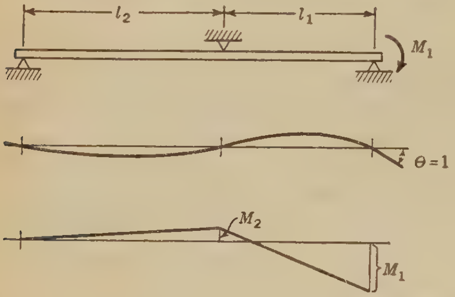
Starting from the same premise, several variations in the detailed application of the method appear possible. In presenting one such variation on the same theme, which might possibly also be regarded as a variation on the slope-deflection theme, the writer is motivated solely by the thought that, because of the great importance he ascribes to the subject, the consideration of any modification in emphasis or point of view appears justified at this stage.

The basic principle in Professor Cross' method appears to be that first all joints are considered locked, and then released one joint at a time. As each joint is released all other joints are assumed as being locked. Each time a joint is unlocked the structure will deform toward the shape it will ultimately assume in its natural state. If all joints are successively unlocked and locked in turn, an infinite number of times, the structure will approach its final natural shape. Professor Cross appears to assume that this final shape will be approximated very closely after only two or three operations of locking and unlocking the joints. This premise appears reasonable. It is not certain, however, that in exceptional cases this convergence will be achieved. A rigorous proof of the aforementioned premise, would be of much value at this stage.

---

[75] **Prof. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.**



$$\frac{E_1 I_1}{l_1} = k_1$$

$$\frac{E_2 I_2}{l_2} = k_2$$

$$M_1 = \frac{12(k_1 k_2 + k_1^2)}{4k_1 + 3k_2}$$

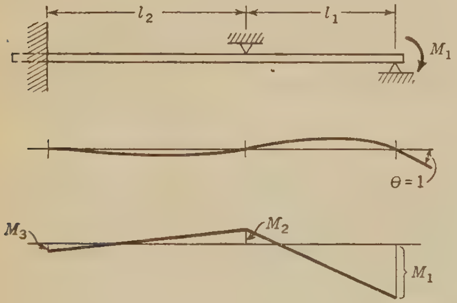
$$M_2 = \frac{k_2 M_1}{2(k_1 + k_2)}$$

When $k_1 = k_2$ then $M_1 = \frac{24EI}{7l}$; $M_2 = \frac{M_1}{4}$

FIG. 68

Instead of conceiving joints successively locked and unlocked, one might conceive all joints except the pin joints as locked. Then proceed to unlock each joint, except those that are fixed, or built in. Note that in this method of approach the pin joints are never considered as locked and the built-in joints are never considered as unlocked. Furthermore, once any of the other joints are unlocked they are never to be considered as locked again.

Figs. 66 to 71 are to be regarded as a set of key diagrams to be used in connection with this method of analysis. In each case let M_1, the stiffness factor, represent the moment necessary to produce unit angular displacement. The elastic coefficient for any member is expressed by $k = \dfrac{EI}{l}$.



$$M_1 = \frac{4k_1 k_2 + 3k_1^2}{k_1 + k_2}$$

$$M_2 = \frac{2k_2 M_1}{3k_1 + 4k_2}$$

$$M_3 = \frac{M_2}{2}$$

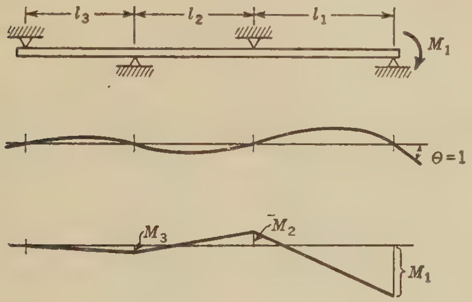
When $k_1 = k_2$ then $M_1 = \frac{7EI}{2l}$;

$$M_2 = \frac{2}{7} M_1$$

FIG. 69

Let Fig. 72 represent a continuous beam of five equal spans, with E and I constant. The left end, Joint A, is fixed; the right end, Joint F, is freely supported. The first three spans and the last span are loaded with a uniformly distributed load, w lb. per ft. The fourth span is unloaded.

The first line represents the moments at the respective joints, with all joints except Joint F locked. The fixed-end moment, $\frac{wl^2}{12}$, at Joints A, B, C, and D, is represented by 100, while $\frac{wl^2}{8}$ at Joint E is represented by 150. The second line represents the effect of unlocking Joints B and C. Since there are no unbalanced moments at these points, no elastic deformations will take place when these joints are unlocked. Next, consider unlocking Joint E, keeping in mind that Joint D is still considered as locked. Fig. 66 provides the key for the stiffness factor of Span EF, while Fig. 67 provides the key for the stiffness factor of Span ED. Let M_1 in each case represent the moment necessary to produce unit angular displacement. Since, in this example, E, I, and l, are assumed equal for all spans, the stiffness factors for Spans EF and ED are in the ratio of 3 to 4. The total moment to be supplied at E, when the joint is unlocked, is (-150). The right end of the beam, DE, supplies $\frac{4}{7} \times (-150) = -85.72$, while the left end of the beam, EF, supplies $\frac{3}{7} \times (-150) = -64.28$. This increment of moment (-64.28) at the left end of EF produces no moment effect at the point, F, which was from the start a pin-connected joint. The moment, -85.72,



$$k_1=\frac{E_1I_1}{l_1};\quad k_2=\frac{E_2I_2}{l_2};\quad k_3=\frac{E_3I_3}{l_3}$$

$$M_1=\frac{3k_1(4k_1k_2+4k_2k_3+4k_2^2+3k_1k_3)}{3k_2^2+4k_1k_2+3k_2k_3+3k_1k_3}$$

$$M_2=\frac{2k_2(k_2+k_3)M_1}{4k_1k_2+4k_2k_3+4k_2^2+3k_1k_3}$$

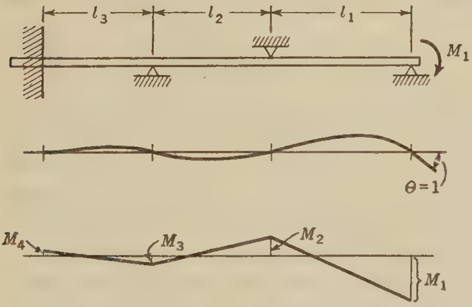
$$M_3=\frac{k_3M_2}{2(k_2+k_3)}$$

When $k_1=k_2=k_3$ then $M_1=\frac{45EI}{13l}$;

$M_2=\frac{4}{15}M_1$;

$M_3=\frac{M_1}{15}$

FIG. 70



$$M_1=\frac{4k_1(3k_2^2+4k_2k_3+3k_1k_2+3k_1k_3)}{3k_2^2+4k_2k_3+4k_1k_2+4k_1k_3}$$

$$M_2=\frac{k_2(3k_2+4k_3)M_1}{2(3k_2^2+4k_2k_3+3k_1k_2+3k_1k_3)}$$

$$M_3=\frac{2k_3}{3k_2+4k_3}M_2$$

$$M_4=\frac{M_3}{2}$$

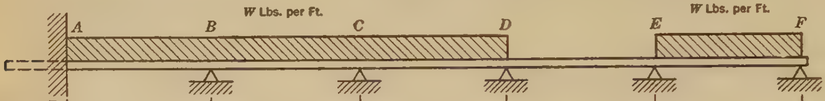
When $k_1=k_2=k_3$ then $M_1=\frac{52EI}{15l}$; $M_2=\frac{7}{26}M_1$;

$M_3=\frac{2}{26}M_1$; $M_4=\frac{1}{26}M_1$

FIG. 71

at the right end of *DE,* induces a moment of $\frac{1}{2} \times (-85.72) = -42.86$ at *D.* These values, induced by the unlocking of Joint *E,* are recorded on Line 3, Fig. 72.

The only joint that remains to be unlocked is the joint, *D.* The stiffness factors for the right and left parts of the structure are taken from Fig. 68 and Fig. 71. In this case, in which the values of $k = \frac{EI}{l}$ for all spans are equal, the respective stiffness factors for *DF* and *DA* are $\frac{24}{7}$ and $\frac{52}{15}$, or 3.428 and 3.467. As Joint *D* is unlocked, a total balancing moment of + 142.86 is to be supplied. The left end of *DF* supplies $\frac{3.428}{3.428 + 3.467} \times (+142.86) = +71.025$, while the right end of *AD* supplies 71.84. These values are recorded under *D* on the fourth line of Fig. 72.



All Joints except *F,* are Locked	+100	-100	+100	-100	+100	-100	0	0	+150	0
Unlock *B* and *C*		0	0	0	0					
Unlock *E*							-42.86	-85.72	-64.28	0
Unlock *D*	+2.76	+5.52	-5.52	-19.34	+19.34	+71.84	+71.02	+17.75	-17.75	0
Resultant Moments at All Joints	102.76	94.48		119.34		18.16		67.97		0

FIG. 72

The effect of change in the moment at Joint *D* on the other joints can be obtained directly from Figs. 68 and 71. Thus, $\frac{7}{26} \times 71.84 = 19.34$ is the effect on *C* of the 71.84-moment change at *D.* The effect on Joint *E* of the moment change of 71.02 at Joint *D* is obtained from Fig. 68. This amounts to $\frac{1}{4} \times 71.02 = 17.75$. The final moments are obtained by adding the values under each joint. The answers in this case involve no approximation other than that involved in the number of significant figures to which the computations are carried. Theoretically, one may provide oneself with any number of key diagrams. It is thought that the six key diagrams offered herewith (Figs. 66 to 71) are sufficient for most practical problems. Fig. 71 shows that for a beam of three equal spans, $M_4 = \frac{1}{26} M_1$. This suggests that the moment change need not be distributed much beyond three spans, if at all. Approximation occurs only when one ignores the effect of a moment change at some joint on another joint so far removed that a key diagram is not available, or when the one available is not used because it is known that the effect involved is negligible.

Consider Fig. 73: Assume Joint *E* as locked, and let M_{EC} be represented by + 100, and M_{CE} by − 100; let $M_{ED} = +60$; $M_{DE} = -60$; and

$M_{EA} = M_{AE} = M_{EB} = M_{BE} = 0$. If $k_1 = k_2 = k_3 = k_4$, then, as the unbalanced moment at E is $+ 160$, each member supplies an equal balancing moment, which is $\frac{-160}{4} = -40$. The key diagram (Fig. 67) applies to all four legs. Thus, one-half the balancing moments is carried along each member to its extremity. The answers, then, are: $M_A = -20$; $M_B = -20$; $M_C = -100 - 20 = -120$; $M_{DE} = -60 - 20 = -80$; $M_{EC} = +100 - 40 = +60$; $M_{ED} = +60 - 40 = +20$; $M_{EA} = -40$; and $M_{EB} = -40$.

Suppose k_1, k_2, k_3, and k_4 are in the ratio, 1:2:3:4; they, as Joint E, Fig. 73, is unlocked, $M_{EA} = \frac{1}{10} \times (-160) = -16$; $M_{AE} = \frac{1}{2} \times (-16) = -8$; $M_{EB} = \frac{2}{10} \times (-160) = -32$; and $M_{EC} = +100 + \frac{3}{10} \times (-160) = +52$.

Suppose Joint C in Fig. 73, is pin-connected, and $k_1 = k_2 = k_3 = k_4$. With the same loading as shown, when Joint E is assumed to be locked, while Joint C is pin-connected, $M_{EC} = +150$. The unbalanced moment at Joint E then is $+150 + 60 = +210$. The stiffness factor for EC now is $\frac{3EI}{l}$, while, for the other three legs, it is $\frac{4EI}{l}$. The ratio, therefore, is 3 to 4. As Joint E is now unlocked, $M_{EA} = \frac{4}{15} \times -210 = -56$; $M_{AE} = -28$; $M_{EC} = +150 + \frac{3}{15}(-210) = +108$; $M_{CE} = 0$; $M_{ED} = +60 + \frac{4}{15}(-210) = +4$; and $M_{DE} = -60 + \frac{1}{2} \times \frac{4}{15} \times (-210) = -88$.

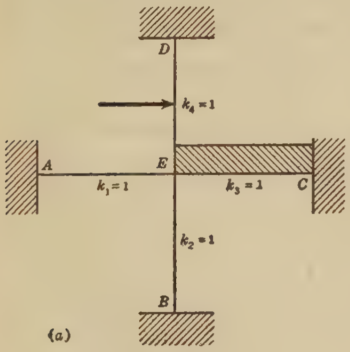


FIG. 73

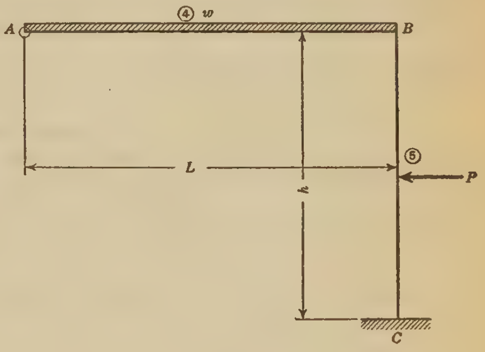

FIG. 74.

The writer's engineering vocabulary does not include the much-loved word "exact"; otherwise, he would feel like applying this adjective to the answers given in the foregoing example. He has little objection to approximations, and certainly no objection thereto worth mentioning in design problems in which the number, 2, is as low as designers dare go in selecting a factor of safety. Professor Cross suggests that two approximations are generally sufficient. However, in his Table 1, it appears that the increment between the third and fourth approximation is greater than that between the second and third. If there is reason to carry on to three approximations, the same reason would then compel one to continue to at least four approximations.

The writer does not want to take space to work Professor Cross' example by the method he has herewith suggested. Joints *B, D, E,* and *F,* of Professor Cross' Fig. 1, might be unlocked successively. The stiffness factor of *CBA* may be taken from Fig. 69. Fig. 66 gives the stiffness factor for *CF;* Fig. 67 gives the stiffness factor for *CG;* while Fig. 68 gives the stiffness factor for *CDE.* After Point *C* is balanced, the carried-over moments for *B* and *A* may be taken from Fig. 69, while that for *D* is taken from Fig. 68. The factor carried over to *F* is zero, while the factor carried over to *G* is taken from Fig. 67. This procedure completes the entire solution. The results thus obtained check the values given by Professor Cross.

One more example might be given. In the L-frame, Fig. 74, the horizontal leg, *AB,* pinned at *A,* is 25 ft. long, and is loaded with 1 000 lb. per ft. (see, also, Fig. 5). Considering Joint *B* as fixed, its fixed-end moment, M_{BA}, would be: $\frac{w l^2}{8} = \frac{1\,000 \times 25^2}{8} = -78\,125$ ft-lb.. The vertical leg, *BC,* fixed at *C,* and 20 ft. high, is loaded with a concentrated load of 20 000 lb. at its center. The fixed-end moment, $M_{BC} = \frac{P h}{8} = \frac{20\,000 \times 20}{8} = 50\,000$ ft-lb. The unbalanced moment at *C* is $-28\,125$ ft-lb. The elastic coefficient, $\frac{I}{l}$, for *BA* is 4, while for *BC* it is 5. The stiffness factor for *BA* from Fig. 66 is $\frac{3\,E I}{l} = 3 \times 4\,E = 12\,E$, while that for *BC* from Fig. 67 is $\frac{4\,E I}{l} = 4 \times 5 \times E = 20\,E$. As the joint is unlocked, the unbalanced moment distributes itself between *BA* and *BC* in the ratio of 12 to 20.

The final moment, $M_{BA} = -78\,125 + \frac{12}{32} \times 28\,125 = -67\,578$ ft-lb. The final moment, $M_{BC} = +50\,000 + \frac{20}{32} \times 28\,125 \triangleq +67\,578$ ft-lb. which compares with the value of 67 360 ft-lb. as determined by the more formal procedure. Once familiar with this method, one obtains in round figures the answer to a problem as simple as the foregoing without putting a figure on paper.

HARDY CROSS,[76] M. AM. SOC. C. E. (by letter).—The writer is indebted to those who have been kind enough to discuss the paper and have added so much to its value by illustrating the application of the principle involved.

Mr. Pilkey thinks the paper too brief. Pascal[77] is quoted as apologizing to a correspondent for writing a long letter on the ground that he did not have time to write a short one. The writer took time to make the paper short; as he looks at the mass of technical literature on his desk, he sincerely hopes the idea becomes popular. He thought best to confine the paper strictly to the fundamental principle and method involved, and not digress into the unlimited variations of this method or the unlimited applications of it. Secondary stresses, wind stresses, Vierendeel girders, continuous arches on elastic piers are special problems; while the elementary procedure is applicable to them, certain modifications are advantageous. The writer has indicated subsequently some of these modifications, but he has not felt justified in elaborating them in this closure.

---

[76] Prof., Structural Eng., Univ. of Illinois, Urbana, Ill.

[77] "Provincial Letters," December 14, 1656.

Questions raised in some of the discussions have been clearly answered in others. The questions of Mr. Lyman have been answered in detail by Professors Martel, Morris, and Witmer, and Messrs. Pilkey, Black, Wessman, and Wilson. The limitations of the method suggested by Mr. Nielsen have also been discussed by others.

Mr. Oesterblom's discussion is interesting and valuable, especially his explanation of the fundamental simplicity of Maxwell's method and of the difficulties which arise in applying it.

The discussions of Professor Shedd and Mr. Oliver call for little special comment. The writer appreciates them and heartily concurs in Professor Shedd's remarks with regard to formulas.

With the discussion of Mr. Vetter the writer differs in practically every statement. Mr. Vetter seems to have some serious objection to the method, but he does not make it clear. His interest in the vertical reactions at F and G is entirely academic. Of course, the total vertical reaction at C may be found by statics. This reaction is distributed between CF and CG in proportion to the "vertical stiffness" of these paths if "vertical stiffness" is defined as the vertical force at C along either path necessary to produce unit vertical deflection at C. Presumably it all goes to CG, unless CF is a "sky-hook." If the members are of constant section and immovable at G and F, the vertical stiffness is $\frac{A\,E}{L}$, and it should involve no difficulties if the section varies.

The effect of shearing distortions is not involved in the problem of the distribution of the total vertical reaction at C between the points, F and G. In the paper the writer makes no assumption at all as to the effect of shearing distortions; if they are taken into account, the fixed-end moments, the stiffness values, and the carry-over factors are different from those used if these distortions are neglected. Of course they should be neglected except perhaps in the most unusual cases. In the rare cases in which their effect in beams should be included, one should be guarded in accepting the conventional mechanics of internal stress in beams.

Whether longitudinal distortions shall be neglected depends on circumstances. It is a simple matter to correct for the effect of shearing and of longitudinal distortions by the method indicated in the paper. After the end moments are found in the beams, one computes the shears and the longitudinal forces and from these the distortions produced. He then finds that the frame is distorted by these displacements so that discontinuities would exist. The fixed-end moments needed to eliminate such discontinuities are then applied and these moments distributed throughout the frame. Theoretically, the procedure should be repeated, but except in the most unusual case, one trial will show the complete futility of the computation.

Mr. Vetter thinks that the engineer should "hitch his wagon to a star." He would do better to keep his feet on the ground. The conception of "mathematical accuracy" of the man on the street is decidedly amateurish; what the engineer needs is to get an answer with the requisite degree of accuracy without a prohibitive amount of labor.

The idea held by Mr. Vetter, that in some way (which he does not make clear), the method of moment distribution is approximate and involves assumptions which the theory of least work and the method of slope deflection escape, shows a fundamental misconception of these methods. Any one who computes the moments in a frame of reinforced concrete will make many assumptions as to the properties of materials, conservation of plane sections, and other matters; E has no definite value and I has no definite meaning in the analysis of frames of reinforced concrete. This is true by whatever method the frame is analyzed. Whether the computer knows that such assumptions are made is quite another matter.

Mr. Vetter seems also to object to the writer's list of incidental problems involved and states that he could add a great many more, "which have just as much, and more, to do with the subject under discussion [moment distribution?]" That is excellent, or it would have been excellent had he done so; one of the things needed in connection with continuous frames is a clear recognition of the complications involved. Another need is for a simple method of studying the effect of such complications; moment distribution is such a method. The three samples of complications furnished by Mr. Vetter are not of the type listed by the writer. Change in length of members due to shrinkage and to change of temperature and the settlement of supports are clearly recognized phenomena, the effect of which, for given data, are easily evaluated by moment distribution exactly as indicated in the text, thus:

> "Imagine any joint in a structure, the members of which are being deformed by loads, or in some other way, to be first held against rotation and then released."

The method is not restricted to analysis for loads on the structure.

Mr. Eremin thinks that,

> "In the limitations of his method, the author omitted to state that the modulus of elasticity of materials was considered to be constant for all members of the frame and also that the lateral rigidity of the members of a continuous frame is sufficient to prevent buckling."

The writer thinks that the first statement is in error. One does not necessarily assume either that E is constant for all members or from section to section in any one member or over any one cross-section of the member. It is merely necessary to have an accurate stress-strain diagram for the material.

If it is first assumed that E is constant and all stresses are computed on this basis, the fixed-end moments, stiffness values, and carry-over factors may then be revised for the values of E indicated by these stresses. The operation may be repeated to any degree of precision. The problem is evidently one for research, not for the office. The writer has studied it in relation to the effect of chance variation of the modulus of elasticity,[78] the effect of plastic flow and time yield in concrete, and the effect of secondary stresses beyond the elastic limit of steel. The common assumption of constant E is a matter of convenience and is not a limitation of method.

The statement that the method is restricted by the assumption that the members do not buckle seems to the writer to mean that the method will give the moment in a member if the member is still there—if it has not failed. This is correct.

Mr. Mitra deplores the fact that the method does not lead to any general equation. Since the avoidance of such general equations was the object of the paper, the writer is pleased by the comment. That the method of slope deflection and the graphical method of conjugate points are more accurate is not true; that these methods are quicker and easier to use is opposed to the experience of hundreds of engineers in the United States.

Professor Hickerson evidently does not like the paper at all, even though he "commends the author." Consequently, he introduces the subject of "Tabular Coefficients." Of course, it is better to use the answer previously determined for a problem than it is to re-work the problem, provided one is sure that the answer is correct and provided the answer is easily found. The trouble with tabular coefficients is that one cannot be sure, unless he checks them, that they are correct, however distinguished their author, and that the one using them may not agree with the basis on which they are computed. Unfortunately, few published tables explain clearly the basis on which they are prepared. Even so careful a scholar as Professor Hickerson fails to state whether the negative moments which he has computed are at the face of the support or at the center, and what allowance, if any, he has made for the increased flexural resistance of the members between the faces of any support.

Professor Hickerson gives a coefficient for an arch frame uniformly loaded between columns. He then states that "if the entire load is concentrated at the central ridge, * * * the foregoing values would be multiplied by $\frac{3}{2}$." This is not quite correct either here or in general. In this case it is nearly true but any one using the tables must determine for himself when it ceases to be approximately true. Thus, any one using the tabular coefficients will still need a method of analysis.

Mr. Floris thinks that the idea of using fixed-end moments in the analysis of a continuous frame is not new. Of course it is not, but Mr. Floris has gone far afield for his references. Fixed-end moments have been used in slope deflection in this country for years and apparently by Manderla before that and probably by others before Manderla. Mr. Floris, moreover, has overlooked the paper presented by Professor W. M. Wilson at the World Engineering Congress at Tokyo. The book in Japanese is not available to the writer and would do him little good if it were. The method of the late Professor Ostenfeld referred to by Mr. Bednarski and by Mr. Floris is apparently an extension of slope deflection along the lines indicated by the writer in his monograph on the column analogy.[79] The presentation by Mr. Bednarski is, unfortunately, not very attractive. The writer fails to find anything like the method of the paper in Hartmann's "Statisch Unbestimmte Systeme."

---

[78] "Dependability of the Theory of Concrete Arches," *Bulletin 203*, Eng. Experiment Station, Univ. of Illinois.

Two conventions of sign are possible for moments at the ends of the members of a frame. The convention of rotation for statical moments is indicated where rotations are involved in the solution and, therefore, is used in the method of slope deflection. The alternative convention is for bending moments. Where a structure is to be designed from the moments found by the analysis the writer still feels that it is best to adopt throughout the analysis the convention commonly used in design. Several who have preferred the convention of rotation have used it in connection with problems of wind stress or of secondary stress. In such problems the writer also prefers the convention of clockwise rotation, for with wind stresses and secondary stresses it usually makes no difference which side of a member is in tension. The object of analyses for secondary stresses is to determine whether they are too high, not to use them in design; the wind may blow in either direction. In any case, one should consistently follow one method, as Mr. Gorman notes.

Some misunderstanding has appeared in the discussions and some misstatement has appeared elsewhere as to the restriction given in the paper for the method. The writer does not confine the method to frames in which the joints do not move, but merely states that these movements must take place in finite jumps so that "the joints do not move during the process of moment distribution." The method is applicable, without special complication, to all frames for any condition of loading, transverse as well as vertical, and for any condition of deformation, whether due to shrinkage, change of temperature, or settlement of support. Several discussions illustrate such applications.

The first part of the paper is restricted to structures in which the joints do not move. The writer explained that if such movement actually takes place, allowance may be made for it as indicated later in the paper. This procedure has been explained in considerable detail by several contributors. With regard to this movement of the joint (referred to in the paper as side-sway), four questions are important: (1) Can side-sway occur in the structure? (2) Does side-sway occur for those conditions of loading which control the design of the structure? (3) Is this side-sway a matter of importance in design and is an approximate solution sufficiently accurate? (4) How shall one determine the exact moments produced by this side-sway?

In most structures side-sway produced by vertical loads only is either impossible or improbable. Thus, the probability of the lateral movement of a floor of a building due to vertical loads is negligible. Even where the forces act transversely, side-sway of individual bents is commonly either prevented or checked. Analysis for the moments produced by crane loads in a mill-building bent are often incorrect. If the load produces side-sway of each individual bent, there would occur, as the load moves, so much lateral vibration as to impair, seriously, the usefulness and the durability of the structure; such movement must be prevented or checked by some system of bracing and the bent then is not free to sway sidewise. Similarly, the bent of an elevated railway is not free to sway because of vertical live loads, but is restrained by horizontal bracing of the girders which frame into or rest upon the bent. The writer has also seen solutions presented for stresses produced in lateral frames of bridges due to unsymmetrical loading of the floor-beams which neglected the restraint against relative movement of the planes of the top and bottom chords of the bridge offered by lateral bracing.

---

[79] "The Column Analogy," *Bulletin 215*, Eng. Experiment Station, Univ. of Illinois.

In those cases in which side-sway due to the vertical loads is possible, it is frequently most improbable. An unsymmetrical vertical load may indicate lateral movement of any one loaded bay in a building of reinforced concrete, but for such lateral movement to occur freely it would be necessary for the entire floor to be loaded in this same way; the probability is that lateral sway will not occur. Attention should be called to the fact that side-sway is often a mitigating influence tending to decrease the maximum stress in certain parts of the structure, especially in the more highly stressed column; the assumption of side-sway where it does not exist may be on the side of danger.

In those cases in which side-sway may occur, it is neither necessary nor desirable to take account of it for each condition of loading. It is more convenient to correct for it only for those combinations of loading which produce maximum controlling moments.

Side-sway is much like the effect of wind. If a frame is analyzed on the assumption that the joints do not move and movement of the joints will actually occur, it will be found that the sum of the shears in the columns is not equal to the known shear. Movement of the joints must then have been prevented by forces acting at these joints. These forces reversed in direction may then be treated as wind loads. Moments may then be found by some of the approximate methods of wind-stress analysis to determine how large are the stresses involved.

In many cases side-sway does not exist; in other cases, it is of no importance; in most of the remaining cases. it is sufficiently unimportant to justify the use of approximate methods of wind-stress analysis without hesitation. In the remaining cases in which it requires precise analysis an indirect method may be used.

"Assume any series of fixed-end moments in the legs such that all legs have the same deflection. * * * Distribute these fixed-end moments and find the total shear in the legs." Add these moments to those assuming no side-sway in such ratio that statics is satisfied. The subject has interested several contributors. The procedure may be by direct proportion as indicated by the writer in another paper,[80] and as shown by several discussers; it may be by finding first the effect of unit shear in one story at a time and combining the solutions by a method of successive convergence, as suggested by Professor Grinter; one may write a series of formal equations, as Professor Constant suggests; or one may use successive approximations to the true values, as indicated in detail by Professor Morris.

It does not seem to the writer that any one of these variations of technique has any general advantage; sometimes one and sometimes another is the more useful. Thus, in a single-story frame, it is undoubtedly more expeditious to find the effect by direct proportion, but in a high building the method used by Professor Morris offers some advantages.

Another variation of method saves time in analyses for wind stresses. The joints are not assumed to be fixed-ended, but it is assumed that all joints not fixed have the same rotation, the moments in the girders being proportional to their K values and the moments in the columns, due partly to rotation of the joints and partly to displacement of the floors, being those determined by the shears. If the ratio of girder moments to K values is chosen with discretion, all the joints may often be nearly balanced before any moments are distributed. In the columns in the first story an adjustment must be made for the fixation at the base.

Fig. 75 shows the revised computations for the building discussed by Professor Morris. Only one distribution and one shear adjustment have been made. The moments given by Wilson and Maney are also given on the diagram (in brackets, thus: [24.0]); it will be seen that the agreement for girder moments is much more satisfactory than in Professor Morris' solution. Too many conclusions should not be drawn from this case, however; the building is too regular to be taken as typical of those variations of framing arrangement which present, in modern design, the real problems of wind stress.

In Fig. 75, two devices have been used to simplify the procedure. In the first place certain moments proportional to K have been thrown arbitrarily into the girders so that, to begin with, all joints are nearly balanced. These represent the effect of equal rotations at all joints except the bases of the columns; this exception is provided for in the columns of the bottom story by use of the factor, $\frac{1}{C}$, discussed later.

In the second place, the analysis is abbreviated by writing only the moments carried over and making one distribution at the end of the procedure. The moments produced by each distribution which would need adjustment to balance the shears are evidently equal to three times the moment carried over in the columns in any story.

The solution is presented here as an interesting variation of the technique of moment distribution and not necessarily as a procedure recommended for the analysis of wind stresses in all cases.

FIG. 75

A valuable by-product in wind-stress analyses is the direct determination of deflections. Each addition of fixed-end moments in any column represents a relative deflection of the floors at the ends of that column equal to $\frac{Mh}{6\,EK}$, in which, M is the fixed-end moment at one end of the column. In the solution just given the total moment added in a column is due partly to rotation and partly to displacement. That due to rotation is $\left(\frac{K}{2}+\frac{K}{10}\right)=0.6\,K$ in columns above the first story. Hence,

$$\Delta=\left(\frac{M}{6K}+0.1\right)\frac{h}{E}$$

in stories above the first, in which, M is the total added moment at one end of the column. In the first story,

$$\Delta=\frac{Mh}{6\,EK}$$

in which, M is the total adjusting moment at one end, which is given separately. Thus, is the first story, in the wall column,

$$\Delta=12\ (27.7+3.2)\ \frac{h}{6\,EK}=0.0211\text{ in.}$$

In the second story, in the wall column,

$$\Delta=12\left[(14.3+4.8)\frac{1}{6K}+0.1\right]\frac{h}{E}=0.0146\text{ in.}$$

The frame analyzed by Mr. Nelidov offers an interesting illustration of the wide application of the method. The problem, however, is solved more readily by the column analogy, as are probably all cases of an arch or bent of one span. The method of moment distribution has the advantage, however, of raising some question as to whether horizontal movement at B, C, and D is restrained by horizontal bracing, as it should be.

Mr. Nelidov divides frames into two classes according to the interrelation of possible linear movements of the joints. It is probably better to classify them according to the number of independent movements possible. Thus, the frame of Fig. 1 may be said to have no freedom of joint movement (assuming that D, say, is a fixed bearing); Fig. 5 has no joint freedom (A is fixed); also, Fig. 7 has one degree of freedom of joint movement; Fig. 8 has one; Figs. 9 and 10, two; Fig. 12, two; Fig. 22, one; Fig. 31 may well be treated as one span with no joint freedom (at A or A'); Fig. 32 has four degrees of joint freedom; Fig. 33 may well be treated as two spans with one degree of joint freedom; and Fig. 65 has two degrees of joint freedom. The degree of joint freedom is important in that it determines the number of simultaneous equations that must be solved in some way to satisfy the equilibrium of linear forces.

Mr. Bruhn suggests that the method has important applications in the field of airplane design. The writer knows that this is true, but is not sufficiently familiar with the problems involved in this field to illustrate its usefulness; he hopes that Mr. Bruhn will find time to do so. Certainly the method should facilitate the analysis of continuous struts subject to flexure. As Mr. Bruhn suggests, there is no difficulty in extending the method to include torsional effects. The writer has used the method in special problems of space frames in which the effect of torsional resistance is included in the analysis.

Mr. Downey has presented an interesting discussion of the application of successive convergence to the method of slope deflection. Slope deflection has more than justified its place in America and Mr. Downey has made a valuable addition to this literature. If, however, Mr. Downey will arrange his computation in the way shown by the writer and, further, if in using moment distribution one writes only the moments carried over in each member, it will be found that his computations parallel closely those of moment distribution; but in slope deflection the moments are first translated into rotations which are finally translated back into moments and this represents additional work not used in the method of moment distribution.

FIG. 76.

These relations are brought out by the problem shown in Fig. 76. This problem has been solved by slope deflection (Fig. 76(*a*)) and by moment distribution (Fig. 76(*b*)). As an additional check it has been solved also by the abbreviated method of moment distribution for a three-span beam in which the converging series are summed at once (Fig. 76(*c*)). By the method of slope deflection, using the method of successive convergence, the values of ϕ

are first found. These values of ϕ are next converted into moments and added to the original end moments. In moment distribution the unbalanced moments are carried over just as the ϕ values were carried over, the amount of computation being the same; but in moment distribution the quantities dealt with are always moments, which are the thing sought; by the method of slope deflection these moments are converted into rotations, from which the moments must be recomputed in the end.

Any frame must satisfy two general groups of conditions. The forces acting on it must satisfy the laws of statics so that the frame shall be in equilibrium. The forces acting on it must also satisfy the conditions of geometry, so that the rotations produced in the frame by these forces shall maintain continuity in the frame. The moments at the joints may be expressed either in terms of the joint rotations in the first place and these rotations found from the equations of static equilibrium at the joints, or the rotations may be expressed in terms of the moments and these moments found from the conditions of continuity at the joints. The latter method is that used in developing the theorems of three moments and of four moments. The former method has been used in the United States by writers on slope deflection. The method of moment distribution clearly belongs in the class with the theorems of Clapeyron, but it should be obvious that all kinds of combinations of the equations of statical equilibrium and of geometry are possible, and that it is worse than futile to discuss whether a method introduces any principle in this field which is not implied in principles already known. There will be no new principles in this field, but by varying the form or arrangement of the equations and by more convenient methods of solution a clearer picture of the procedure of analysis can be found and the labor involved may also be reduced substantially.

What has just been written with regard to the theorem of three moments and the method of slope deflection is equally applicable to the method of work. The method of work is simply a deduction from elementary geometry.

Professor Richart suggests modification of the K values in certain stock cases. General relations to be used in direct distribution may be stated as follows. The moment needed to produce unit rotation at one end of a member may be written in terms of the physical properties of the member and the ratio of the changes in end moments in the member due to rotation.

Let M_a = change in moment from the fixed-end condition at the end, A, under consideration;
M_b = change in moment from the fixed-end condition at the other end of the member, B;
S_a = stiffness of the member at A, defined as the moment necessary to produce unit rotation at A when B is fixed;
r_a = carry-over factor at A (from A to B); and,
r_b = carry-over factor at B (from B to A).

Then, for unit rotation at A,

$$M_a = S \frac{1 - r_a r_b}{1 - r_b \dfrac{M_b}{M_a}} = S_a \frac{1}{C}$$

If, then, the ratio, $\frac{M_b}{M_a}$, is known for all members at a joint, the unbalanced moment at that joint may be distributed directly.

In certain cases the ratio, $\frac{M_b}{M_a}$, is known from inspection. When the member is fixed at B, $\frac{M_b}{M_a} = r_a$; when the member is free at B, $M_b = 0$; in cases symmetrical as to form and loading, $M_b = M_a$; and in anti-symmetrical cases, $M_b = -M_a$.

Values of the constant, $\frac{1}{C}$, are shown in Table 21. The general expression may be deduced, of course, in several ways; many will deduce it from area moments. This general relation leads also to a check on the analysis. It is easy to see whether the conditions of statics are satisfied by observing the balance of the joints. The conditions of geometry are satisfied if $M_a - r_b M_b$ is proportional to $\frac{S_a}{1 - r_a r_b}$, or, in the case of beams of constant section, if $M_a + \frac{1}{2} M_b$ is proportional to K at any joint.

As one uses the method of moment distribution it soon becomes evident that it is not necessary to write the distributed moment each time. One may write only the moment carried over and make all distributions in one operation at the end of the process. Time is saved, since almost one-half the figures are omitted, but the simple physical picture of the operation is considerably obscured.

TABLE 21.—VALUE OF CONSTANT, $\frac{1}{C} = \frac{1 - r_a r_b}{1 - r_b \frac{M_b}{M_a}}$

Description of beam	Unsymmetrical haunching, $r_a >$ or $< r_b$	Symmetrical haunching, $r = r_a = r_b$	Uniform section, $r_a = r_b = -\frac{1}{2}$
Beam fixed at far end	1	1	1
Beam simply supported at far end	$1 - r_a r_b$	$1 - r^2$	¾
Symmetrical	$\frac{1 - r_a r_b}{1 - r_b}$	$1 + r$	½
Anti-symmetrical	$\frac{1 - r_a r_b}{1 + r_b}$	$1 - r$	$^3/_2$
Beam continuous at far end	$(1 - r_a r_b)$ to 1	$(1 - r^2)$ to 1	¾ to 1

This procedure may be carried further in any case where the value, $\frac{1}{C}$, is known for all spans but one in a frame. Carry over the proper proportion of the unbalanced moment in this span and repeat. Let a and b be the proportions carried over at the two ends. If the procedure of carrying over moments is continued it will be seen that they run to an infinite converging series the sum of which equals $\frac{1}{1-ab}$ times the sum of the first two terms. Thus, the total moments carried over may be written after two terms and the total unbalanced moment may be distributed.

Fig. 76(*c*) shows the procedure. The unbalanced moments at *B* and *C* are carried over twice. The sum of the moments thus carried over is then multiplied by $\frac{1}{1-ab} = \frac{1}{1-\frac{1}{5}\times\frac{1}{6}}$. The sum thus found for the moments carried over is then added to the original fixed-end moments and the total is distributed at the joint.

This method of writing at once the sum of the converging series may be extended to frames in which the value, $\frac{1}{C}$, is unknown for more than one span in the frame. The general procedure of exact moment distribution by summing the convergent series is of great interest and, in some cases and for some purposes, of great value; but such methods are not properly a part of a paper the object of which is to present a single general method involving no special paraphernalia.

It is interesting to note that, to determine moments in any span, any system whatever may be reduced with close approximation to an equivalent structure of three spans, such as *A B C D* in Fig. 76, by estimating or computing the fixation of the outer ends of all members except *BC*. Professor Van den Broek indicates the use of such substitute frames; so also does Professor Richart. The writer also used the concept of equivalent stiffness in his paper, "Continuity as a Factor in Reinforced Concrete Design," previously mentioned.

As another illustration, in the truss analyzed by Mr. MacLean, the members meeting at *C* are known to remain fixed at the end at this joint; also, the member, *BD*, is known to be symmetrically distorted and $\frac{1}{C} = \frac{1}{2}$. The value, $\frac{1}{C}$, is then known for all members except the end posts. By twice carrying over distributed moments in this member and then summing the series by multiplying by $\frac{1}{1-ab}$, the total change in end moment due to carry over is at once determined and can be directly distributed.

In secondary stresses this method of convergence is usually only of academic interest. In the problem solved by Messrs. Thompson and Cutler it is not applicable, but the procedure used by them is much shortened if all distribution is made once for all at the end of the analysis.

Extension of the method of moment distribution to the study of the effect of gusset-plates on the secondary stresses is of some interest and presents no great analytical difficulty, the members being treated as of varying section. Any one who has analyzed on this basis will recognize more clearly the futility of great precision in computations on the usual basis.

Mr. Hartmann suggests that time may be saved by distributing unit unbalanced moments at the individual joints and then combining for any combination of loading. Mr. Dillingham uses the method in connection with moving load systems. This procedure has much merit where many combinations of loading are to be considered. It is not necessary, however, to distribute a unit moment in each member, but only at each joint. The distribution at each joint being known, any unbalanced moment from any of the members meeting at that joint may be distributed at once. The writer always uses this method where moving concentrated loads are under consideration. The fixed-end moments are found from influence lines. These are available for beams of varying section in a recent paper by Mr. L. T. Evans.[81] The unbalanced end moments are then distributed by the factors already found. On a string polygon for the load system, one then lays off the end moments at the supports, draws the closing lines in each span, and thus constructs the entire curve of moments for any position of the loads.

(*d*) UNIT UNBALANCED MOMENT AT *D*

APPLICATION OF DISTRIBUTION FACTORS, IN (*b*) (*c*) (*d*) AND (*e*), TO FIG. 1.

FIG. 77.

This procedure may be abbreviated by distributing moments at a support near the center of the structure. This joint is then held rigid while distribution is made at adjacent joints on either side, the resulting unbalanced moment at the first joint being then distributed from the values already found. Thus, the distribution of individual moments becomes more rapid as the ends of the structure are approached.

Fig. 77 shows the application of this procedure to the problem solved in the original paper. An unbalanced moment is first distributed at *C*. Then, when unbalanced moments are distributed at *B* and *D*, *C* is first treated as fixed and the values previously found are used to distribute the unbalanced moment at *C*. Similarly, when an unbalanced moment is distributed at *E*, Joint *D* is first treated as fixed. The total end moments got by distributing the unbalanced fixed-end moments are shown at the end of the problem. The advantage of the method, however, seems to be chiefly in those problems where many different combinations of moments are to be considered. The abbreviated method of distributing moments only once is used; the convention of signs herein is that for statical moments.

---

[81] "The Modified Slope-Deflection Method," by L. T. Evans, *Journal*, Am. Concrete Inst., October, 1931.

Mr. Larson has made a valuable addition to the paper. The method of moment distribution is applicable to beams which are curved as well as to those which are straight, and is applicable to the distribution of forces as well as of moments. In order to use it conveniently, however, it is important that the convergence be rapid.

In the solution indicated by Mr. Larson it will be seen that the convergence is not very rapid. This is due to the large unbalanced thrusts and moments thrown back into the system each time by the pier. This disturbing factor may be avoided by distributing moments not about the pier top, but about some point so chosen that when the moments are distributed by rotation of the pier top about this point, the resulting thrusts are also balanced. It will also be true that there will be no unbalanced moment produced about this point due to distribution of unbalanced thrusts.

If this is done the pier may then be neglected during the process of distributing thrusts and moments. Indeed, the side arches may be neglected also, since only those thrusts and moments are distributed that are carried over from adjacent joints, none being carried over from the fixed ends. If it is desired to treat either one of the end arches or a pier as hinged at the foundation, its elastic properties may be determined for this condition and then it may be neglected during the procedure of distributing thrusts and moments.

The procedure indicated, then, is as follows:

(*a*) Locate a point (referred to subsequently as *O*) on the pier axis so that rotation of the pier top about this point (the other ends of the pier and the connecting arches being immovable), will produce no unbalanced thrust.

(*b*) Determine the thrust needed in each member alone to produce unit horizontal displacement at the pier top without rotation. Determine from this the distribution factors to the connecting arches.

(*c*) Determine the moments needed in each member alone to produce unit rotation of the end of the member about the point, *O*. Find from these the distributing factors for moments about *O* for the connecting arches. Locate also the thrust lines for such rotations. From the percentage of unbalanced moment distributed to each arch find the percentage carried over to the other end.

This gives all the essential data to be used in the distribution of the thrusts and moments. Now, proceed as follows:

(1) Distribute and carry over the unbalanced thrusts. Do not write the distributed values, but only the values carried over. Continue to convergence and find the total thrusts carried over.

(2) These thrusts produce unbalanced moments equal to the thrust multiplied by the vertical distance from the point, *O*, to the thrust line.

(3) Distribute and carry over the unbalanced moments just found, together with the original unbalanced moments about the points, *O*. Write only the moments carried over. Continue to convergence and find the total moments carried over.

(4) These moments produce unbalanced thrusts equal to the moments divided by the vertical distance from *O* to the thrust line.

Repeat the cycle to any desired accuracy. Next, by addition, find the total thrusts produced by displacements and the total thrusts produced by rotations. Since their lines of action are known, any other quantities may be determined by statics.

Since it is now necessary to deal only with the arches during the process of distribution, a somewhat more convenient convention of signs for thrusts than that used by Mr. Larson may be adopted. If the usual convention of signs is followed for moments used in the design of arches and girders that positive moment produces tension on the lower side, then a thrust acting above the axis—on the positive side—produces positive moment. Thrust in the arch is positive and tension negative. This makes it possible to add thrusts carried over to opposite ends of the arch without confusion.

Fig. 78 shows the solution of the problem given by Mr. Larson, using this technique. The percentages to be carried over and the lever arms of the thrusts have been determined from the data given by Mr. Larson. The final solution is obtained by adding the different thrusts and is indicated at the bottom of the diagram. The solution is shown here only to illustrate how, in this special case, a modification of the technique facilitates the convergence. The writer hopes to elaborate this procedure, elsewhere. It has a wide field of application in studies of continuous arch series in bridges or in buildings and of combinations of girders and arches.

It is not the function of this paper to discuss methods of deriving the elastic properties to be used in distributing the fixed-end moments and thrusts to the piers and arches. The writer prefers to use the theorems of the column analogy, according to which, the stiffness values and lines of thrust are defined as follows: (1) The stiffness for thrust is the stress at unit vertical distance from the neutral axis of the analogous column section for unit moment about the horizontal axis of this section; (2) the stiffness for moment is the stress on the analogous column section at the center of rotation for unit load at this center; and (3) the lines of thrust are the neutral axes of the analogous column section for these loadings. These theorems are equally applicable whether the arches are symmetrical or unsymmetrical.

The point about which rotation should be applied in order that the resulting thrusts shall balance may be found as "the centroid of the values for horizontal stiffness," or so that the sum of the products of vertical distances to the thrust lines for displacement multiplied by the horizontal stiffness shall equal zero.

Professor Large, and Messrs. Earl and Gordon have discussed cases in which the moment of inertia of the members is variable. As stated in the paper, there is no difficulty in applying the method to such structures; the fixed-end moments, the values for stiffness, and the carry-over factors are different if the members are of varying I. It may be well to observe that, at least in reinforced concrete, the case of variable section is the rule rather than the exception, although this fact is not yet generally recognized. Even where the members seem to be of constant section, the moment of inertia is very much increased beyond the faces of the supports. Note carefully that the sum of fixed-end moments at the center of intersections is to be distributed, not the sum of moments at the faces of supports. Neglect of this requirement of statics invalidates the entire analysis. Tables or curves that purport to give the moment at the face of the supports of continuous frames without reference to the ratio of the width of support to span length are necessarily incorrect and may be very seriously in error. Note, also, that traditional practice in the use of moment coefficients is based on the clear span, as is pointed out by Mr. Wessman in his interesting discussion.

FIG. 78.

The writer has discussed elsewhere the computation of the constants for beams of varying section, and thought it best to exclude such material from the paper.[79,80] There is no great difficulty in determining these constants. In any given case five quantities are involved, the area, centroid and moment of inertia of the $\frac{1}{EI}$ diagram, and the area and centroid of the $\frac{M}{EI}$ diagram, in which, M is from any trial moment curve. These quantities are then to be combined. There are evidently endless variations of detail in doing this, the principal rule being to follow a definite procedure and avoid repetition of computation. The writer prefers to use the column analogy which converts the entire procedure into the familiar process of computing fiber stresses in beams.

In his paper previously mentioned, Mr. Evans has given constants for members of varying sections. It will be of interest to those who use moment distribution to note that the values for moment coefficients given by Mr. Evans are for fixed-end moments, the beam coefficients, C_1 and C_2, are for stiffness, and the carry-over factor at one end is $\frac{C_2}{C_1}$, and at the other end, $\frac{C_2}{C_3}$.

Curves and constants for the properties of haunched beams of reinforced concrete based on the assumption that I varies as the cube of the beam depth, however, should not be taken too literally. The effect of cracking, and the action of the flange in tension and in compression, introduce many uncertainties.

All kinds of ingenious tricks may be used to shorten the procedure. This is all right for the specialist who is engaged daily in this field. The general method presented in the paper originated from studies made by the writer in the analysis of three-span frames and is his final choice for ordinary daily use from many variations of method that he has developed and used. Any one can develop an unlimited number of such variations. Their novelty is no virtue; what is wanted for daily use is maximum simplicity consistent with reasonable facility. Such variations present a fascinating occupation to dilettantes who amuse themselves in the field of indeterminate structures; for the ordinary designer who analyzes such frames not as a vocation or for amusement, but as a passing incident to the design of the structures, it is essential that the procedure be simple and without special exceptions. The structural engineer has so many things to think about that it seems very unfortunate to load up his "tool chest" with a great many pretty but rather complicated "gadgets." Although developed in a class-room, the method of this paper was intended for use in offices.

The writer is especially pleased that so many have found the method useful in the design of actual structures. Professor Caughey and others have given estimates showing savings of from 80 to 90% of the time required by other methods; the writer knows of cases in which complete studies have required only one-twentieth of the time formerly used.

The writer is indebted to Mr. Findley for emphasizing the accuracy of the method. The writer called it a method of successive approximation; a better term which the writer has often used in this connection is "successive convergence." As Professor Van den Broek states, the word "exact" scarcely has a place in the engineer's vocabulary; but the term "approximate" is one which many people misunderstand. The quest of the absolute is a beautiful thing; but he who seeks in engineering analysis a precision that cannot be ultimately translated into such units as pounds of steel and yards of concrete is misled. Structures are analyzed so that they may be designed; not for the pleasure or practice of analyzing them. As Professor Finlay well states, "between the analysis of a given structure, which is essentially mathematics, and the design of a required structure, which is essentially art, lie many difficulties."

SOME ASPECTS OF WATER CONSERVATION[1]

By R. A. Sutherland,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. E. C. Eaton, A. W. Simonds, W. H. R. Nimmo, C. R. Olberg, John W. Pritchett, A. J. Gilardi, and R. A. Sutherland

Synopsis

Development of water conservation in the past has frequently been made in a piecemeal and haphazard manner, resulting in a less effective and economical exploitation of rivers than could be obtained by a systematic and coordinated study of all the factors concerned. In this paper formulas are developed for studying, in a preliminary manner, the merits of various storages and dam sites. The formulas have been tested in practice and were found to give reasonably correct results in most cases. Methods are also given for studying the relative economy of different types of dam, where the site admits of alternative types. The economic limits of specific capacity, or water stored per cubic yard of masonry in the dam, are discussed by means of examples from practice.

The paper represents an attempt to reduce to general and simple terms those factors which admit of generalization, but it is recognized that each case has peculiarities which must be studied in the light of local conditions.

The original manuscript of this paper, containing many tables, curves, and illustrations, which are not published herein, may be found on file at the Engineering Societies Library.[3] An abstract that forms the nucleus of it was published in Australia in 1928.[4]

Importance of Water Conservation

Water conservation, especially in countries where rivers show marked irregularity of flow, has become a question of such importance that Government departments have been set up to handle the whole question, particularly with regard to irrigation and water power. In addition, many private agencies or local authorities are actively undertaking conservation works in connection with irrigation, water power, or water supply projects. Immense sums of money have already been expended on such works, and with increasing population the necessity for the most economical and effective organization of all works for water conservation will become ever more insistent.

In most countries the systematic collection and recording of data with regard to water conservation has been entirely neglected, due probably to the fact that so many different authorities are represented in the field. Notable exceptions are the publications of the United States Bureau of Reclamation and other Federal Departments, and those of a branch of the Italian Ministry of Public Works ("Consiglio Superiore delle Acque").

The total storage for irrigation already developed or proposed by the U. S. Bureau of Reclamation is equal to 13 792 500 acre-ft. in 49 reservoirs. In California, power companies and municipalities have created for power purposes alone no less than 76 reservoirs with an aggregate storage of 1 724 402 acre-ft.[5]

Canada is richly endowed with water resources; the total available storage of 22 of the most important lakes and artificial reservoirs used for power purposes is 30 030 000 acre-ft.

South Africa, which geologically is a country ill-adapted to water conservation, has storages exceeding 750 000 acre-ft.

The States of New South Wales and Victoria in Australia are, in proportion to population, among the foremost in the conservation of water, which is mainly used for irrigation. The total storage for this purpose in New South Wales is about 1 900 000 acre-ft., or 0.84 acre-ft. per capita, while a further storage of 2 500 000 acre-ft. is proposed. Victoria has a total storage of 900 000 acre-ft. for irrigation, or 0.54 acre-ft. per capita, and an added quantity of 950 000 acre-ft. is proposed.

The State of Queensland, which is the most recently developed of the Eastern States of Australia, has, at present (1930), storage equal to only about 30 000 acre-ft., while projects involving a total storage of about 3 000 000 acre-ft. are either proposed or being developed.

In Europe, the climate does not in general require, nor does the geological nature of the continent usually permit, the formation of large storages. Italy, however, has an immense number of storages of moderate size, totaling more than 675 000 acre-ft. in 86 reservoirs used for power, while works under construction will add a further 626 000 acre-ft. in 27 reservoirs. The largest of these reservoirs is that of the Tirso, with a capacity of 285 000 acre-ft.

Switzerland has many storages of small size, the total capacity of the 9 reservoirs which exceed 10 000 acre-ft. being 271 900 acre-ft.

An immense number of small storages exist in various countries for purposes of irrigation and water supply, but no complete list of these storages has ever been compiled. Some appreciation of the magnitude of the conservation of water for irrigation may be obtained from the fact that the estimated world area irrigated is more than 137 000 000 acres.[6]

---

[5] The data here given were up to date in 1928. For notes on large dams, see "*New Reclamation Era*," January, 1930, "The Highest and Largest Dams in the United States and Abroad," by P. I. Taylor.

[6] *New Reclamation Era*, September, 1927.

The storage required per acre irrigated varies from zero to as much as 20 acre-ft. An average figure for projects under the U. S. Reclamation Bureau appears to be about 4 acre-ft. of storage per irrigated acre, while, in order to cope with the prolonged droughts occurring in Australia, a proposed plan there involves a storage of about 30 acre-ft. per irrigated acre. Taking a conservative all-round figure of only 0.5 acre-ft. of storage per irrigated acre, the world storage for irrigation would amount to about 69 000 000 acre-ft.

FUTURE DEVELOPMENT

Great as has been the progress already made in water conservation, it is only a fraction of that required to achieve the complete hydraulic development of the various countries of the world. Some countries are already so highly developed in this regard that the completion of their program of hydraulic development, if not already in view, will be so within the next ten or twenty years. Of such countries, Switzerland and Italy may be cited as examples. Italy has now (1930) reached such a stage that all the most promising storage sites have already been exploited, and a Government department is actively collecting data relating to the stream flow and potential storage sites of the remaining streams. Practically all the main rivers and streams have been accurately leveled, storage sites surveyed, and catchment basins defined. Other countries such as Brazil, Central Africa, Queensland, New Zealand, etc., have as yet developed only a small percentage of their hydraulic resources.

When it is realized that the present total world area irrigated is just a fraction of that for which water would be available with adequate conservation, and that in the field of hydro-electric power the present world development is only 25 000 000 h.p. out of an estimated total of about 440 000 000 h.p. available, it is considered safe to say that present water conservation is probably not more than 10% of that which will ultimately be required. Accurate data, however, are lacking on which to base any forecast of the rate of development.

In addition to storages needed for irrigation and water power, an increasing number will be required also for water supply and flood control; but development on these lines depends so entirely on sectional requirements that it is useless to attempt any forecast of what may be required. It is interesting to note, however, that, in recent times,[7] considerable sums of money have been spent on flood control by the construction of detention basins. The works of the Miami Conservancy District in Ohio, of the City of San Antonio, Tex., and of Los Angeles County, California, are examples.

The investigation and development of water conservation in the past have been frequently haphazard, unscientific, and uneconomical. Common errors have been:

1.—The use of insufficient stream-flow data;
2.—The use of rainfall records and assumptions as to run-off without adequate data showing the relationship between them.
3.—An under-estimation of flood flows, and insufficient spillway provision;

---

[7] The Furen's Dam (1866) was the first large modern dam built for flood control. Until recently, large expenditure for this purpose alone was exceptional.

4.—Insufficient geological examination of reservoir basin and dam site;
5.—Incorrect design or faulty construction of dam; and
6.—Choice of site, and design of dam without regard to economic considerations or future development of other sites on the same stream.

NOTATION

The following notation is used in the paper:

a = area of a cross-section at a dam site, to any height, h.
A = total area of a cross-section at a dam site, to height, H.
w = capacity of a reservoir to any height, h_1, measured at the dam.
w_s = specific capacity. Other subscripts refer to the type of dam.
W = total capacity of a reservoir to height, H_1.
s = submerged area of a reservoir, corresponding to a height, h_1, measured at the dam.
l = width of a dam site at any height, h.
t = thickness of dam at any height, h.
t_1 = crest thickness of a dam with a trapezium section.
K = sum of face batters (ratio of horizontal to vertical) of a dam. Proper subscripts refer to type of dam.
K_R = sum of face batters of a dam with a trapezium section.
h = height of dam site to any elevation.
h_1 = depth of water at the dam.
H = total height of a dam of any type.
V = volume. Proper subscripts refer to type of dam.
V_R = volume of a dam with a trapezium section.
R_u = up-stream radius of an arch dam.
R_1 = up-stream radius of a constant-angle arch dam, at the crest.
R_2 = up-stream radius of a constant-angle arch dam, at the base.
R_h = up-stream radius of a constant-angle arch dam, at any elevation, h.
f = cylinder stress in an arch dam, in pounds per square inch.
ϕ = a subtended angle in an arch dam.

C_A = a coefficient (Equation (1)) $= \dfrac{a}{h^n}$.

C_w = a coefficient (Equation (2)) $= \dfrac{w}{{h_1}^m}$.

D = a coefficient (Equation (6)) $= \dfrac{l}{h^v}$.

n = an exponent (Equation (1)) $= \dfrac{\log a - \log C_A}{\log h}$.

m = an exponent (Equation (2)) $= \dfrac{\log w - \log C_w}{\log h_1}$.

v = an exponent (Equation (6)) $= \dfrac{\log l - \log D}{\log h}$.

J = a coefficient (Equation (20))

$$= \frac{0.217\,\phi}{n\,C_A\,H^{n-1}\sin\dfrac{\phi}{2}}\left[\frac{n\,R_1 + 2\,R_2}{n\,(n+1)\,(n+2)}\right].$$

J_A = a coefficient (Equation (14)) $= 0.434\,\dfrac{R_u}{L}\left(\dfrac{n}{n+1}\right)\left(\dfrac{\phi}{2\sin\dfrac{\phi}{2}}\right)$.

J_{CA} = a constant $= J\,n^2$.

Q = a constant (Equation (25)) $= L \frac{V_A}{V_g}$.
g = a subscript denoting gravity dams.
A = a subscript denoting arch dams.
$C\,A$ = a subscript denoting constant-angle arch dams.

NOTES ON RIVER SECTIONS AND PROFILES

Koechlin[8] has shown that for a river in a state of equilibrium, the shape of the bed is sinusoidal and depends only on the slope and the nature of the ground traversed. This shape he calls the "normal cross-section." In order that this section may be attained, the following conditions must be fulfilled:

(1) The river must have arrived at a state of equilibrium; that is, the longitudinal profile must be constant.
(2) The flow must be as constant as possible.
(3) The ground must be homogeneous.
(4) The banks must be bare.
(5) The river must be straight.
(6) The river, even at high flood, must be contained entirely within the bed.

Actually few of these conditions are ever satisfied simultaneously, so that the theoretical profile does not hold good in practice. The effect of departures from the conditions mentioned is examined by Koechlin in some detail.

Over certain limited tracts of river, all the conditions cited except Condition (2) may be fairly well fulfilled. This is generally the case in gorges or valleys suitable for the construction of dams, and, here, it might be expected that the sinusoidal shape of section might be most frequently found.

The area enclosed within a sine curve, can be shown to vary nearly as the $\frac{3}{2}$ power of the height measured from the crest of the curve. By computing areas carefully and plotting them against heights, on logarithmic paper, the writer obtained an index of 1.51. The cross-sectional areas of dam sites can generally be expressed closely in terms of height by means of an equation:

$$a = C_A\, h^n \qquad \text{(1)}$$

The mean value of n for thirty-seven sites examined was found to be 1.54. This close agreement between theory and average practice appears to confirm the correctness of Koechlin's work.

It is a matter of common experience that the longitudinal profile of rivers is approximately parabolic in shape. Fig. 1(*a*), Fig. 1(*b*), Fig. 1(*c*), and Fig. 1(*e*) show the profiles of various rivers and illustrate the parabolic shape.[9] Land surfaces as a whole vary in slope in a similar manner.[10]

In the vast majority of cases, a river flows through country of varying geological character, and the profile is far from regular. At certain points the river breaks through more or less well-defined ridges, the areas above these points constituting self-contained catchment areas. When the ridges are well defined, the river is usually in a gorge, and such a formation is frequently suitable both for a dam site and for an efficient storage basin. Each catchment above its respective gorge has its own characteristics, which depend on the geology of the region and a variety of other factors. The general land slope above each gorge will be parabolic. Hence, the profile of many rivers consists of a series of parabolas, the whole again forming roughly one large parabola.

[9] See, also, "Mécanisme de l'Eau," by René Koechlin, Vol. 1, 1924, Fig. 48, p. 136.
[10] "Géographie Physique," by Martonne, 1913, p. 49.

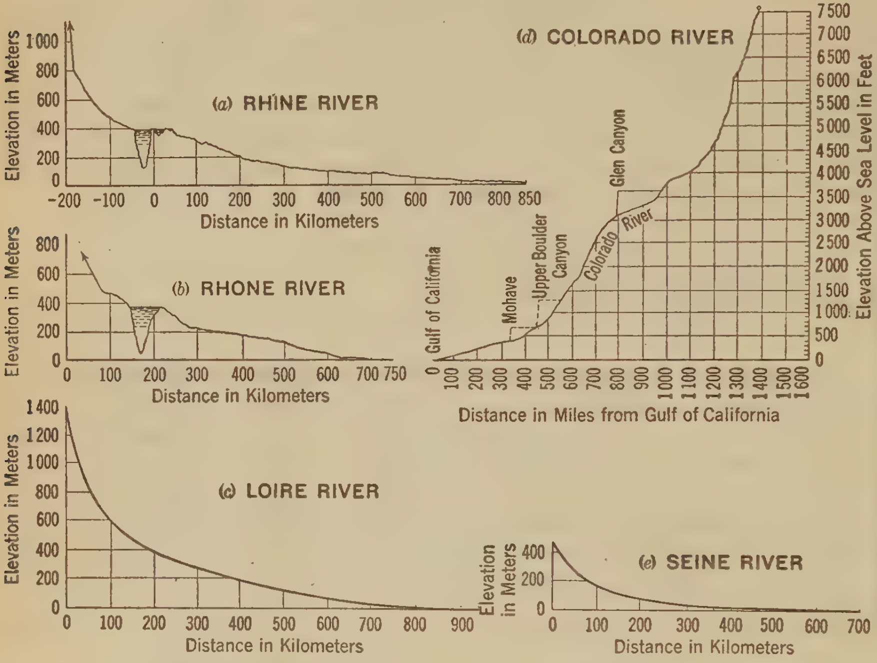

Fig. 1.—Longitudinal Profiles of Various Rivers.

Fig. 1(*d*) shows the profile of the Colorado River,[11] in which two major and several minor parabolas are readily distinguishable. The ideal case is shown in Fig. 2 in which the river is assumed to break through two successive ridges. The longitudinal profile then consists of three curved sections, each of approximately parabolic shape.

In the upper basin, the river has a relatively small flow but carries considerable gravel and many boulders, and, in general, the stream bed will be deeply eroded and the landscape scarred by numerous tributaries. The general nature of the cross-section, therefore, will be as shown by Section *A*.

In the second basin the stream bed will be wider and less deeply eroded, somewhat as shown at Section *B*, while even farther down the land may be almost level, and the river bed very wide, the normal dry-weather flow occupying only a small winding channel in a wide bed (Section *C*).

The Reservoir

Suitable dam sites generally occur at points such as those marked *A* and *B* (Fig. 2); that is, some distance down the transition from one parabola to the next. An examination of the slopes above and below almost any storage dam will verify this fact.

---

[11] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), Fig. 13, p. 341.

From a consideration of the profile and cross-sections of Fig. 2 it will be seen that the storage obtained for a given height will generally be less for the upper reservoir shown than for the lower one. On the other hand, the rate of increase of storage with increasing depth of water will be greater. Hence, the reservoirs will have certain well-defined characteristics and may be classified accordingly. The classification adopted will be: (1) Gorge type; (2) hill type; (3) foothill and flood-plain type; and (4) lake type.

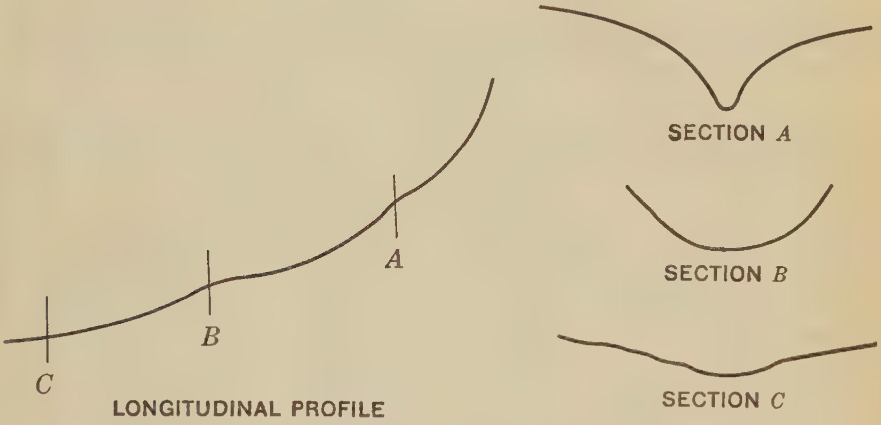

FIG. 2.—PROFILES AND SECTIONS OF AN IDEAL RIVER (DIAGRAMMATIC).

A classification such as this was proposed by W. H. R. Nimmo, M. Am. Soc. C. E., when this paper was first discussed before the Institution of Engineers (Australia), but the criteria now adopted differ from those proposed by Mr. Nimmo.

Reservoir *A* would be of the first class, Reservoir *B* of the second, and a reservoir at a site, such as *C*, of the third class. The lake type of storage is a special case and may occur at any elevation. As the name implies, it is a reservoir formed either by artificially raising an existing lake, or by impounding water in what was once a lake or in a basin of similar general form.

CHARACTERISTICS OF RESERVOIRS

In 1911,[12] Capt. A. ff. Garrett, R. E., defined the capacity of a reservoir as a function of the depth, by expressing the area and capacity as series in ascending powers of the depth, and showed that the first three or four terms of such series sufficed to give quite accurate values of the quantities considered. Hence, he deduced rules for determining the capacity curve with the minimum amount of survey work. For this purpose Garrett's method is valuable. Later, Hillman[13] showed that the capacity of a reservoir can be expressed closely as an exponential function of the depth of water, but he made practically no use of this fact.

---

[12] "The General Theory of the Storage Capacity and Flood Regulation of Reservoirs," Tech. Publication, Govt. of India, 1911.

[13] "The Capacities and Capacity Equations of Some Western Australian Dam Sites," *Transactions*, Inst. of Engrs. (Australia), Vol. 11, 1921.

Fig. 3 represents a few of the large number of capacity curves which have been plotted by the writer on logarithmic paper, and shows that the relationship first suggested by Hillman is generally very close. When the capacity curve has been drawn as a straight line on logarithmic paper (with horizontal and vertical scales equal) the slope of this line will give the index of the height in the general capacity equation:

$$w = C_w \, h_1^{\,m} \ldots\ldots\ldots\ldots (2)$$

It will be seen that Equation (2) not only gives in general a close representation of the capacity at any depth, but enables the "characteristics of any reservoir to be crystallized into a single line."

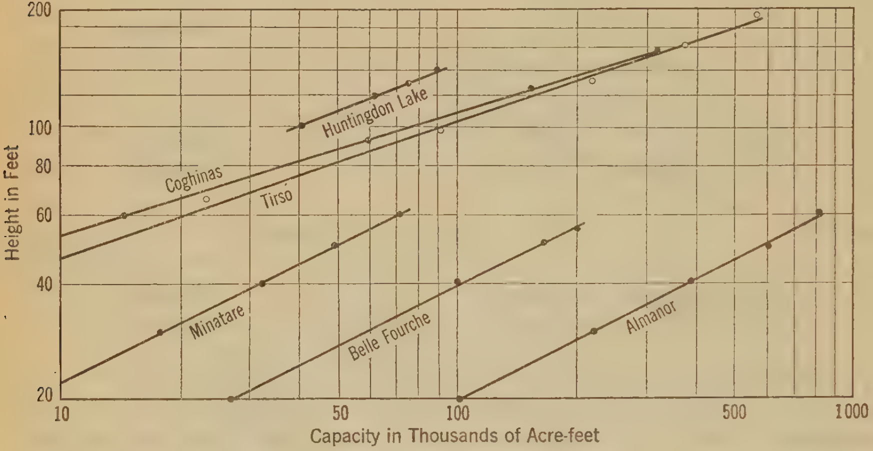

FIG. 3.—LOGARITHMIC CAPACITY CURVES.

In Table 1 a number of reservoirs have been classified into types, and the characteristics of each reservoir (as represented by C_w and m) have been tabulated. The basis of classification arbitrarily adopted is as follows:

	Values of m.
Lake type	1.0 to 1.5
Flood-plain and foothill type	1.5 to 2.5
Hill type	2.5 to 3.5
Gorge type	3.5 to 4.5

This classification is not intended to be hard and fast, since the different types merge into each other, but is a sufficiently definite basis for describing the general nature of any reservoir.

The constant, C_w, may be readily determined by taking the capacity from the straight line for a depth of 100 ft., then:

$$\log C_w = \log w_{100} - 2\,m \ldots\ldots\ldots\ldots (3)$$

The value of m is the ratio of maximum depth to average depth, the latter being defined as maximum capacity divided by maximum water-spread area.

TABLE 1.—CHARACTERISTICS OF STORAGE RESERVOIRS

Item No.	Name of reservoir.	Purpose.	*m*.	C_w.	Maximum depth, in feet.	Capacity, in acre-feet.
	LAKE TYPE: $m = 1.0$ TO 1.5.

	Weighted mean		4.23			
	Arithmetical mean		3.97			

The ratio of mean depth to maximum depth has been given by Charles Slagg[14] for seventy-five different reservoirs. The maximum value of this ratio is 0.612, corresponding to m = 1.64, and the minimum value is 0.281, corresponding to m = 3.57, the mean values being 0.456 and 2.2, respectively. In Table 1, fifty-one reservoirs are arranged according to the writer's classification. The arithmetical mean value of m is 2.75 and the weighted mean, 2.87, for the fifty-one cases. Both these values are greater than the figure deduced from Slagg's table.

Certain of the reservoirs cited occur on the same river, and a study shows that their values of m are functions of elevation. The following reservoirs are arranged in order of descent of the river, and the values of m show a corresponding decrease:

	Values of m.
Upper Buller River	3.94
Lower Buller River	2.63
Upper Stanley River	3.77
Lower Stanley River	3.37
Glenn Canyon, Colorado River	3.97
Boulder Canyon, Colorado River	2.35
Mojave Reservoir, Colorado River	1.76

Furthermore, the general deduction may be made that for reservoirs of similar type, C_w will vary usually with the catchment area.

REPRESENTATION OF RESERVOIR CAPACITY

Equation (2) may be represented by means of an alignment chart, such as Fig. 4, in which the outside scales are graduated for height and capacity, the

---

[14] "Water Engineering," by Charles Slagg, First Edition, 1888, p. 24, Crosby Lockwood and Son.

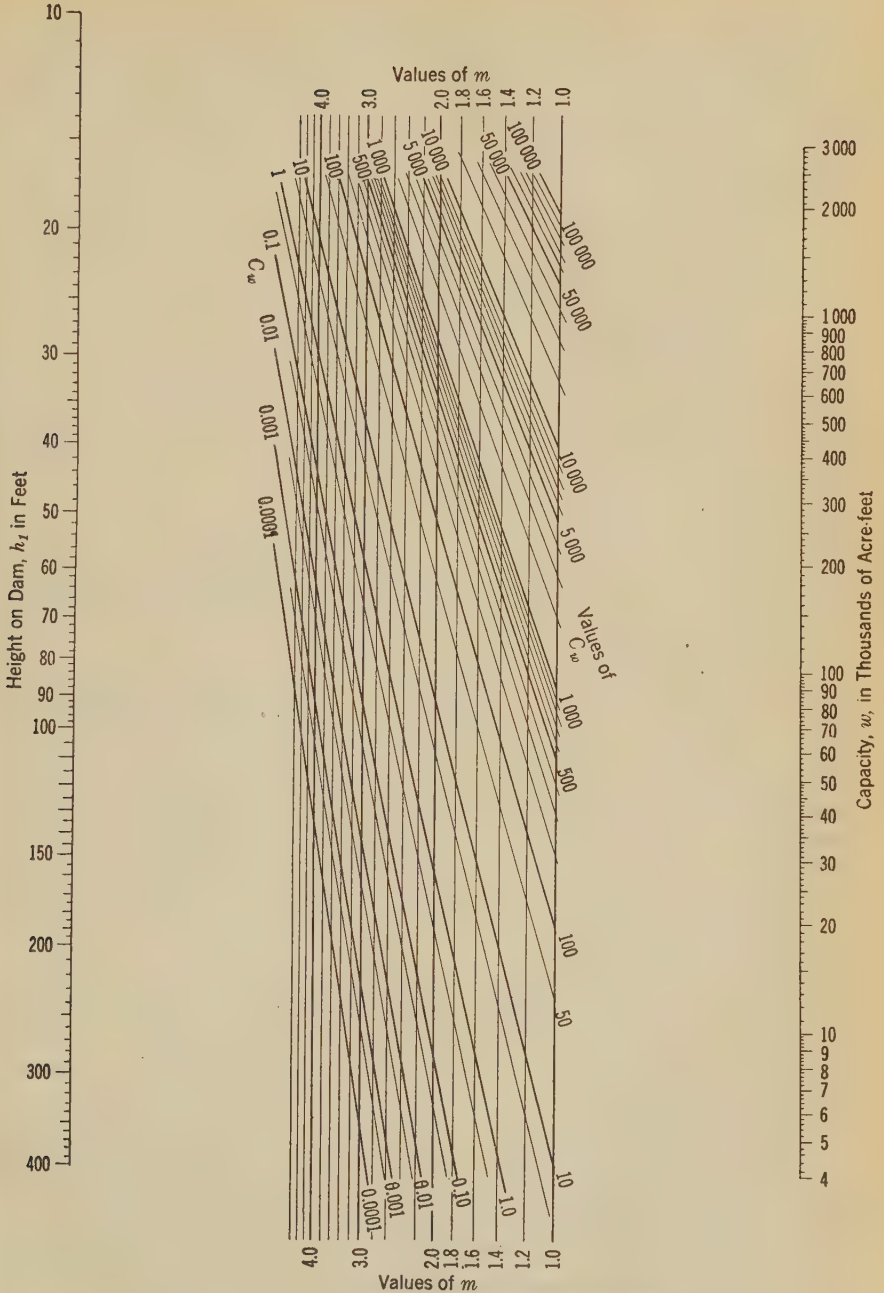

FIG. 4.—RESERVOIR CAPACITY DIAGRAM BASED ON THE EQUATION, $w = C_w h_1^m$.

central field representing various values of m and C_w, over a range such as occurs in practice. A moment's reflection will show that the C_w lines are concurrent at the point, 1, on the height scale. If the values of m and C_w have been obtained as previously described, or by computation, a point is defined in the central field which represents the properties of the reservoir, and by using this point as a fulcrum for a straight edge, the capacity at any height can be at once obtained.

The alignment chart for capacity (Fig. 4) is useful in the following ways:

1.—As a convenient alternative to the usual cartesian capacity diagram for one or a number of reservoirs.
2.—As a means of finding the values of C_w and m when the capacity of a reservoir is known at two or more depths.
3.—For comparing the properties of various reservoir basins.

The use of the logarithmic scales gives more satisfactory results than can be obtained with the usual cartesian capacity curve in which the lower portion is usually very flat and the upper portion very steep. Several reservoirs may readily be represented on one diagram without confusion, which cannot generally be done with the usual method of plotting.

For Use No. 2, intersecting lines are drawn connecting corresponding values of depth and capacity, and an optimum point of intersection is selected by inspection. Values of capacity for depths greater than those for which the capacity has been actually determined can then be readily found. This case not infrequently arises where a dam is to be raised.

Fig. 5 illustrates the use of alignment charts for comparing reservoirs. It shows the pivot points for the reservoirs cited (by Item No. 3) in Table 1 (the central field of lines has been omitted for clearness.) The ideal reservoir basins, irrespective of depth, are those lying on the upper margin of the constellation of points and the poorest are those lying on the lower margin. The average basin would be represented by a point lying on the central dotted line (inserted by judgment). It is very interesting to note from the diagram that this agrees very nearly with Kanthack's conclusion[15] that any reservoir basin better than Van Ryneveld's Pass (Item No. 50, Table 1) is satisfactory for South African conditions.

It should be noted that this comparison relates merely to the physical properties of the reservoir basin, and is not a final criterion of the usefulness or cost of a reservoir, which would be expressed generally in terms of cost per unit of regulated run-off or, perhaps, with very large reservoirs, in terms of cost per unit of water stored.

An interesting application of the exponential method of expressing reservoir capacity lies in determining mathematically the behavior of retarding basins for flood control. The properties of the flood wave and of the basin are both expressed approximately by mathematical formulas, and the reaction of one to the other can then be derived. A particular case of this general application was used for studying the retarding basins of the Miami Conservancy District[16] with great economy of time and effort.

---

[15] "The Principles of Irrigation Engineering," by F. E. Kanthack, 1924, p. 153.

[16] "Hydraulics of the Miami Conservancy District."

SUBMERGED AREA

The differentiation of Equation (3) with respect to depth gives the submerged area equation:

$$s = m\, C_w\, h_1^{m-1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

A comparison of actual submerged areas for a number of cases, with the theoretical areas found from Equation (4), shows that this equation is less accurate than Equation (3). It is sufficiently accurate, however, to be used for preliminary purposes for determining the constants, C_w and m, from the areas at two or three levels only. Fig. 6 is convenient for this purpose. It is well known that for one reservoir proposal adopted, many may be examined and discarded, and the methods mentioned are quite suitable for this preliminary study.

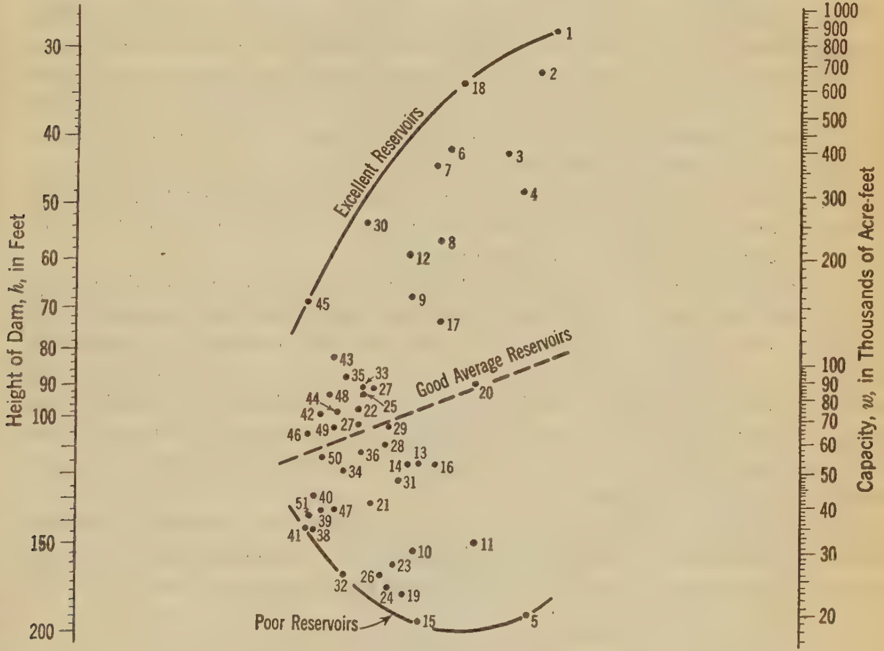

FIG. 5.—COMPARISON OF RESERVOIRS.

It is interesting to note that the value of m has an important bearing on the effect of evaporation, which has sometimes to be considered very carefully in studying large storages in dry climates.

The effect of evaporation being to remove the top slice of water impounded, it is clear that, other things being equal, evaporation causes a much more serious loss in the case of reservoirs characterized by a high value of m, than with those having a low value of m. For long storage in dry climates, a low value of m, is, therefore, a desirable property for a reservoir to possess.

The Assuan and Elephant Butte Reservoirs are excellent examples, while the Nathan Reservoir is unfortunately handicapped in this respect by its high value of m. To illustrate this point it will be sufficient to state that the evaporation losses for the Elephant Butte Reservoir over a period of twenty years would be equal to about 20% of the inflow, while for the Nathan Reservoir over a period of fifteen years these losses would be 40.5% of inflow. The depth lost annually is practically the same for each reservoir, so that the cases are comparable. The losses over a shorter drought period would be even more to the disadvantage of the Nathan Reservoir. It is unnecessary to add that sites suitable for the creation of such large storages are rare, so that there is not usually any opportunity of selecting the reservoir site with regard to its desirability or otherwise from the point of view of evaporation losses.

THE DAM

The location and design of a dam depend primarily on geological considerations, as affecting both the site and the materials available for construction. The treatment of the geology of dam sites is outside the scope of this paper, but a systematic investigation into the whole question of the geology of dam location is urgently needed.[17] Such an investigation, if based on an examination of the hundreds of dams built in gorges or narrow valleys, would be of intense scientific and practical interest.

As a general rule, a synclinal valley is most favorable for the construction of a dam; but it is of the rarest occurrence. In the majority of cases, the strata are either anticlinal or of uniform dip.

In the formation of an anticline, the upper strata are subjected to great tension and the rock is fractured. The more readily erodible portion of this fractured rock is removed by the river, but even when the river is of great age, much of the remaining rock is still highly jointed and fractured, although statically sound. Hence, an anticlinal dam site will frequently require considerable cut-off excavation and pressure grouting to prevent leakage. Fault sites may vary greatly, but they generally require deep excavation and may even be geologically inadmissible.

In the large class of sites that have horizontal or uniformly inclined strata, the excavation required in the rock itself will generally be relatively small, but this may be offset by heavy excavation through detritus.

FACTORS AFFECTING TYPE OF DAM

The selection of the most economical type of dam for any site, which geological examination has shown to be feasible, depends on a large number of factors, such as the purpose for which the storage is intended, economic considerations, flood conditions, the dimensions of the sites available, etc.

Purpose.—In certain cases the purpose of storage may influence the choice of a dam. Thus, the gravity dam is frequently preferred for water supply projects, because of its monumental proportions. In other cases, a hollow dam may be chosen, partly because it may afford housing for a power station or filter plant.

---

[17] A good sketch of the subject is that of Segré, "Cenni sugli studi geognostici applicati all'impianto di Laghi Artificiali", *Annali*, 1920; see, also, *Technical Publication No. 215*, Am. Inst. Min. and Metallurgical Engrs., "Geology and Engineering for Dams and Reservoirs."

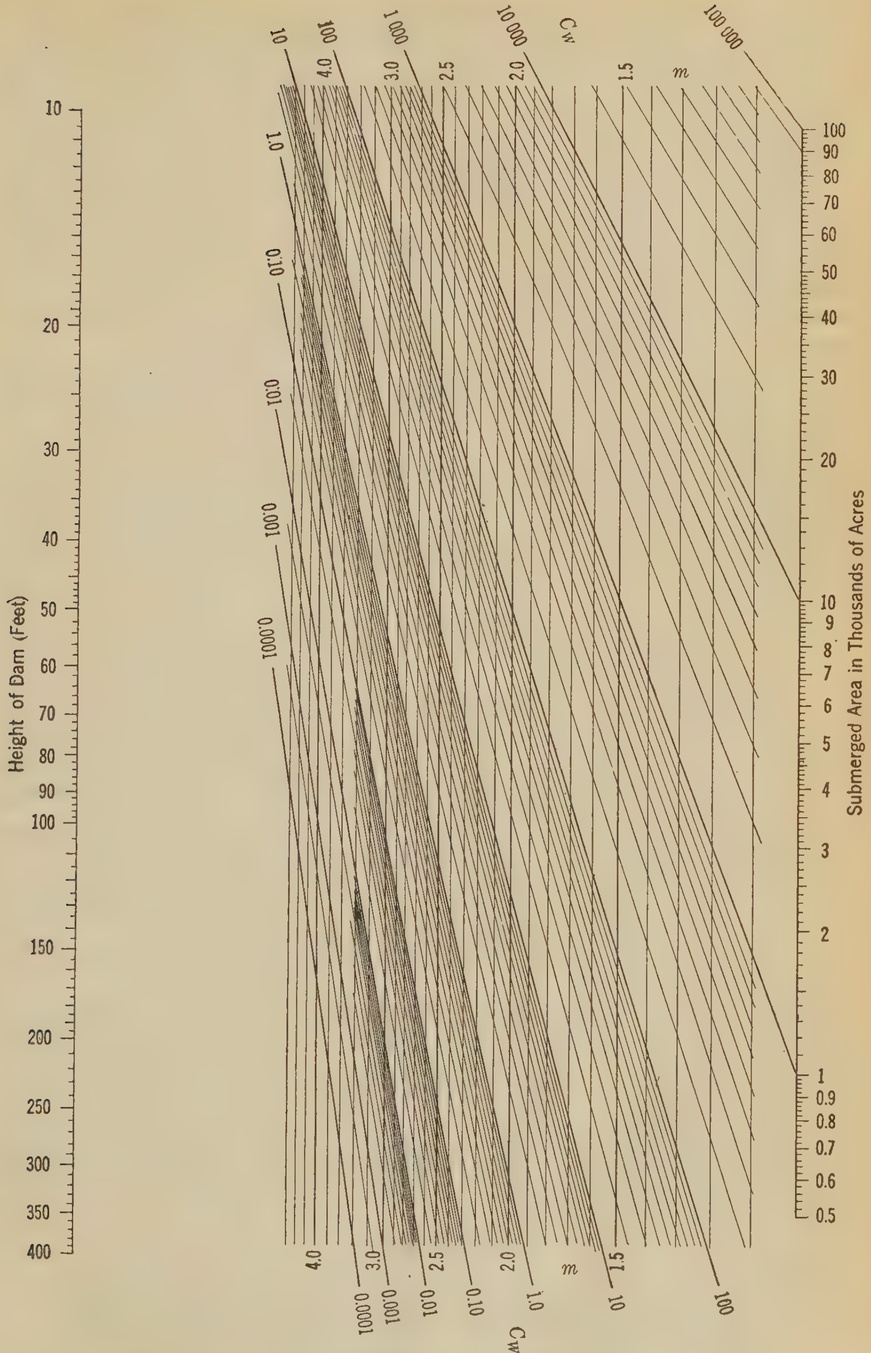

FIG. 6.—SUBMERGED AREA DIAGRAM.

The purpose of storage has an important bearing on the subject, not so much as affecting the choice of one particular type of dam, as in deciding whether the cheapest type is economically practicable. As a general rule (to which, of course, there are exceptions), the heaviest expenditure is permissible for water supply dams, less for power dams, and least for irrigation dams.

Economic Considerations.—Economic factors such as accessibility, cost of materials and labor, etc., and the return on capital outlay, are of prime importance in deciding the choice of dams. Where accessibility is poor, but timber abundant, the multiple-arch or Ambursen type is indicated. Where accessibility is poor and timber scarce, the earth or rock-fill type may be selected. No generalization is possible, and each case is treated on its merits, frequently by the preparation of estimates for alternative types.

Floods.—The necessity of providing for heavy floods will frequently have an important bearing on the choice of type of dam. Thus, heavy floods in a narrow gorge contra-indicate the choice of a high arched dam, unless the dam is to be built to a height sufficient to allow for the provision of a separate spillway or spillways away from the dam. Several fairly high arch dams constructed to pass heavy floods have been built, but unless the bed-rock is of exceptional hardness, it is considered good practice to avoid this. Good examples of overflow arch dams are seen in the following:

(*a*) Kerckhoff Dam, California, 94 ft. high from foundation to crest, and designed to spill 60 000 cu. ft. per sec. over the crest, with detached nappe.

(*b*) Cismon Dam, Italy, 140 ft. high from foundation to crest, and designed to pass 6 ft. of water over the crest with detached nappe. In this case erosion of the down-stream toe was avoided by the provision of a horizontal platform, level with the crest and extending about 75 ft. down stream. This platform is carried by a central pier and vertical arches.

(*c*) Turrite Dam, Italy, 130 ft. high from foundation to crest, of the over-fall type, but subject to relatively small flood flows.

(*d*) Baker River Dam, United States, 233 ft. high, passing heavy floods over the crest. This dam has a down-stream batter of 0.376 and is provided with a substantial curved bucket at the toe.

(*e*) Calderwood Dam,[18] Tennessee, 230 ft. high, can pass floods of 200 000 sec-ft.

Some high arch dams built in narrow gorges have been provided with spillway tunnels, the best example being that of the Shoshone Dam, and the shaft spillway is now coming into favor. The first spillway of this type appears to be that on the Bassano Canal, Italy,[19] which has a shaft diameter of 8.4 ft. and is designed to pass 1 120 cu. ft. per sec. More recent and much larger examples of almost perfect hydraulic design are the spillways of the Davis Bridge Dam, and of the Gibson Dam, both in America.

DAM SITES

The dimensions of the proposed site have a predominant influence on the choice of type of dam. Sites may be divided, broadly, into three types:

---

[18] *Engineering News-Record,* Vol. 103, No. 25, p. 954, December 19, 1929.

[19] "Sfioratori a Pozzi," Mario Luiggi, 1917.

(1) Those which are very narrow at the bottom but which broaden considerably at the top (see Fig. 2, Section *A*).
(2) Those with V-shaped walls that are practically straight.
(3) Those that are approximately U-shaped.

It may be said at once that the first or convex type of site is exceedingly rare, three examples being the Morena, Pacoima, and Jogne Dams. The second or V-type is also quite infrequent, an example being the site of the Stevenson Creek Experimental Dam.[20] The majority of dam sites belong to the third or concave type.

Characteristic canyon profiles may be represented by parabolic curves, using the word, "parabolic," in its mathematical sense[21] as the shape of curve represented by the equation,

$$y^p = Q\,x^q \dots\dots\dots\dots\dots\dots\dots\dots (5)$$

These curves may be represented by the general equation,

$$l = D\,h^v \dots\dots\dots\dots\dots\dots\dots\dots (6)$$

It will be obvious that the shape of the curve depends only on the index, v, while the scale, or the width at any height for curves of the same shape, depends on the value of the constant, D. Hence, the dimensions of any dam site, if the natural surface were perfectly smooth, could be represented by Equation (6) by selecting the appropriate values of the constants. The convex type would be characterized by values of v greater than unity, the V-type by $v = 1$, and the concave type by values of v less than unity. The site need not be symmetrical to comply with Equation (6).

Any attempt to determine from the section of a site the constants in Equation (6) is generally unsatisfactory, because of the marked irregularities of natural surface which generally occur. The writer has found, however, that the equation derived by integrating Equation (6) with respect to h, affords a satisfactory means of representing the average dimensional properties of almost any dam site. Equation (1) which is used for this purpose will be called the "site area equation." In this equation the value of n is a criterion of the type of site. Thus, the convex, V, and U-types of site are typified by values of n greater than, equal to, and less than 2.

The writer has computed and plotted site areas for more than fifty dams of all descriptions, and has found that although marked irregularities of natural surface are present the hypothesis of Equation (1) is well supported in practice. Fig. 7 shows the site-area curves for only a few of the profiles examined.

It should be noted that in the case of arched dams, the site section to be used is not that taken on a vertical section across the gorge, since the whole of the arch dam does not rest on this section. The section should be taken on chords across the curve of the dam. In the case of a proposed arch dam, this curve can be drawn on the contour plan in such a way that the arch at all points will abut satisfactorily on the sides of the gorge. Of course, when the contour lines are parallel, a vertical cross-section may be taken.

---

[20] *Proceedings,* Am. Soc. C. E., May, 1928, Pt. III.
[21] Frost in "Curves and Curve Tracing."

It may be thought that the use of the site-area curve is a somewhat roundabout way of defining mathematically the properties of a dam site. The method, however, has the great advantage that when the area is plotted against height on logarithmic paper, the straight line which best represents the points may readily be drawn by inspection, and this cannot easily be done if width is plotted against height. As a method of representation, the site-area equation is, of course, equally as good as the site-width equation, from which it is derived by integration. The process is seen to consist practically in replacing the actual site by another theoretical site having the same general properties.

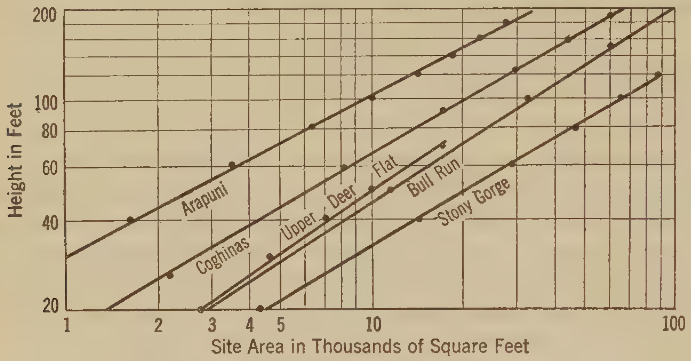

FIG. 7.—LOGARITHMIC SITE AREA CURVES.

Equation (1) may be represented graphically by means of an alignment chart (Fig. 8). This chart may be used to find C_A and n for any site by drawing straight lines between different points on the height scale, and corresponding points on the area scale, and selecting an average of the points of intersection. This point will define C_A and n.

VOLUME OF DAMS

Having seen that the dimensions of most dam sites may be approximately represented by a mathematical equation, it will be clear that the volume of dams built, or to be built, in such sites may be determined mathematically, since the cross-sectional dimensions of dams may also generally be represented by mathematical equations.

Gravity Dam.—The early profiles proposed by Rankine, Krantz, Harlacher, and others, which had curved faces, were dealt a severe blow by Atcherley,[22] and the modern gravity dam is practically triangular in cross-section. Wegmann's[23] practical profiles, and those recently proposed by Koechlin[24] are in effect triangular (except for the additional thickness of the crest), and where variations do occur, the profile may be represented for the present purpose by an equivalent triangular profile.

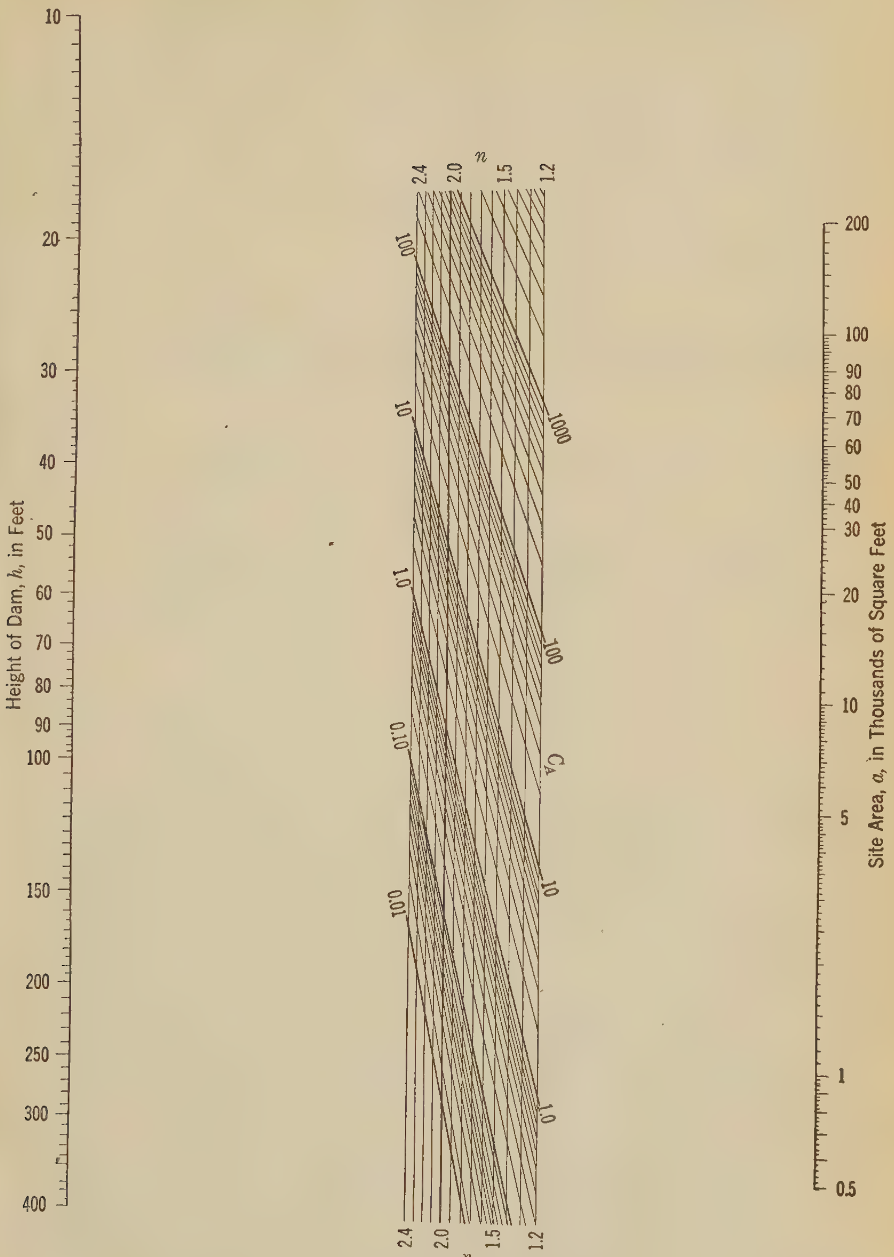

FIG. 8.—SITE-AREA DIAGRAM FROM EQUATION (1).

Referring to Fig. 9 in which the actual site is shown in full lines and the theoretical site in broken lines, and differentiating Equation (1):

$$l = D\,h^v = n\,C_A\,h^{n-1} \dots\dots\dots\dots (7)$$

For the triangular cross-section shown in Fig. 9,

$$t = K_g\,(H - h) \dots\dots\dots\dots (8)$$

The value of K_g is generally about 0.7 to 0.8; hence, the volume of an elementary slice of a dam in the theoretical site is:

$$d\,V = l\,t\,dh = n\,C_A\,K_g\,(H\,h^{n-1} - h^n)\,dh \dots\dots\dots\dots (9)$$

By integration, the total volume is:

$$V_g = \frac{C_A\,K_g\,H^{n+1}}{n+1} \dots\dots\dots\dots (10)$$

If the foot has been used as a unit throughout the paper, the result will be in cubic feet.

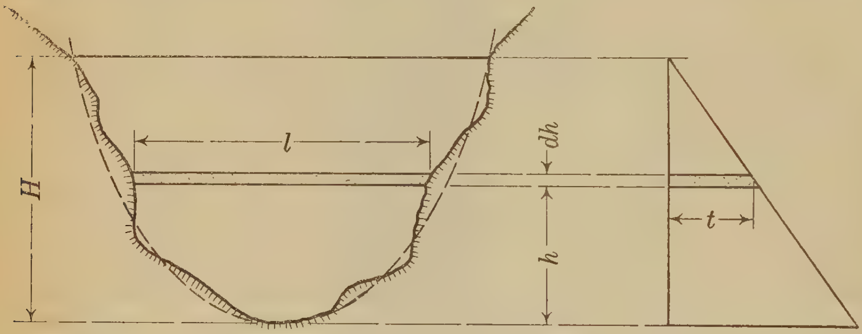

FIG. 9.—DIAGRAM OF A DAM SITE.

Equation (10) gives the volume of a gravity dam assumed to be built in the theoretical site, by which the actual site was tacitly replaced when Equation (1) was adopted for the computation. The volume thus found agrees very closely with that of a dam in the actual site, provided ordinary judgment has been used in drawing the site-area graph (Fig. 8) to represent the plotted points, and the values of C_A and n have been correctly derived.

All dams are excavated to a greater or less depth into the bed-rock, but the basis on which Equation (10) rests, does not allow for this. It will be seen, however, that a very small error is made by adding an appropriate height to H, the net height of the dam, in order to allow for foundation excavation.

Equation (10) neglects the masonry of the crest in excess of that required by the triangular profile. The volume of the crest may be computed very easily, or a percentage added to the volume found by formula.

The alignment chart is convenient for representing Equation (10) in a form suitable for rapid use, and such a chart is shown in Fig. 10. This chart will give the same results as the formula, with an error (in reading) within 2 per cent.

Fig. 10 is based on a value of K_g equal to 0.7 and includes 5% excess volume for crest thickness, this having been found by experience to be an average value. The chart may be used as it stands to determine approximately the volume of a gravity dam of moderate height in a site for which the values of C_A and n have been determined. In other cases, as, for example, very high dams, or those in which allowance is made for a high degree of uplift, a preliminary design of cross-section is required to determine the appropriate value of K_g.

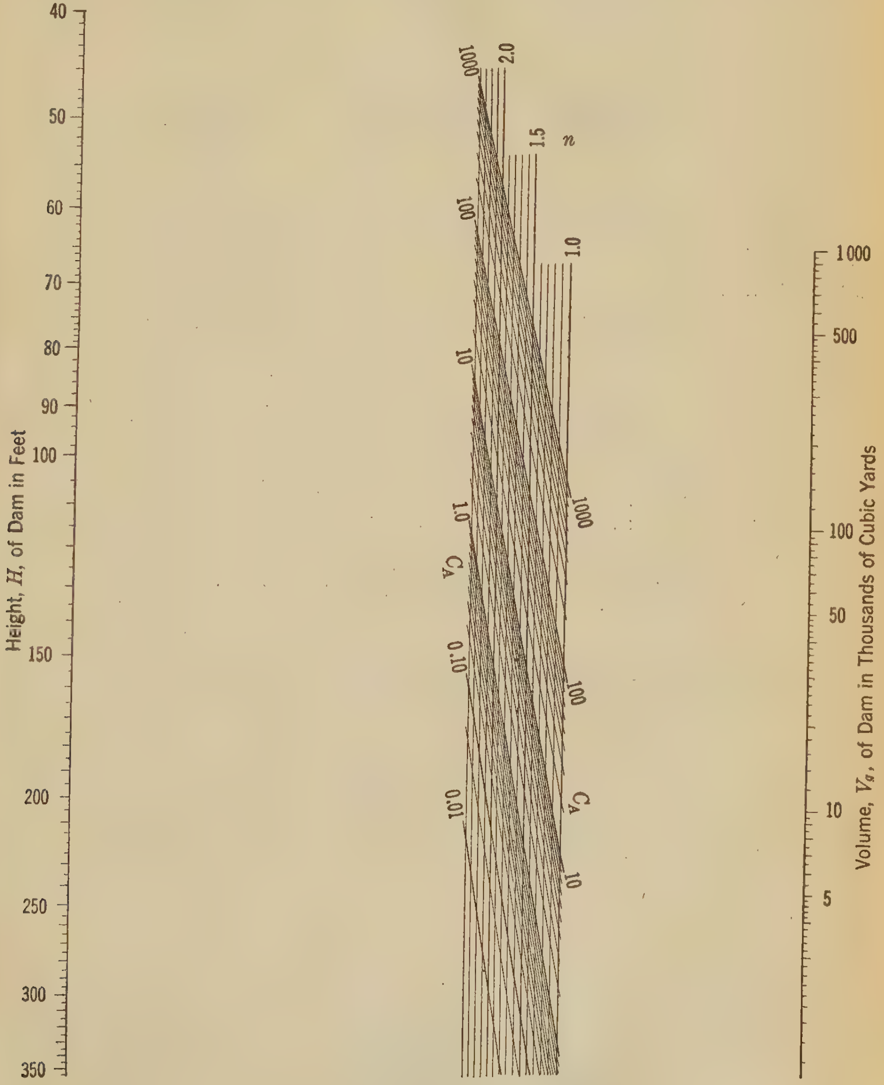

Fig. 10.—Volume of Gravity Dam.

It may be stated at once that the writer does not suggest that the equation or chart should ever be used for an accurate computation of quantities, as for a contract, since the mensuration, although itself mathematically accurate,

is based essentially on an approximation, and no engineer would stake his reputation on an approximate method. The method is valuable, however, for many preliminary studies, and the use of the chart enables a volume to be found in a few minutes, which by the usual methods of calculation would require many hours' work.

In Table 2 are given the values of C_A and n for a number of sites as determined from the site area graphs, such as Fig. 8. These data, together with the actual height above foundation, and the total batter, are used to obtain the theoretical volume, which is compared with the actual volume.

The values of n and C_A for Item No. 2 of Table 2 refer to the developed up-stream face. A correction was made for arch curvature in this case by multiplying the computed volume by a factor,

$$\frac{\text{Up-stream radius} - \frac{1}{4}\text{ base width}}{\text{Up-stream radius}} = 0.92$$

Thus, an allowance is made for the reduced radius, measured to the center of gravity.

The computed volumes for Items Nos. 4 and 16 were multiplied by 1.03 and 1.06, respectively, to allow for curvature. Due to an added width of base, 64 000 cu. yd. were added to the volume of Item No. 14 as computed by the charts.

The actual volumes given for Items Nos. 1, 11, and 17 include estimates of quantities in the spillways, access bridges, etc., the amount of which was not known.

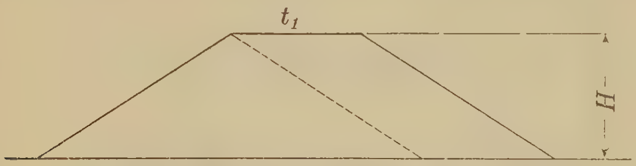

FIG. 11.—TYPICAL TRAPEZIUM CROSS-SECTION.

DAMS OF TRAPEZIUM CROSS-SECTION

The earth and rock-fill dam is almost always trapezoidal in cross-section. In some cases, one or more berms are provided and the batter may vary slightly from crest to base. In such instances, an equivalent trapezium section may be drawn. Gravity dams are also sometimes of trapezium cross-section. For example, the cross-section in Fig. 11 may be divided into two parts. One part is triangular, and the equivalent volume may be found from the same formula as for a gravity dam (Equation (10)), by inserting K_R for K_g. In this paper the batter is defined as the ratio of horizontal increment to vertical increment. The reciprocal of this ratio is sometimes referred to as the batter. The volume of the second part is simply the site-area to height, H, multiplied by t_1.

The total volume in cubic feet, therefore, is,

$$V_R = C_A \left(\frac{K_R\, H^{n+1}}{n+1} + t_1\, H^n \right) \dots\dots\dots\dots\dots\dots (11)$$

The volume in cubic yards can also be readily found from the charts by taking $\frac{K_R}{0.735}$ times the volume of a gravity dam to height, H, from Fig. 10, plus $\frac{t_1}{27}$ times the site-area to height, H, from Fig. 8. In Table 2, Items Nos. 18 to 24, inclusive, have been prepared to furnish a comparison between the actual volume of a number of dams and the volume obtained by Equation (11). In the case of arch dams, a factor of 1.05 is introduced to allow for the additional length along the mean arc. For Items Nos. 19 and 21, the value of H is listed as 218 and 328, respectively. In computing the volumes by Equation (11), the values used were 223 and 338, respectively, in order to make allowance for excavation.

PLAIN ARCH DAMS

A plain arch dam with vertical up-stream face and uniform cylinder stress is theoretically of triangular section. The cylinder stress is the arch stress computed by the cylinder formula. As is well known, it may differ considerably from the stress that actually exists. The down-stream batter is uniform and is equal to,

$$K_A = \frac{62.4\ R_u}{144\ f} = 0.434\ \frac{R_u}{f} \ldots\ldots\ldots\ldots\ldots\ldots(12)$$

The volume may best be found by the same formula as for a gravity dam by inserting K_A for K_g in Equation (10) and multiplying by a factor to allow for curvature. The factor, 1.05, which corresponds to a mean subtended angle of about 60°, may be used for this purpose. For other values of the mean subtended angle the factor may be read from the curve in Fig. 12.

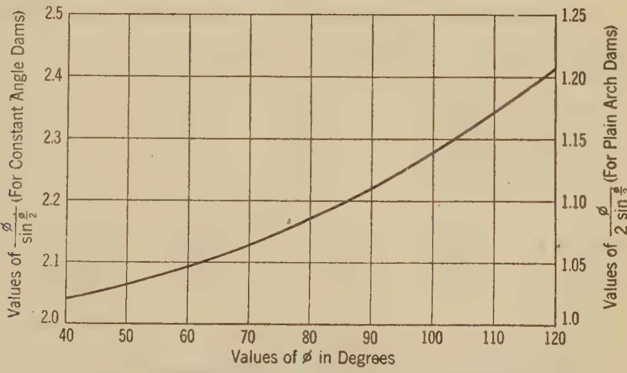

FIG. 12.—CURVATURE FACTORS FOR ARCH DAMS.

In Table 2, Items 25 to 29, inclusive, show volumes for five arch dams. In all cases, 5% has been added for additional material in the crest. Another 5% has been added in all cases to take account of curvature. The quantity given as actual volume in Item No. 27 includes the volume of the bucket on the down-stream side of the dam.

From the fact that the use of the formula for the volume of a gravity dam has been recommended for finding that of an arch dam, it must not be assumed that this volume varies directly as C_A, or as the $(n + 1)$ power of the height. This is not so. A formula can be derived as follows: Take a crest angle of 110° and write,

$$R_u = 0.613\, n\, C_A\, h^{n-1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

Inserting this value of R_u in Equation (12) and the resulting value of K_A in Equation (10), and also introducing a curvature factor, $\dfrac{\phi}{2 \sin \dfrac{\phi}{2}}$, the result is,

$$V_A = \frac{0.266 \left(\dfrac{n}{n+1}\right) C_A^2\, H^{2n}}{f} \times \frac{\phi}{2 \sin \dfrac{\phi}{2}} = \frac{J_A\, C_A^2\, H^{2n}}{f} \ldots\ldots (14)$$

To determine the values of J_A in terms of n for different crest angles, several "type" designs were developed for a crest span of 600 ft. and a height of 100 ft. (the values used are immaterial). The values of the curvature factor were obtained by weighting the value of the ratio, $\dfrac{\text{arc}}{\text{chord}}$, at different points by the volume per foot of height at that point and thus obtaining the weighted mean. Values of this curvature factor and of J_A are given in Table 3.

TABLE 3.—VALUES OF CURVATURE FACTORS AND J_A.

Crest angle, in degrees.	n.	$\dfrac{\phi}{2 \sin \dfrac{\phi}{2}}$	J_A.

CONSTANT-ANGLE ARCH DAMS

Constant-angle arch dams are generally designed in the first place by the use of the cylinder formula, modifications being then made on the basis of more accurate and frequently involved analyses. In any case the cylinder stress is readily determinable.

It will be assumed that the up-stream radius varies linearly from crest to base, an assumption which is generally valid.[25] It will also be assumed that the cylinder stress and the subtended angle are uniform from crest to base. Actually, this is not always true,[25] but average values may be chosen to represent, fairly well, the actual value. In the case of a preliminary design, the cylinder stress is taken to be uniform throughout.

---

[25] Due to Mr. Nimmo, in his discussion previously mentioned.

Now, the thickness at the height, h, is,

$$t = \frac{0.434}{f} R_h (H - h) \qquad (15)$$

in which,

$$R_h = R_2 + \frac{h}{H} (R_1 - R_2) \qquad (16)$$

Substituting this value of R_h in Equation (15):

$$t = \frac{0.434 (H - h)}{f} \left[R_2 + \frac{h}{H} (R_1 - R_2) \right] \qquad (17)$$

The length of arc is $\dfrac{n\, C_A\, h^{n-1}\, \phi}{2 \sin \dfrac{\phi}{2}}$. The volume of an arch element at a height, h, is, therefore,

$$d\,V = \frac{0.434\, n\, C_A\, \phi\, h^{n-1} (H - h) \left[R_2 + \dfrac{h}{H} (R_1 - R_2) \right]}{2\, f \sin \dfrac{\phi}{2}}\, dh \qquad (18)$$

Integrating between $h = 0$ and $h = H$ and reducing:

$$V_{CA} = \frac{0.217\, n\, C_A\, \phi\, H^{n+1} \left[\dfrac{n\, R_1 + 2\, R_2}{n\, (n + 1)\, (n + 2)} \right]}{f \sin \dfrac{\phi}{2}} \qquad (19)$$

Theoretically, the constant-angle dam has the same subtended angle from crest to base. The most economical angle is about 133°, but comparatively wide variations do not cause very much alteration in the quantity of material in the arch. It is due to this fact that the method of analysis leading to Equation (19) is legitimate. The subtended angle for constant-angle arch dams is generally about 110° to 120° over the upper portion of the dam, the angle falling away rapidly toward the base. For use in Equation (19), a value of 85° to 95° gives satisfactory results. Values of the factor, $\dfrac{\phi}{\sin \dfrac{\phi}{2}}$, for various angles are given in Fig. 12.

Table 2, Items Nos. 30 to 40, inclusive, shows a comparison between actual quantities for a number of dams and those obtained by Equation (19). In Item No. 32, the writer added 15 ft. for foundations and reached an assumed value of H, equal to 70 ft. Likewise, for Items Nos. 35 and 36, 10 ft. were added to the net height to allow for foundations. For Items Nos. 37 and 39, 5 ft. were added for foundations. The heights of these four items were further increased 5% to make allowance for the crest. The actual volume listed for Item No. 39 includes approximately 24 500 cu. yd. of extra material in the gravity base. This dam (Lake Spaulding) was partly constructed as a gravity dam and later was altered to a constant-angle type. The concrete in the constant-angle dam is, therefore, about 167 500 cu. yd. The computed volume of Item No. 40 is as presented by Mr. Nimmo.[26]

A comprehensive formula for the volume of a constant-angle arch dam can also be found in much the same way as Equation (14) was derived for the volume of an arch dam. Three "type" designs were prepared on the following basis:

Height, in feet	100
Crest span, in feet	800
Crest angle, in degrees	116
Cylinder stress, in pounds per square inch	300

$n = 1.6$, 2.0, and 2.4, respectively.

The up-stream radii were made to reduce linearly from the crest to one-fifth of the height, at which point the radius was taken as R_2. Furthermore, the radii were naturally made as small as possible without undercutting on the up-stream face. From these trial designs, the factors involving radii and angle in Equation (19), can be expressed in terms of n and of crest span, on which alone the radii and angles depend, under the assumptions stated.

In Equation (19) let, $0.217 \dfrac{\phi}{\sin \dfrac{\phi}{2}} \left[\dfrac{n R_1 + 2 R_2}{n(n+1)(n+2)} \right]$ be made equal to $J \times$ the span, or $J \times n\, C_A\, H^{n-1}$, in which, J is a function of n only.

Inserting this value in Equation (19),

$$V_{CA} = \frac{J n^2 C_A^2 H^{2n}}{f} = \frac{J_{CA} C_A^2 H^{2n}}{f} \quad \ldots\ldots\ldots\ldots (20)$$

which is similar to Equation (14). For practical purposes, J_{CA} may be taken as 0.147. Equation (20), therefore, may be reduced to,

$$V_{CA} = \frac{0.147\, C_A^2 H^{2n}}{f} \quad \ldots\ldots\ldots\ldots (21)$$

which is a very simple expression for the volume of a structure of relatively complicated design.

Equation (21) may be solved by the use of the alignment chart, Fig. 13. For this purpose, f is assumed as 300 lb. per sq. in. For other values of f the volume can be adjusted proportionately. To allow for crest thickness increase the volume from 2 to 5 per cent. The error introduced by using this equation is not greater than that by Equation (19), and the alignment chart introduces only a small reading error.

USE OF VOLUME FORMULAS

Equations (10), (11), (14), and (20) have been evolved for gravity, rock-fill (or trapezoidal dams of any type), arch, and constant-angle dams, respectively. They have been found by test to give errors in most cases within 5%, as compared with the actual volume of constructed dams, or the carefully computed volume of proposed dams. For many preliminary purposes these equations, or the charts derived from them, therefore, may be used to estimate

---

[26] In his discussion previously mentioned.

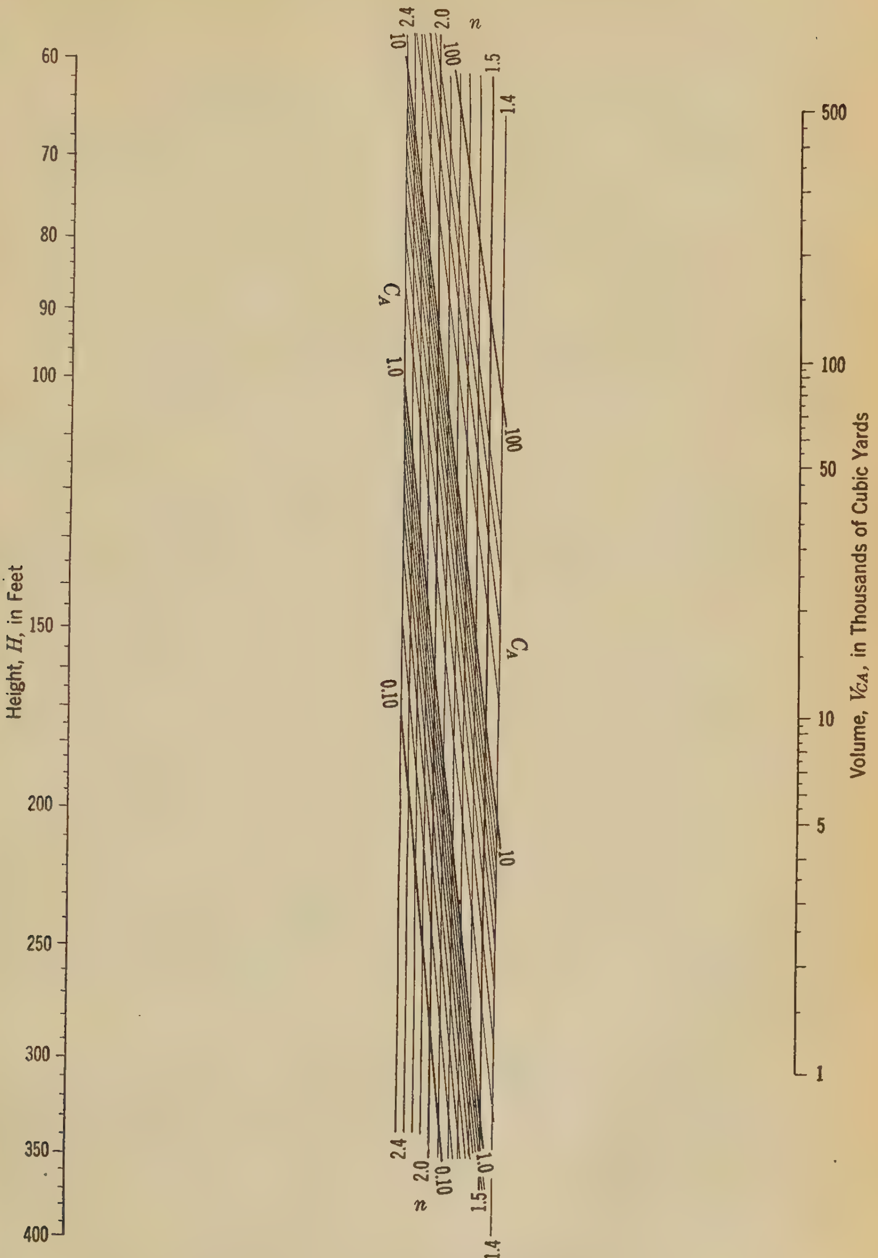

FIG. 13.—VOLUME OF CONSTANT ANGLE ARCH DAM.

roughly the volume and cost of a proposed dam. In this connection it should be stated that the comparison made between volumes computed by the formulas and volumes of actually constructed dams is not quite a fair one. Before work is commenced on a dam, quantities are always computed very carefully, on the basis of the best information obtainable as to excavation, etc. It is a matter of common knowledge, however, that the computed quantities may be largely exceeded, and, in any case, there is a fairly large probability of error because of unknown factors. A comparison between actual quantities and quantities computed in the ordinary way would show the occurrence of errors in many cases as large as those shown in Table 2.

Another useful purpose to which the formulas may be put is to determine approximately the effect on volume of some alteration in the design of a proposed dam. For instance, in a rock-fill dam it may be desired to vary the crest thickness or the batters. The additional volume required in a gravity dam to allow for a certain degree of uplift may be determined, and the cost compared with that of a method (such as drainage or water-proofing) intended to prevent uplift. The effect of small variations in height is also seen.

Volume per Foot of Height.—For some purposes, such as the design of chuting equipment and the planning of the construction program, it is desirable to know the volume per foot of height at different elevations.

This can readily be found for a gravity or plain arch dam from Equation (9), by placing $d\,h = 1$. It will be obvious that the lower the value of n, the greater will be the volume of concrete in the lower part of the dam, as compared with the higher part. That is, the lower part will be the center of gravity. If the curve representing volume per foot plotted against height is drawn, the shape of this curve depends only on the value of n. The horizontal scale depends on C_A and the vertical scale on the height. Thus, a set of curves for different values of n could be drawn up and applied to any dam by using appropriate scales depending on the height and the value of C_A.

In the case of the arch dam the shape of the curve is similar, but the volume per foot varies as C_A^2 and not as C_A (assuming the same subtended angle and stress). Actually, most of the volume of a gravity or plain arch dam is in the lower portion. In the case of a constant-angle dam, the point of maximum volume is generally between 0.5 and 0.7 of the height, the lower value occurring with relatively low values of n and the higher value with high values of n.

SUITABILITY OF SITES FOR DAMS OF THE ARCH TYPE

There is a large class of sites that apparently may be suitable for a dam of the arch type, although the site is not so narrow as to indicate at once the choice of an arch dam. It is convenient to have a criterion for the rapid examination of such sites.

If,

$$J_A = 0.434\,\frac{R_u}{L}\left(\frac{n}{n+1}\right)\left(\frac{\phi}{2\sin\dfrac{\phi}{2}}\right)$$

Equation (14) may be written,

$$V_A = 0.434\ \frac{R_u}{L}\left(\frac{C_A^2\ H^{2n}}{f}\right)\left(\frac{n}{n+1}\right)\left(\frac{\phi}{2\sin\frac{\phi}{2}}\right) \ldots\ldots\ldots\ldots(22)$$

The volume of an arch dam may then be determined in terms of that of a gravity dam and relative to the theoretical crest span. For this purpose note that,

$$V_G = C_A\ K_G\left(\frac{1}{n+1}\right)H^{n+1} = \frac{n\ K_G\left(\frac{1}{n+1}\right)C_A^2\ H^{2n}}{L} \ldots\ldots\ldots(23)$$

Hence,

$$\frac{V_A}{V_G} = \frac{0.434\ \frac{R_u}{L}\ \frac{\phi}{2\sin\frac{\phi}{2}}}{f\ K_G}\ L \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(24)$$

or,

$$V_A = V_G\ Q_A\ L \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(25)$$

Let $f = 300$ lb. per sq. in. and $K_g = 0.7$, and insert in Equation (24) the values already found for the other terms; then successive values of Q_A for various crest angles and spans are as listed in Table 4.

TABLE 4.—VALUES OF Q_A IN EQUATION (25).

Crest angle, in degrees.	n.	Q_A.	Maximum span.
120	2.0	0.125	800
	1.6	0.127	787
	1.2	0.134	746
100	2.0	0.140	715
	1.6	0.141	710
	1.2	0.147	680
80	2.0	0.1646	608
	1.6	0.1654	603
	1.2	0.169	591
60	2.0	0.209	477
	1.6	0.210	476
	1.2	0.212	472

The constant, Q_A, is seen to express the volume of an arch dam (cylinder stress, 300 lb. per sq. in.) in terms of that of a gravity dam (total batter, 0.7) as a percentage per foot of the theoretical crest span. The figures given for "maximum span" represent the spans which would make the volume of the arch dam equal to that of the gravity dam. The practical span, of course, will be less.

For a constant-angle dam, a similar procedure can be followed, but because the volume is, within practical limits, only very slightly dependent on the subtended angle, the expression derived is simpler. Thus,

$$\frac{V_{CA}}{V_G} = \frac{100\ J_{CA}\ (n+1)}{210\ n}\ L = Q_{CA}\ L \ldots\ldots\ldots\ldots(26)$$

Values of Q_{CA} for use in this equation are listed in Table 5. The practical use of these results (Tables 4 and 5) is to determine rapidly for any given site and height of dam, what degree of economy may be effected by the use of an arch as against a gravity dam. The arch dam will be required to show considerable economy in material for the following reasons: (1) The design and setting out of the dam is more complicated; (2) the cost of form work per cubic yard is higher, since the faces are curved and frequently warped and the sections are less massive; (3) the concrete is frequently made either richer in cement or with a less quantity of large rock added; (4) greater care is generally required in construction; and (5) the cost of spillways and accessory works may be higher since the arch dam is less conveniently adapted for passing floods over the crest.

TABLE 5.—VALUES OF Q_{CA} IN EQUATION (26)

n.	Q_{CA}.	Maximum span.
2.4	0.1055	958
2.0	0.1054	959
1.6	0.1138	878
1.2	0.1288	776

Table 6 has been prepared to show the relative suitability of various sites on which dams of the plain arch or constant-angle arch type have been constructed, or for which they have been proposed. The table is based on the following assumptions:

1.—The cylinder stress in all cases is 300 lb. per sq. in.
2.—The correct values are given for the crest angle where it is known. Other values are assumed.
3.—In Items Nos. 1 to 10, inclusive, the dams have a vertical up-stream face.
4.—In Items Nos. 11 to 27, inclusive, the up-stream radii at other points than the crest are made as small as possible without undercutting.
5.—The gravity dam used for comparison has a value, $K_g = 7$.

Table 6, therefore, compares, on a uniform basis, the merits of the sites only, and has no reference to existing or proposed dams on the sites. This is considered the most reasonable method of comparison, since the design of the actual dams may vary considerably from the bases assumed, because of a variety of factors, such as the strength of rock, the predilections of the engineers, or local peculiarities of the site, and it would be difficult to make just allowance for all these factors.

Items Nos. 8, 9, 10, and 22 to 27 inclusive, contain data relating to sites at which actually other types of dam are constructed or proposed, but where dams of the arch or constant-angle arch type, under certain circumstances, might be suitable.

It appears evident that, for economy, the volume of an arched dam should not exceed 80% of that of a gravity dam, on the assumptions mentioned. In other words, the theoretical crest span should not exceed 80% of the maximum permissible span. It must be remembered, however, that favorable circumstances such as very resistant rock may influence the design of an arched dam to a much greater extent than in the case of a gravity dam. The profile of the latter may be varied only between comparatively narrow limits, no matter how excellent the site, but an arch dam may be designed so as to use more effectively the strength of the foundations and of the material of construction. The Gibson Dam exemplifies this fact, and it represents no doubt the first step in the direction of broadening the scope of arch dams by a more rational system of design and technique of construction.

MOST ECONOMICAL SIZE OF INSTALLATION

For every installation involving storage there exists a size of storage which gives the most economical result in terms of cost per second-foot of regulated outflow.[27] By means of the procedure outlined in this paper, and following the general lines of the method previously used by the writer,[28] the curve of specific cost (total cost of installation per second-foot of regulated outflow), may be found very readily for any particular case, and the most economical size of installation determined.

---

[27] "The Most Economical Size of a Hydro-Electric Installation," by A. B. Mead, *New Zealand Journal of Science and Technology*, 1921.

Whether the installation adopted will be of the size indicated by considerations of lowest specific cost depends on a large number of local conditions, which must be considered for each particular case. In general, there will be a tendency to push the size somewhat beyond the point of lowest unit cost, although the installation may be developed in stages.

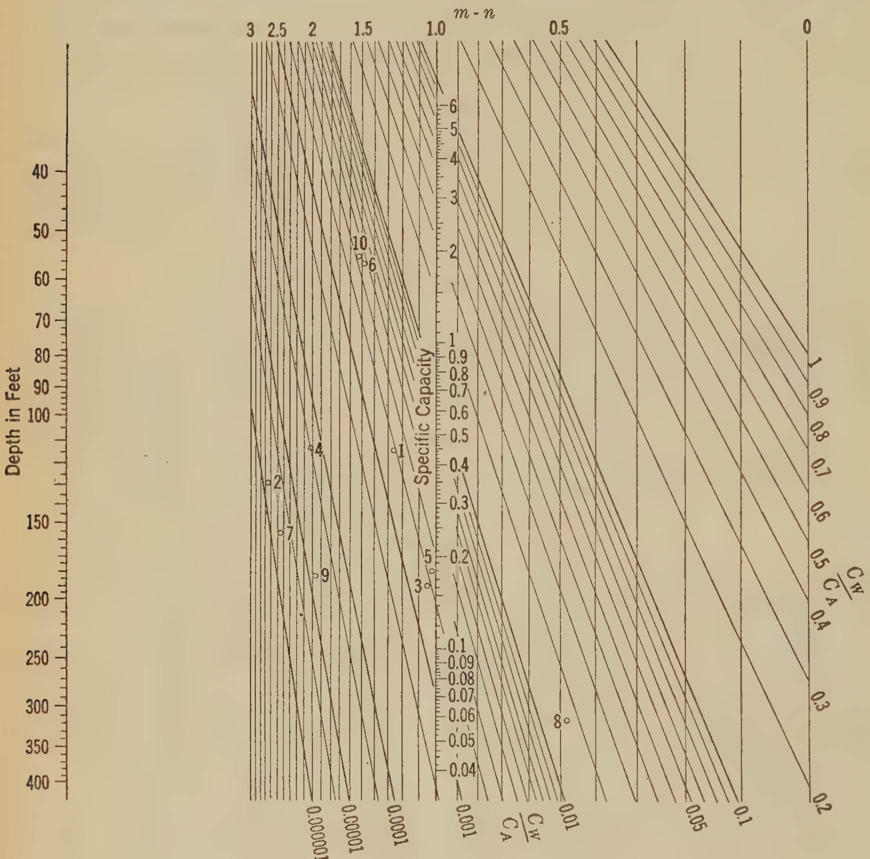

FIG. 14.—SPECIFIC CAPACITY OF GRAVITY DAMS.

The method is useful in the study of any proposed plan, but is not intended to constitute a hard and fast rule by which the size of installation is to be fixed. It may be stated, however, that many economically and technically unsound projects would never have been adopted had such a method of study been in general use in the past.

SPECIFIC CAPACITY

Specific capacity will be defined as the acre-feet of reservoir capacity per cubic yard of material in the dam. By means of formulas developed herein, the specific capacity can be determined approximately for gravity, arch, and constant-angle arch dams. The results are useful in enabling an opinion to be formed as to the economic nature of any storage proposal, or for comparing quickly the merits of different reservoirs and sites.

Gravity Dams.—Let $h_1 = 174$, $H = 194$, and $n = 1.64$ (average values from Table 2). Then Equations (2) and (10) can be modified by the insertion of these quantities, and combined to form the following formula for specific capacity of a gravity dam:

$$w_{SG} = 72.9 \frac{C_W}{C_A} h_1^{m-n-1} \dotfill (27)$$

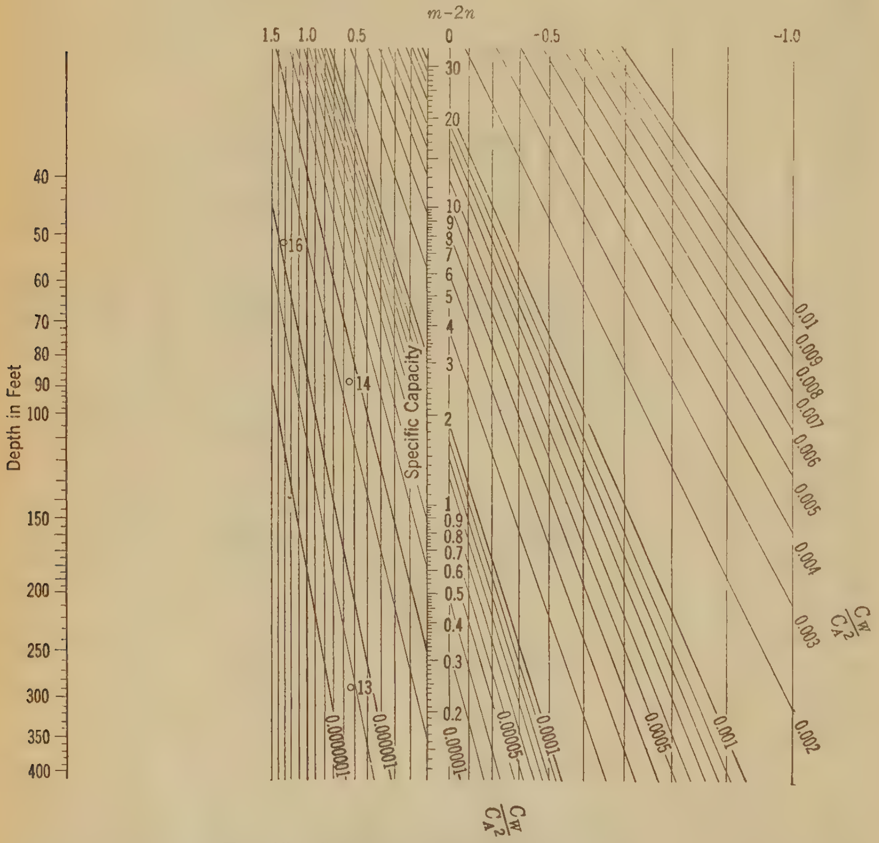

FIG. 15.—SPECIFIC CAPACITY OF ARCH DAMS.

This formula will give reasonably correct results for dams of about the height mentioned, when the depth of excavation below the river bed is relatively unimportant, but it may be considerably in error for low dams, or for sites at which heavy excavation below the river bed is involved.

Equation (27) has been represented as an alignment chart in Fig. 14, and a comparison of the results obtained from the chart with actual values is shown in Table 7, Items Nos. 1 to 10, inclusive. No allowance has been made for the fact that in some cases the batter differs somewhat from the value of 0.7, on which the formula is based. Discrepancies are due to this variation in K_g, and to variations of n, height, and difference between height and depth, from the values assumed. The "actual" specific capacity for Items Nos. 5, 6, and 9 (see Column (13), Table 7) are estimated. Values of the quantity, $\frac{1}{n+1}$, vary from 0.322 at Item No. 4 to 0.435 at Item No. 5. In solving Equation (27) for values in Column (13) a mean value of 0.380 was used. Errors due to this cause alone may therefore be equal to about 20 per cent.

Arch Dams.—The assumptions necessary to derive a simple formula for specific capacity for gravity dams have been seen in Table 7 to lead to only approximate results. In the case of arch dams the variables are even more numerous, and the degree of approximation, therefore, is even less close. Let $\phi = 90°$, $n = 1.50$, $h_1 = 200$, and $H = 220$. Then, as before, Equations (2) and (14) may be combined to form an equation for specific capacity, in acre-feet per cubic yard, as follows:

$$w_{SA} = 30\ 000 \frac{C_W}{C_A^2} h_1^{m-2n} \dots\dots\dots\dots (28)$$

This formula is represented graphically in Fig. 15, and a comparison of results obtained by its use with the actual values of specific capacity is shown in Table 7, Items Nos. 11 to 15, inclusive. Unfortunately, the number of arch dams for which particulars are available regarding both the storage and the site is rather limited. Table 7, therefore, shows also the values of specific capacity for certain other sites in which dams of the arch type might be constructed (see Items Nos. 11 and 13). The values for Items Nos. 11 to 15, inclusive, in Column (12), were corrected for stress only.

Constant-Angle Arch Dams.—Let $n = 1.75$, $h_1 = 210$ ft., and $H = 230$ ft. Then, as before, the expression for specific capacity for a constant-angle dam may be written:

$$w_{SCA} = 38\ 000 \frac{C_W}{C_A^2} h_1^{m-2n} \dots\dots\dots\dots (29)$$

This formula is represented in Fig. 16 and the results obtained are given in Table 7, Items Nos. 16 to 21, inclusive.

It is also interesting to compare values of the specific storage for actual dams which have been built for different purposes, irrespective of the type used. In Figs. 17 and 18 only masonry dams have been included, since for dams built of this material the relative costs of storage can be compared roughly on the same basis. These diagrams may be taken as showing broadly values of the specific capacity which have been found economic for the purposes named, although naturally a number of local factors will alter the economic limits in each particular case. The upper and lower limits for specific storage are such that, for storages of 10 000 to 100 000 acre-ft., a much lower specific storage (and, hence, higher unit cost) is permissible for water supply purposes than for irrigation or power.

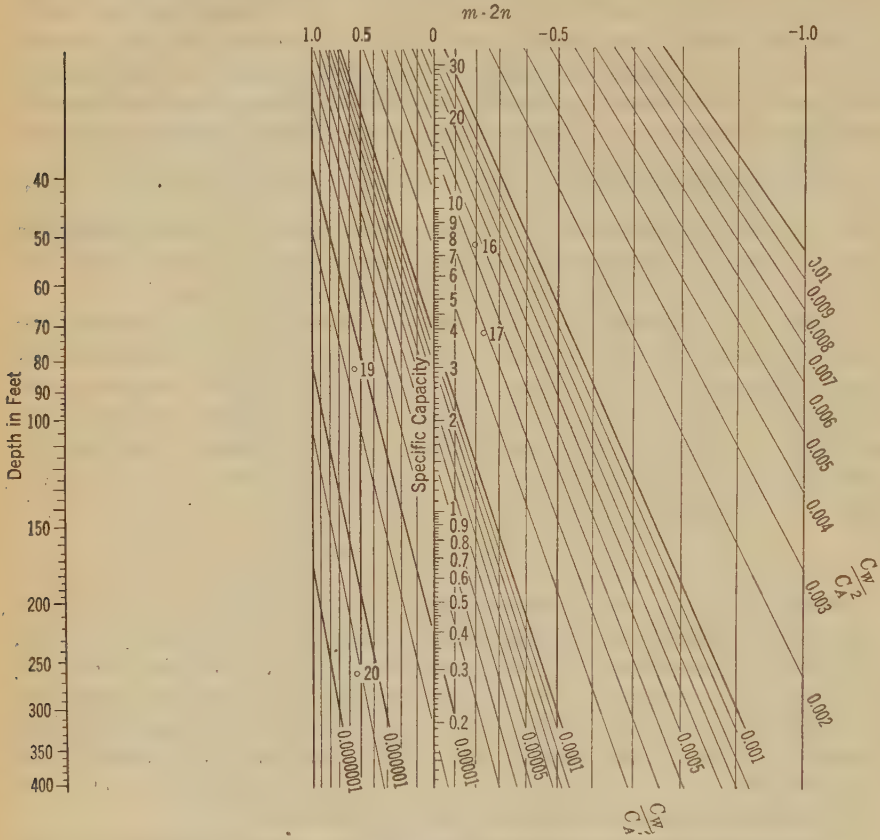

Fig. 16.—Specific Capacity of Constant-Angle Arch Dams.

It is usually desirable that "specific capacity," should increase with the height of dam; in other words, that, for gravity dams, m should exceed $n + 1$, and, for arch dams, m should exceed $2n$; but in practice this is quite frequently not so, as will be seen from the values given in Tables 1 and 2. When these conditions are not fulfilled, it would theoretically be cheaper to build two or more dams of less height instead of one; but suitable sites are generally lacking.

Average Cost of Storage

A number of writers have quoted figures for the cost per acre-foot of various storages. Thus, Wilson[29] quotes unit costs for a large number of storages, mainly for irrigation, in different countries. The reservoirs are arranged in order of increasing magnitude, and with increasing capacity the unit cost tends to fall. Exceptions are due to the reservoirs having been constructed in different countries, at different times, and under a variety of different conditions.

---

[29] "Manual of Irrigation Engineering," 1893, Table XI.

A better method of stating "unit costs" is by means of the volume of dam per acre-foot of storage. Actually, the cost of a dam is not strictly proportional to the volume, but it is approximately so. By this means, the physical merits of various storages may be compared, irrespective of the time at which they were completed or the economic conditions of the country.

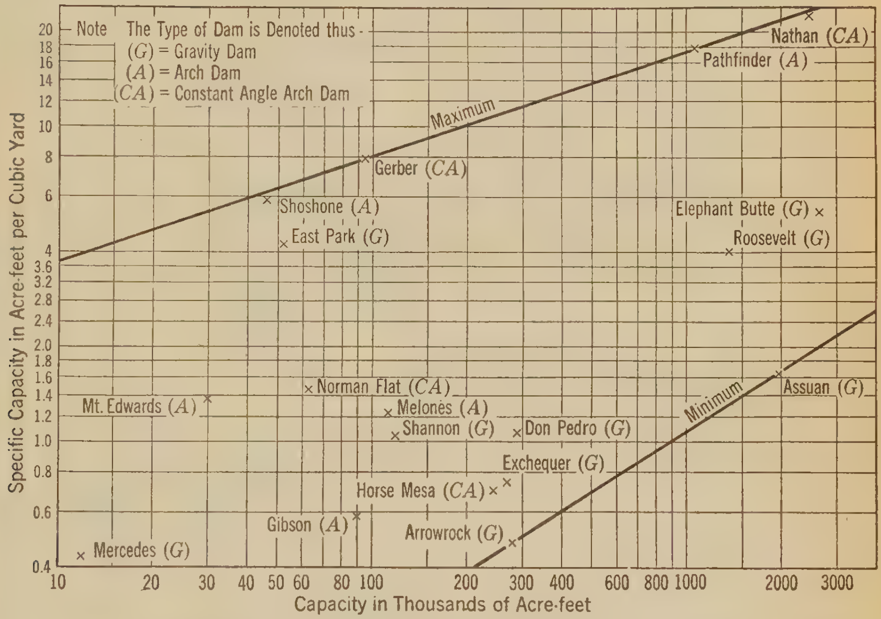

FIG. 17.—COMPARISON OF SPECIFIC CAPACITY FOR DAMS BUILT FOR IRRIGATION PURPOSES.

The various types of dam, such as masonry, earth-fill, and rock-fill, are then comparable in each group, but not between groups without introducing factors depending on the relative costs of the materials of construction.

CONCLUSION

It is the writer's hope that this outline, although "sketchy" in parts, will point the way to a more scientific treatment of the many aspects of water conservation. Some at least of the factors which have been treated in the past by rule-of-thumb or trial-and-error methods have here been shown to be susceptible of graphical or mathematical treatment.

Many agencies are engaged in taking stock of water resources in various countries, and the use of the methods outlined will enable development to be planned in the most economical manner.

ACKNOWLEDGMENTS

The writer wishes to acknowledge the use of information culled from many sources. Some of these are cited in footnotes, but much matter noted during

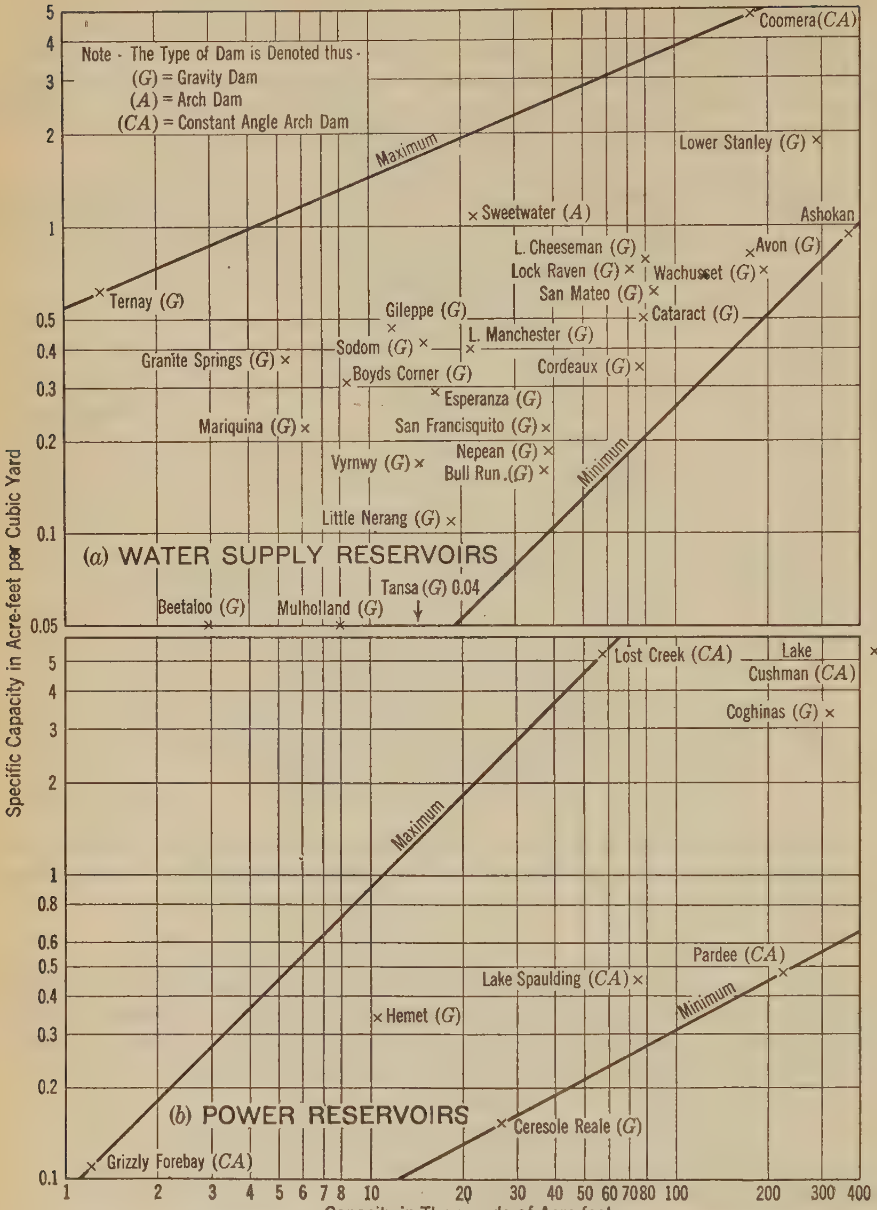

Fig. 18.—Comparison of Specific Capacity for Dams Built for Water Supply and Power Reservoirs.

the course of his professional work, from current and past technical literature, from information privately supplied by friends, notably W. H. R. Nimmo, M. Am. Soc. C. E., and from other sources, has been incorporated.

He also wishes to thank A. F. Partridge, Commissioner for Irrigation and Water Supply, Queensland, for permission to use information relating to proposals in Queensland, and R. J. Spowart, Jun. Am. Soc. C. E., for much valuable assistance in the preparation of diagrams and with the computations.

DISCUSSION

E. C. Eaton,[30] M. Am. Soc. C. E. (by letter).—The writer has read with interest and benefit the excellent paper by Mr. Sutherland. The subject is particularly applicable to many of the problems facing engineers in Los Angeles County, California, where lack of water is the only limitation to expansion and prosperity, and where regulation and conservation by dams of various types are absolute necessities.

California is known generally in the East as an arid or at least a semi-arid State, while the truth is that the State enjoys within itself many unparalleled possibilities for water conservation, the development of which has hardly been scratched on the surface.

Take Los Angeles County as an example; it consists of a broad sloping valley area with a background of high mountains roughly equal to the valley area, from which ages of erosion have built deltas to known depths of more than 1 000 ft. These tremendous cones of gravel, sand, cobbles, and large boulders, forming the underlying strata of practically the entire valley areas, have been built by erosion of the many violent stream flows from more than one hundred and fifty separate water-sheds in the County, each with its individual stream channel debouching on the plains. Many of these water-sheds are small, more than 10% of them being individually less than 3 sq. miles in area, while the largest is only 222 sq. miles in total area. The annual fluctuation of stream flows is great, ranging from 8 to 358% of normal in the thirty-five years for which authentic records are available.

The low average annual rainfall (about 21.1 in.) has been insufficient to wash off completely the heavy cover of disintegrated loose material which, were the rainfall greater, would have already been washed down, lowering the mountain areas and correspondingly building up the valley areas. This loose material of disintegrated granite is held together solely by the root growth of the mountain vegetation, consisting of grasses, chaparral, and some timber. During eight months of the year rain is practically unknown and during this period the fire risk is imminent, requiring a most thorough system of policing and fire patrols by Federal and County agencies.

Fires leave the mountain areas without the binders of brush, and even moderate storms following such fires cause a heavy débris flow on to the valleys. A storm having a duration of 10 min. and an intensity of less than 2 in. in 1 hour has been known to bring down as much as 25 000 cu. yd. of débris from a single square mile of water-shed.

The tremendous area and great depth of the gravel cones are in reality of the greatest benefit to this southern County. These gravel areas, sloping from the base of the foothills to the ocean, are cut by dikes of clay and impervious materials which by damming the underflow to the ocean form a series of underground reservoirs, fed partly by the water issuing from the mountains and partly by the direct valley rainfall. These underground reservoirs are responsible for the entire early development of the County and supply two-thirds of the water used in the County to-day. By the construction of the impermeable covering of the valley, modern development of buildings and roads has not only deprived the underground reservoirs of the natural replenishment, but has increased the rate of run-off.

---

[30] Chf. Engr., Los Angeles County Flood Control Dist., Los Angeles, Calif.

The keynote to the flood protection and conservation of waters in this County lies in a series of regulating reservoirs in the mountains ironing out the peak flows to a rate that will not be of a destructive nature, but will be such that the gravels may absorb the stream flow and cause it to pass into the underground basins.

Twelve of these structures have been built to date (1930) and twice this number will ultimately be required ranging from almost every known type of arch dam, including the highest dam in the world (the Pacoima Dam), to earth, rock-fill, gravel-fill, and gravity concrete dams.

The remaining dam sites in Los Angeles County mountain territory are relatively costly and of small capacity when compared to storage sites in many other localities, the cheapest mountain dam built by the Flood Control District costing about $60 per acre-ft., a few being as much as $500 and more, with an average of more than $100. Many "off stream" storages are available, however, ranging from $20 to $50 per acre-ft. of storage space, some of which have been constructed and many more of which are still to be built.

While these costs may appear high the reservoirs are not, in actual practice, used for direct storage. They are merely used for regulation or "ironing out" of peak flows down to a rate such that they can be absorbed by spreading grounds below. These spreading grounds are built over pervious areas overlying the underground reservoirs of which the capacity for water is enormous compared with surface storages. Each of the flood-control regulating dams, therefore, may regulate several times its total capacity in a single year.

In its search for additional regulating reservoirs which are recognized as necessary for the fullest development of the underground reservoirs, the Los Angeles County Flood Control District has investigated scores of dam and reservoir sites, and has felt the need of some satisfactory short-cut method of comparing the capacities and approximate costs of a number of possible sites. The methods proposed by Mr. Sutherland, therefore, have been studied with great interest and tested to a limited extent as to their application to local conditions.

Mr. Sutherland sets forth a method by which it is possible to compare quickly the merits of various locations and types of dams as regards cost per unit of storage capacity alone. This applies equally well to all uses, whether conservation, regulation for flood control, or power, or any other use for which water is stored. The amount by which the results attained by this approximate method differs from those by the more exact and slower methods depends upon the variation from a straight line of the capacity curve platted on logarithmic paper and upon the judgment used in establishing a dam site cross-section which is equivalent to the true cross-section. The method appears to be quite satisfactory in the case of large reservoirs.

In the case of relatively small reservoirs, requiring high dams, such as those built by the Los Angeles County Flood Control District, the errors introduced by the approximations are likely to be relatively large. Mr. Sutherland cites three uses for the alignment chart, Fig. 4. Puddingstone Reservoir, which is the only County Flood Control Reservoir constructed to date that falls within the limits of the chart, was studied from the standpoint of Use No. 1. Adopting the value of m determined by a depth of water of 132 ft. at the deepest point, the capacities corresponding to various depths as shown by the alignment chart and by the ordinary capacity curve are as given in Table 8 for comparison.

TABLE 8.—Comparison of Reservoir Capacities

Maximum depth of water, in feet	From alignment chart, Fig. 4, in acre-feet	From capacity curve, in acre-feet	Variation, percentage
57	920	1 056	12.9
82	3 493	3 639	4.0
107	9 267	9 406	1.5
132	20 012	20 012	0

The variation results from the fact that for any of the reservoirs of the District, the value of m varies when different depths of water are used in its determination.

Many considerations determine the justified expenditure for a dam. The benefits to be derived from, and the cost of, the project as a whole are the determining factors. The cost of channels below flood-control dams depends on the degree of control effected by the reservoir. The justified total cost for the system depends on the amount of damage prevented through its operations. It is estimated that without protection, $50 000 000 of direct and indirect damage would result from a flood on the San Gabriel River equal to that which occurred in 1914. It is obvious that a reservoir on this river would be in reality of greater value than a reservoir on some other stream on which little or no damage would result, but which was classified as excellent. From the conservation standpoint the cost per unit of water delivered to the consumer is the determining factor. Systems designed for conservation may be beneficial in two ways:

1.—By causing the retention for use of water which would otherwise be wasted; and,

2.—By effecting a decrease in cost of delivery to consumers through holding the water at more favorable locations until such time as it is to be used.

The expense justified in carrying out the first of these items depends upon the use to which the water is to be put and the value of crops which it is possible to raise under the existing climatic and soil conditions. In general, it might be stated that the least cost at which water can be supplied in sufficient quantity to the entire area under consideration is the factor which fixes the cost justified in any case. Thus, in the case of domestic supply, a reservoir costing much more per acre-foot stored might be more necessary and, therefore, more valuable than a cheaper reservoir supplying some area where reservoir sites are plentiful and water is easy to obtain.

In the area covered by the Los Angeles County Flood Control District, the storage capacity available is limited, not only by the general steepness of the topography, but by the fact that foundation conditions preclude the use of many dam sites. This limited storage must be used for two purposes, flood control and conservation. In many cases the total storage space available is insufficient to control the stream completely. The storage required for economical control is of greater importance than the cost of this storage per acre-foot.

The foregoing shows that reservoir sites can not be classified as excellent, good, average, or bad, depending upon their cost per acre-foot of capacity. However, where other conditions are equal, two or more dam sites can be compared and one can be shown to be better in this respect than the others. Mr. Sutherland states that these other factors must be considered, but their importance far outweighs that of cost of storage per acre-foot, in the case of flood-control dams in an area of high productivity, such as this one.

Nevertheless, a comparison of capacities and costs of possible sites, between two or more dam sites has often been found necessary here, even though the unit capacity costs of such sites are so high as to eliminate their consideration in other parts of the United States where conditions are more favorable.

In general, to make such a comparison, it is desirable to answer either or both of two questions, other things being equal:

(*a*) Of two or more dam sites the reservoirs of which overlap and which serve about the same water-shed, which will be most economical?

(*b*) Where two or more small reservoirs compare with one larger reservoir for the same water-shed, what combination will be the most economical?

The following short-cut method has been developed by the Los Angeles County Flood Control District, largely through the efforts of C. B. Gibbons, Designing Engineer, and has proved very satisfactory for preliminary studies, serving to eliminate from further field investigation all the less advantageous sites. The method may be described in fifteen successive steps as follows:

1.—A topographic map is prepared. Aerial surveys give results close enough for such investigation, and have been used extensively.

2.—The topographic map is divided into zones along the stream bed by vertical planes (sometimes broken in plan), cutting along every important ridge and roughly segregating portions of the reservoirs between successive bottle-necks or narrows. (See Fig. 19.)

3.—For a distance of 300 to 400 ft. vertically above the stream bed, each contour, by zones, is measured by a planimeter.

4.—Beginning at the point at which each contour crosses the stream bed, the partial areas within this contour are cumulatively totaled for each zone, so that at each bottle-neck or narrows, the relation between depth of water and reservoir area is determined.

5.—Beginning at the stream bed at each bottle-neck or narrows, the cumulative areas are cumulatively totaled, and these totals, multiplied by the contour interval, give the usual data for a reservoir capacity curve at each such point.

6.—To serve as abscissas in Fig. 20 (which is described in Step 8), distances along the stream bed are roughly measured, and both bottle-necks and contours noted.

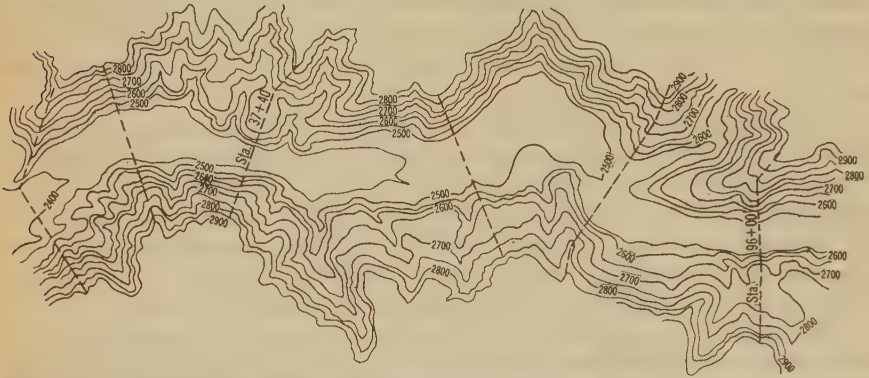

FIG. 19.—EXAMPLE OF TOPOGRAPHICAL MAP FOR USE IN COMPARING CAPACITIES AND COSTS OF DAM SITES.

7.—Using stream-bed distances as abscissas and acre-feet of reservoir capacity as ordinates, graphs are drawn (to 300 or 400 ft. above stream bed) for each contour measured. (See solid lines in Fig. 20.)

8.—From the reservoir capacity curves thus drawn and the points at which each contour crosses the stream bed, other graphs are drawn for each height of dam (in even multiples of the contour interval). (See broken-line curves in Fig. 20.)

9.—Graphs such as Fig. 20 portray continuously, over the range being investigated, the relation between reservoir capacity and height of dam. This graph has been called a capacity profile. By inspection, certain narrows or bottle-necks may be selected, which are favorable because the capacity is large as compared with the cross-section.

10.—At such selected points, a cross-section of the canyon is drawn, and for different heights of dam, a trapezoid is constructed, which roughly averages the cross-section. Increasing weight must be given to the lower portions where the dam is thicker. A reasonable amount of stripping or excavation must be assumed.

11.—Prior to field inspection and geological study, it may be assumed that these sites are equally feasible. Some type of structures, such as a rock-fill or concrete gravity dam, is then estimated at each site to various elevations, care being taken to allow for increased average width at the stream bed where higher dams straddle a rounded nose.

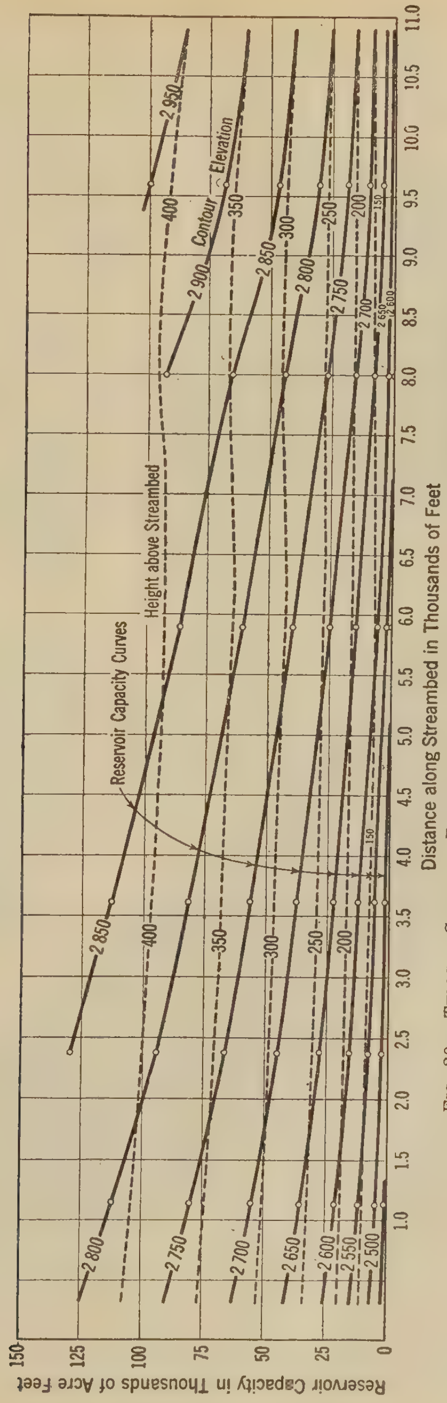

Fig. 20.—Typical Capacity Profiles for Continuous Study of Reservoir Capacity.

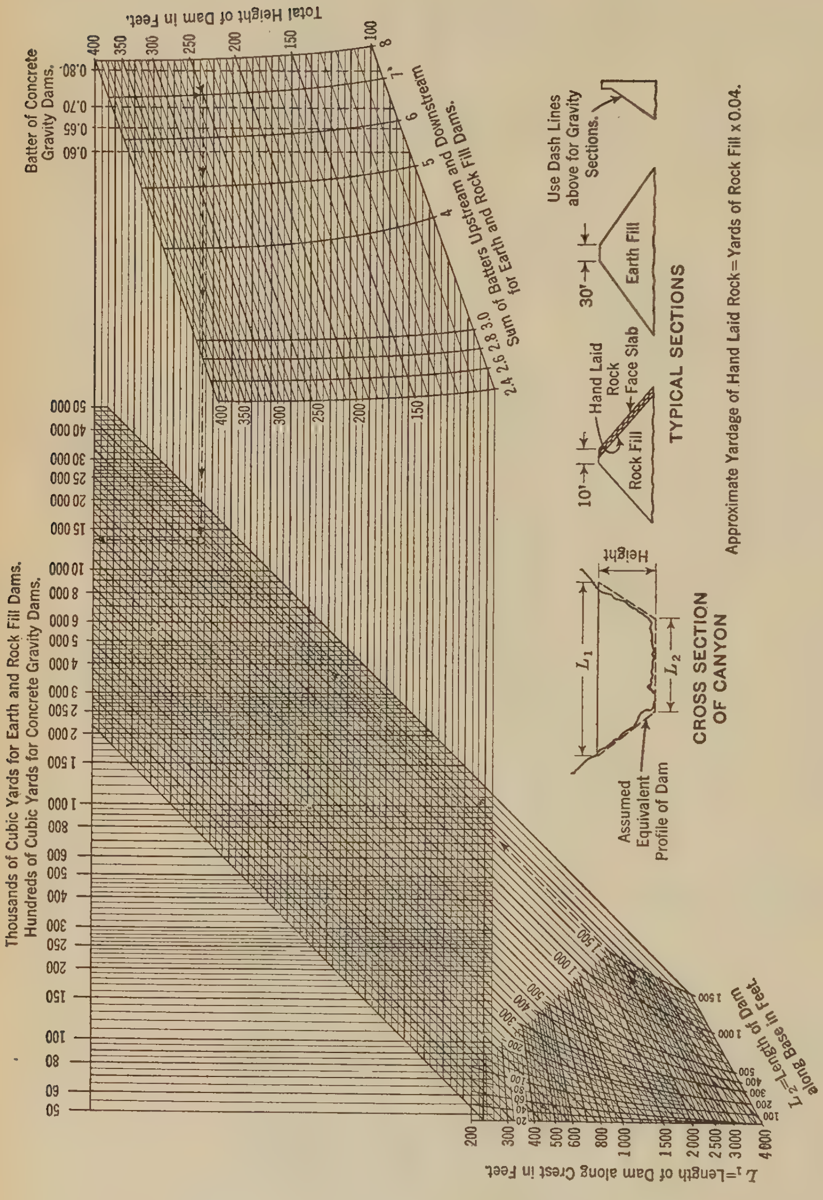

FIG. 21.—DIAGRAM FOR ESTIMATING DAMS.

12.—By the use of Fig. 21 the quantities for various heights of dam at each feasible site are computed. The successive steps are:

(*a*) Draw a cross-section of the canyon on the axis of the dam.
(*b*) Construct an equivalent straight-line profile of the dam, neglecting small deviations near the top.
(*c*) Find the yardage at the top of the diagram for the given height and assumed values of L_1, L_2, and batter.

For example, let $L_1 = 2\,000$ ft.; $L_2 = 1\,400$ ft.; height $= 250$ ft.; and the batters, 4 on 1 and 3 on 1 (total 7). Following the dotted lines, for this example in Fig. 21, a volume of 13 400 000 cu. yd. is indicated.

13.—By assigning a reasonable unit cost, the cost per acre-foot (at intervals of height equal to the contour interval) may be determined. For purposes of comparison the costs in Fig. 22 are estimated for gravity dams with a 10 on 8 batter at $8 gross per yd. of concrete. The depth of excavation is assumed as 50 ft. Quantities are estimated from Fig. 21.

14.—From the foregoing data assuming that the total reservoir capacity has been determined, a schedule can be prepared which makes possible a study of the various combinations of high dams and low dams at all feasible sites, with a view to obtaining the requisite capacity for the minimum total expenditure.

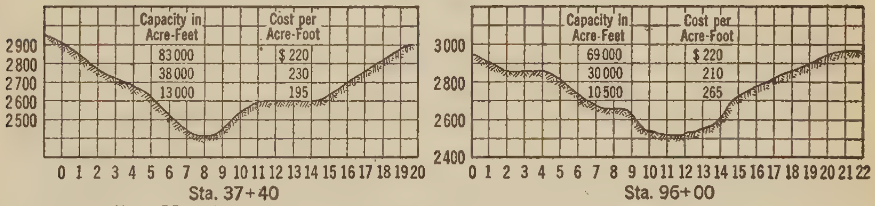

FIG. 22.—COMPARISON OF COSTS PER ACRE-FOOT AT VARIOUS HEIGHTS.

15.—Field inspection and geological study of the obviously desirable sites or combinations may reveal a wide discrepancy due to either:

(*a*) The availability of an arch dam;
(*b*) A considerable difference in the requisite excavation or stripping; or,
(*c*) The existence of faults which exclude all except a more expensive flexible dam.

In the latter case a revision of the comparative cost figures at the different sites may be made, retaining only the data which correlate capacity with height of dam.

The foregoing method has been described as an alternative means of arriving at the same objective as that sought by Mr. Sutherland's methods, and is felt to be more applicable perhaps to the special conditions existing in Los Angeles County as outlined.

Mr. Sutherland's paper has been the object of much interest in Los Angeles County and will undoubtedly prove of great value, particularly where the method is applied to reservoirs of considerable size and uniform cross-section.

A. W. Simonds,[31] Assoc. M. Soc. C. E. (by letter).—This paper briefly covers a great many points of interest in the problem of water conservation, indicating that the author has spent much time in the study of this subject. Water conservation is a geologic as well as an engineering problem. Too much emphasis can not be placed on this phase, particularly where a failure would involve the loss of considerable life and property. The engineer who disregards the geologic factors may invite disaster to his work. Some glaring examples of this are the failures of the Colorado River Dam at Austin, Tex., and the St. Francis Dam in California. The Colorado River Dam was built across a badly shattered fault zone which was inadequately excavated and not grouted. The result was that a section of the dam over the fault zone slid out. Some years later the dam was repaired, but as a storage reservoir the project was a failure, owing to the rapid loss of capacity due to silt deposition. If the services of a competent geologist or an engineer with a knowledge of geology had been engaged before the dam was built, these results might have been foreseen.

Successful projects in one locality might be failures elsewhere, due to different geologic conditions. Such dams as the Cheesman and Barker Dams in Colorado and the Gibson Dam in Montana are successful as a means of conserving water in their respective localities. They are situated high in the Rocky Mountains where their reservoirs are fed with clear water for the greater portion of the year. If these dams were placed across some heavy silt-bearing streams, such as the Brazos or Colorado Rivers of Texas, or the Rio Puerco of New Mexico, their reservoirs would lose capacity rapidly due to silt and would become useless as agents of water conservation.

The dam site should be thoroughly explored by diamond drilling, particularly if the structure is to be of masonry or concrete. Even then an engineer's eyes cannot see very far into rock. In the case of the Gibson Dam, in Montana, sub-surface exploration was made by drilling. In excavating for the structure, it was found unnecessary to cut as deep at the crown section as was originally intended, but at a point about half way between the crown section and the north abutment, it was necessary to cut deeper than the original line of assumed excavation.

The curves for submerged area (Fig. 6), site area (Figs. 7 and 8), and volume (Figs. 10 and 13), are interesting, but are of doubtful practical value. Dams and reservoirs are expensive structures, and their cost warrants a careful engineering investigation. A topographic survey of the reservoir and dam site is one of the first requirements. A carefully made topographical map will be found much more reliable for computing volumes in dams than the use of curves. This is particularly true in the case of the Deadwood Dam in Idaho. If the location of this dam were to be shifted a short distance either up stream or down stream its volume would be materially changed.

In connection with Table 2, it is of interest to note that the engineer's pre-construction estimate of the volume of Gibson Dam (Item 25) was 160 000 cu. yd. The contractor's final estimate for payment was 160 700 cu. yd.

---

[31] Assoc. Engr., U. S. Bureau of Reclamation, Denver, Colo.

W. H. R. NIMMO,[32] M. AM. SOC. C. E. (by letter).—The part of this paper dealing with reservoir capacities is based on the fact (which has been demonstrated by Hillman[33]) that the capacity of a reservoir at any level may be expressed very closely as an exponential function of the depth of water, and it is of interest to inquire why this should be so.

The size of the particles which a stream can transport depends to a considerable extent on their shape and the material of which they are composed, but if they were all spherical and of the same material, their diameter would vary as the square of the velocity of the stream and their volume as the sixth power of the velocity.[34] If it is assumed that all particles are spherical then the force exerted by the stream on a stationary particle is proportional to the change of momentum in that portion of the stream passing the particle and varies as the square of the mean diameter, D_p, of the particle and the square of the velocity, V, of the water, that is,

$$F = k\, D_p^2\, V^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

The frictional resistance due to the weight of the particle varies as the cube of the diameter so that, when the particle is about to move,

$$F = f\, D_p^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

Equating Formulas (30) and (31),

$$V^2 = \text{constant} \times D_p \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

but from the Chezy formula,

$$V^2 = \text{constant} \times r\, s \ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

therefore, $r\,s$ varies as D_p and, if the hydraulic radius does not vary greatly, the slope, s, will vary as D_p.

If it is assumed that the size of particles increases uniformly in an up-stream direction, then the slope must also increase at a uniform rate which is a property of a parabola. The foregoing appears to provide a physical explanation for the observed fact that the longitudinal section of a stream tends to be parabolic throughout most of its length.

Considering the case of the denudation of a slightly sloping block of land, such as a plain ($k\,m$) uplifted above the sea, as represented in Fig. 23, it will be noted that, at first, there can be no permanent stream, and denudation will take place only by weathering and the intermittent removal of material when rain falls. Gradually, run-off from storms will collect into runnels and, finally, into consequent streams running in the direction of the slope. Once formed, these streams will increase in volume and velocity as they proceed. Therefore, their erosive power will increase also, and they will steepen their beds to a convex curve such as $a\,b$ (Fig. 23). The stream will continue to erode until a narrow valley has been cut back to the position, $c\,d$; and the process will tend to continue to the position, $e\,f$ (Fig. 23), etc., back to the water-shed.

---

[32] Designing Engr., Main Roads Comm., Brisbane, Queensland, Australia.

[33] "The Capacities and Capacity Equations of Some Western Australian Dam Sites," *Transactions*, Inst. of Engrs., Australia, Vol. II, 1921.

[34] "Physical Geography," by P. Lake, Cambridge Univ. Press, 1925.

Erosion, however, cannot take place below the sea level at *c* and, having reached this point, the stream will commence to deposit material. At any point, such as *e*, erosion cannot take place below a level determined by the slope necessary to maintain a velocity that will transport the load which the stream is carrying. Consequently, a concave curve, such as *c e g*, will now be superimposed on the previous convex curve and the line of the valley will be eroded in gradual stages back to the position, *c e h k*, the portion, *c e h*, being concave and parabolic and the portion from *h* to the water-shed at *k* being convex. The term, concave, is used relative to the surface of the earth, which is considered to be flat over a limited area. Usually, the bed of a river will not be concave to the sky. The concave curve cannot proceed beyond the actual source of the stream, which will usually be a spring at about the point, *h*, since above this point there will not be sufficient accumulation of ground-water to maintain a flow during the interval between storms. Therefore, denudation here will proceed by weathering and the water-shed will usually remained rounded.[35]

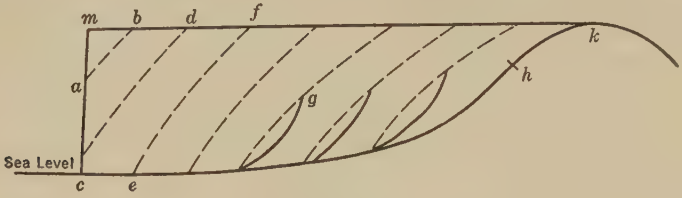

FIG. 23.

A young stream which is eroding the bed of a narrow gorge near the head of its drainage area will usually be fully loaded with detritus. It will not also be eroding the sides of the valley which will be of a convex shape. The shape of a storage basin in such a locality will be similar to that shown in Fig. 24. Adopting the author's notation as far as possible, the area of any typical cross-section, such as *b c d*, is given by,

$$a = \int l\, dh = \int D\, h^v\, dh = \frac{D}{v}\, h^{v+1} = C_A\, h^n \quad \text{..........}(34)$$

and the capacity of the reservoir will be,

$$w = \int a\, d\, l' = \frac{D}{v} \int h^{v+1}\, d\,(P\, h^z) = \frac{D\,P}{v} \int h^{v+z}\, dh = \frac{D\,P}{v\,(v+z)}\, h^{v+z+1}$$

$$w = C\,\dot{w}\, h^m \quad \text{..........................}(35)$$

Equations (34) and (35) are identical with Equations (1) and (2).

As the author points out, the value of *n* for a convex valley, such as Fig. 24, will be greater than 2 and, therefore, the value of *v* will be greater than unity. Since dams are usually built at control points such as *A*, *B*, or *C*, of Fig. 2, the longitudinal section of the stream may be considered to be parabolic and the value of *z*, therefore, will be 2. Hence, the value of $m = v + z + 1$ will be greater than 4; values of *m* greater than 4.5 do not seem to occur. In a previous discussion of this subject before the Institution of Engineers (Australia), the writer suggested the classification of reservoirs into gorge, hill, foothill, flood-plain, and lake types according to their values of *m*. The author has developed the idea in rather more detail, combining the flood-plain and foothill classes into one type, and adopting a definite range of values of *m* for each type, and his classification appears to be satisfactory.

---

[35] See, also, "The Curve of Stream Erosion," by John Challinor, *The Geological Magazine*, Lond., Vol. LXVII, No. 2, February, 1930.

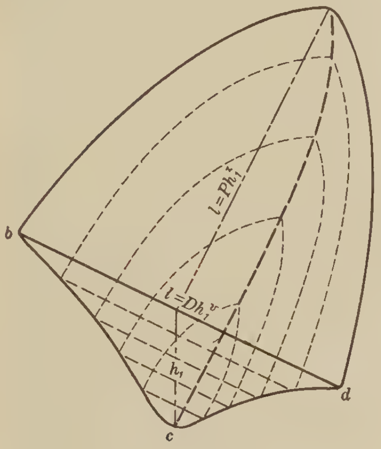

FIG. 24.

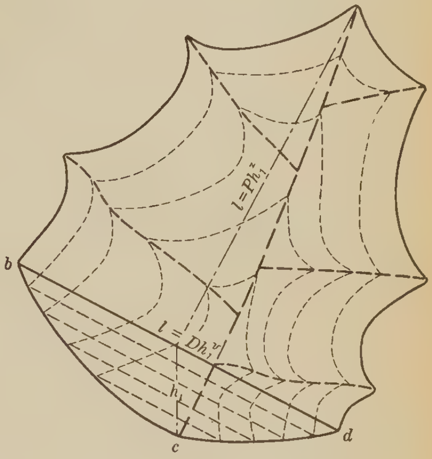

FIG. 25.

If a reservoir is located some distance from the water-shed, but in hilly country, there will be a larger flow of water to transport eroded material than in the foregoing example and the stream will have cut lateral valleys of parabolic section. Generally, the lower portion of the sides of the main valley will have become parabolic and concave although the actual water-shed will still be convex, so that the value of v will be 2. The longitudinal section of the main stream will now be on a flattened portion of the parabola so that z will be nearly unity. Such a reservoir is illustrated in Fig. 25 and its value of m would be about 4. Following down the main stream still farther, the lateral valleys will also become flattened, and the valley will be V-shaped with $v = 1$, $z = 1$, and $m = 3$, corresponding to the author's hill type. Still farther down stream the grade of the main stream may be so slight that z approaches zero while v may still be nearly unity, and $m = 2$, corresponding to the author's flood-plain and foothill type. For the lake type the floor is approximately flat in all directions and for large shallow lakes both v and z will be nearly zero, so that m will be rather greater than unity, but it can never be less than unity. The lowest value of m thus far encountered by the writer was 1.04 for the Great Lake, in Tasmania.

A true U- or box-shaped canyon having a nearly flat floor and nearly vertical sides may occur at any portion of a stream where it has been forced by uplift to erode its channel through hard horizontally bedded sedimentary rocks. In such a case, the value of v will be small and that of z may approach 2, so that m will probably be between 3 and 3.5.

The writer suggests the addition to the classification of a compound type to cover such reservoirs as Lake Cushman, Washington, which for the down-stream half of its length consists of the narrow gorge of the Skokomish River and for the up-stream half of the expanse of Lake Cushman itself. For the lower portion of the capacity, water is stored in the gorge only and $m = 4.09$. As the water level rises, a greater percentage of the storage is in the lake and the value of m decreases gradually until for the upper 100 ft. its value is only 1.4. The capacity line on logarithmic paper is a curve, whereas for all the other reservoirs investigated by Mr. Sutherland or the writer it is a straight line.

From Equation (35) it is evident that as the values of v and z decrease (they usually do in a down-stream direction), the value of C_w must increase and this is clearly indicated in Table 1.

The application of the exponential formula may save much expenditure on investigational surveys since the capacity of a storage can usually be determined with sufficient accuracy from areas at two or three levels only.

Logarithmic site-area graphs plotted by the writer for a number of actual dam-sites confirm the results obtained by the author and show that the area of any site to any given height can be represented closely by an exponential equation. The writer has also plotted widths against heights on logarithmic paper for a number of dam sites and, in many cases, the plotted points depart considerably from a straight line. Evidently, Equation (7) holds less closely than Equation (1) from which it is derived and, since the author's formulas for the volume of dams are based upon Equation (7), it might be expected that they would yield results which were considerably in error.

The writer computed the volume of a number of existing or proposed gravity dams by means of the formula given by Mr. Sutherland and compared the result with the volume calculated by the usual methods. It was found that, for sites which were fairly symmetrical, the formula gave quantities agreeing closely with the actual quantities. Even for decidedly unsymmetrical sites the formula gave results which were sufficiently accurate for preliminary estimates, since the error did not exceed that usually present owing to uncertainty as to the amount of foundation excavation which will be necessary. For earth or rock-fill dams, the formulas will also give satisfactory results.

The formulas for the volume of constant-angle arch dams (Equation (26)) involve the assumption that the contours of the foundation are both straight and parallel to the axis of the valley, or that the line, on which the cross-section is taken and from which the site-area equation is derived, is such that the effect of convergence or divergence of the contours is neutralized. Some of the most favorable sites for constant-angle arch dams exhibit considerable convergence of the contours and for such sites errors exceeding 30% in the computed volume of the dam may occur if the site-area equation is determined from a single cross-section taken along a chord. The composite section which is now proposed by the author will usually eliminate most of the convergence error.

The factor, $\frac{\phi}{2 \sin \frac{\phi}{2}}$, represents the ratio of the arc to the chord. The writer computed the ratio at the crest of fourteen dams and found that the value varied from 1.40 for the Pathfinder Dam to 1.015 for the Upper Otay Dam. He concluded that a constant factor of 1.05 would not be suitable for all dams. The factors given by the author in Table 3 vary with the value of n and the value of the crest angle, and their introduction will eliminate much of the error due to the use of a constant factor.

The author's equations also involve the assumptions that the radius varies uniformly from crest to base and that the subtended angle and the cylinder stress are constant from crest to base. For the Warragamba, Pacoima, King River, and Bullards Bar Dams, the writer has found by plotting curves that the value of the radius does vary almost uniformly from crest to base, and that the subtended angle varies greatly near the base. In high dams it is only approximately constant for the upper half of the dam. For the Warragamba and Pacoima Dams, the sites of which are fairly symmetrical, the cylinder stress is approximately constant at all levels; but for the Bullard's Bar, Salmon Creek, King River, and Lake Cushman Dams, it varies by as much as 50 per cent.

The site of the proposed Warragamba Dam is a straight gorge cut in sandstone, and the contours are practically straight lines parallel to the river. The computed volume of 261 000 cu. yd., given in Table 2, is for a preliminary design of a constant-angle arch dam made some years ago by the writer for this site, by means of the cylinder formula. The site is unusually symmetrical, and the probable depth of foundation excavation was allowed for in determining the site-area equation. The radii vary uniformly from crest to base, and the cylinder stress is unusually constant throughout. The actual volume calculated by ordinary methods is 284 000 cu. yd., so that the result given by the formula is 8% too small. The subtended angle is not constant, and the site-area equation was obtained from a section along a chord, instead of along the arc, and the error must arise from these two causes since all the other conditions required by the formula were satisfied.

Notwithstanding the various assumptions on which the author's formula for the volume of constant-angle arch dams is based, it appears from practical applications that in most cases the formula will give a quantity that is sufficiently near the true volume to be useful in making preliminary investigations, but the results may be expected to be usually less accurate than those obtained by the formula for the volume of gravity dams.

With the exception of the Gibson Dam, the actual volume of which is not shown, Table 2 does not include quantities for any dams designed by the trial-load or similar methods, or for any of the recently proposed high dams in which high compressive stresses are adopted. There is, therefore, no evidence to show what error would be involved in computing the volume of such dams by the author's formulas. The volume of the earlier arch dams, designed before the publication of the Cain formulas, are now of little practical interest.

A V-shaped valley, for which $n = 2$, is the most favorable for a constant-angle arch since the subtended angle can be kept approximately constant. For a valley with flat floor and vertical sides, $n = 1$, and a constant-angle arch becomes identical with a constant-radius arch.

For any valley with sloping sides (no matter how steeply), the constant-angle type of arch will contain less material than the constant-radius type. The comparison of specific capacities for different purposes in Figs. 17 and 18 is very instructive.

The writer has read this paper with much interest, and its value for practical use is much enhanced by the addition of the alignment charts.

C. R. OLBERG,[36] M. AM. SOC. C. E. (by letter).—The author has performed a distinct service to the profession in calling attention to the use of logarithms as providing a means of comparison between reservoir sites and dam sites, respectively. As Mr. Sutherland advises, the quantities derived from his methods cannot be used as a basis for final estimate, but they promise to be invaluable for the purpose of preliminary estimates and they also afford a method for direct comparison between various dam sites, and between different types of dams of various heights of the same site, with a minimum of work.

It is a definite achievement, since heretofore this was not possible, without days or even weeks of arduous labor, as those who have to pass on the relative excellence of proposed dam sites, or the respective merits of various types of dam at the same site, are well aware.

Most of the items considered are clearly and ably presented, but the author himself confesses that through the necessity of reducing the length of his original paper, the discussion of some of the subjects is somewhat "sketchy". It is to be regretted that Mr. Sutherland felt constrained to limit his discussion on "economic installation" to references to previous publications, which unfortunately are not readily available.

Reservoir Sites.—It has long been observed that capacity and area curves of reservoirs, follow some form of exponential curve, but it has remained for the author to demonstrate this fact in the application of logarithms to determine the equation.

The general form of an exponential curve in the nomenclature of the author (see Equation (2)) is $w = C_w h^m$.

Passing to logarithms,

$$\log w = \log C_w + m \log h \dots\dots\dots\dots\dots\dots (36)$$

Obviously, this is the equation of a straight line, in which, m is the tangent of the slope and $\log C_w$, the intercept on the y-axis.

Regarding a reservoir, if the logarithms of corresponding depths and capacities are plotted on co-ordinate paper with equal horizontal and vertical scales, it will be found that they will be nearly on a straight line. The straight line that best satisfies the points is the logarithmic equation, from which the algebraic formula, Equation (2), may readily be written.

---

[38] Tifiis, Union of Socialistic Soviet Republics.

Since two points are required to determine a straight line, the capacities corresponding to two depths are all that is necessary to obtain the approximate capacity of a reservoir at any other depth. However, three or more points will permit a better adjustment of the theoretical to the actual curve. As pointed out by the author, it is remarkable how close the theoretical agrees with the actual capacity.

The general equation can readily be used to extend the capacity curve of a reservoir beyond the limit of the original survey, a necessity that sometimes arises. The first derivative of the general equation with respect to h_1 is, $dw = C_w\ m\ h_1^{m-1}\ dh_1$, or, $s = C_w\ m\ h_1^{m-1}$, which is Equation (4) in Mr. Sutherland's paper. From Equation (4) the area of the reservoir, s, at any depth, h_1, may be computed.

The corresponding logarithmic equation is,

$$\log a = \log C_w + \log m - (m - 1) \log h_1 \qquad (37)$$

Equation (37) is also a straight line for which $m + 1$ is the tangent of the slope and $\log C_w + \log m$, the intercept on the y-axis. Equations (4) and (37) may be of assistance in problems of evaporation and seepage losses and, also, in extending the area curve.

The author's classification of reservoirs into types in accordance with the value of m is interesting, but in the writer's opinion this is important only as a means of definition and comparison.

It is not clear what particular means of mathematical legerdemain was used to demonstrate that m is the ratio of the maximum depth to the average depth of the reservoir. The writer must also confess ignorance of the real meaning of the constant, C_w, except that h_1^m may be regarded as a unit of measurement for each particular type of reservoir, and C_w, a scalar number denoting the number of times the quantity is taken as a unit.

The preparation and use of line charts is an ingenious method of determining quickly the values of C_w and m, but the writer believes that there is an advantage in plotting the logarithmic line, in order to permit an adjustment of the theoretical to the actual curve. Possibly the same results may be secured by adjusting the points within the polygon formed by three or more lines on the line chart somewhat analogous to a solution of simple three-point problems in plane-table work.

Dam Sites.—Mr. Sutherland points out that the theoretical area of a dam site may be found in a manner similar to that for determining the theoretical capacity and area curves of a reservoir. To the writer the simplest method of procedure would be to plot the logarithm of the width of the dam site at critical elevations against logarithms of the corresponding depths.

The tangent of the slope of the straight line adjusted through the points will be the exponent, p, of the independent variable, h, and the intercept on the y-axis will be the coefficient, B, in the general equation,

$$w = B\ h^p \qquad (38)$$

in which, w is the theoretical width of the dam site at any height, h. Equation (38) is the trace, on a vertical plane, of the theoretical dam site.

Integrating Equation (38) with respect to h,

$$A = p\ B\ h^{p-1} \dotfill (39)$$

which is the general area equation.

In Equation (38) letting w equal l, $B = nC_a$, and $p = n - 1$; then $l = n\,C_a\,h^{n-1}$, which appears to be derived by the author directly from the capacity equation for the reservoir (see Equation (7)). Until the relation between reservoir and dam site is more definitely established, the writer feels that this is putting assumption to rather a severe test.

Dams.—Equation (9) is proposed by the author for determining the volume of a triangular dam. Substituting for t and l in this equation, their equivalents, $Kg\ (H - h)$ and $n\ C_a\ h^{n-1}$, respectively, and integrating with respect to n, he derives Equation (10) as an expression for the volume of the dam. Substituting for n and C_a in this equation, their equivalents, $p + 1$ and $\frac{pB}{p + 1}$, respectively, results in the formula,

$$V_g = \frac{B\ K_g\ H^{p+2}}{(p + 1)\ (p + 2)} \dotfill (40)$$

in which, the exponent, p, and the coefficient, B, are derived from Equation (39), the integration of the theoretical curve of the dam site. The same result could have been obtained by integrating Equation (39).

If suitable allowances are made for the concrete in the foundations along the base and abutments, and an appropriate quantity is added for crest width, Equation (40) will give a close approximation of the volume in a gravity dam, at the site under consideration.

The author has done a large amount of work and displayed considerable ingenuity in developing approximate formulas for arch and constant angle dams. These two types, with the variable radius dam, are more dependent than others on the shape of the dam site for their stability and volumetric contents, and for this reason cannot be compared directly with a gravity dam.

The proposed formula and the presentation in alignment charts will be of great assistance since it renders this comparison possible, without the labor required to design a series of curved dams for each site. The error involved in the use of the cylinder formula, however, may be considerable, and the writer suggests the possibility of applying a factor to the volume as determined by the cylinder formula that will reduce, if not eliminate, the error.

The volumes of other types of dams, including the nail-head, multiple-arch, multiple-dome, and Ambursen, can be compared almost directly to the volume of a gravity dam of equal height, since they are only slightly affected by the shape of the dam site. It is probable that some of the factors will vary as a power of the height, but the relation should approximate a straight line.

Specific Capacity.—The writer believes that a more accurate determination of the "specific capacity", as defined by the author, could be secured by making an adjustment, providing for the clearance of the crest of the dam above the reservoir surface and the depths of the foundations below the bottom of the reservoir, so that the variable, h, of the reservoir would correspond to the variable, h, of the dam. It would complicate the equations somewhat, but it is not believed the difficulty would be insurmountable.

While the specific capacity will afford a ready means of comparing dams of variable heights of the same type, the reciprocal of the specific capacity (or the number of cubic units of the dam per unit of storage capacity) would afford a better means of comparison between dams of different types.

Costs.—A factor, as suggested by Mr. Sutherland, applied to the various materials will then give a direct comparison of cost between the various types of dams. This information could be plotted on a logarithmic chart, on which the variation in costs of the several types of dams of varying heights, for the same site, could be clearly and concisely shown.

The cost of the accessories of a dam, including spillways, outlet gates, etc., depends directly upon the type selected, and it is evident that the size, which influences the cost, is more a function of the reservoir than the dam. For dams of the same height of different types, the capacities of the spillways and outlet gates will be the same, and if the same type of accessories is used, the cost will be a constant. For different heights of dams of the same type, the capacity of the spillway will vary as some negative power of the depth of reservoir, and the capacity of the outlet gates will remain practically constant.

On account of these varying conditions, it appears to be hopeless to apply a factor to the cost of a dam to determine the cost of the accessories, except as the roughest kind of an approximation. These costs, like the cost of rights of way, must be computed separately and added to the cost of the dam, to give the total cost of the project.

Conclusion.—The form in which the author presents his equations dispels any lingering hope the writer may have had respecting a maximum specific capacity. It was a fond hope that had been long entertained. The economic height must be sought in other relations than those which exist between the height of a dam and storage capacity. The loss in this respect, however, is more than compensated for by the assistance which the data, so ably presented by the author, have been to the work at hand. It must be recognized that the results are approximate, but in an instance under observation they have been close approximations and serve as a firm basis, on which to form an opinion respecting the relative merits of various heights and types of dams for the same site, and to form a means of comparison between various dams and reservoir sites.

JOHN W. PRITCHETT,[37] ASSOC. M. AM. SOC. C. E. (by letter).—The author's estimate of total storage for irrigation already developed or proposed by the U. S. Bureau of Reclamation does not include proposed reservoirs in Texas which have not been investigated by the Federal Reclamation Bureau. The developed storage for irrigation in Texas is more than 1 000 000 acre-ft., not including the Lower Rio Grande Valley, where permits have been granted for the storage of about 275 000 acre-ft. Surveys and estimates have been made of sites that show favorable opportunities for the development of more than 3 500 000 acre-ft. of storage. The storage developed for water power in Texas amounts to about 25 000 acre-ft. Storage being developed for water power, or for which State permits have been granted for water power, are equal to more than 2 500 000 acre-ft. The storage developed or being developed (1930) for municipal water supply equals 900 000 acre-ft. That being developed for flood control in connection with other uses amounts to 500 000 acre-ft. In addition to the foregoing, a preliminary district has been created by the Legislature, looking toward the development of the entire Brazos River water-shed for irrigation, municipal supply, power, and flood control. The area of this water-shed is about 40 000 sq. miles, and the mean annual run-off is 5 500 000 acre-ft. The reservoir sites that have been surveyed in this water-shed give a total storage capacity of more than 4 500 000 acre-ft.

---

[37] Engr., State Board of Water Engrs., Austin, Tex.

Some of the common errors noted by the author, in the investigation and development of water conservation, are among those generally encountered in the investigations in this section of the United States, namely:

1.—The use of insufficient data on stream flow.
2.—The use of rainfall records and assumptions as to run-off without adequate data showing the relationship between them.
3.—An under-estimation of flood flows, and insufficient spillway provision.

Mr. Sutherland's method of studying the characteristics of storage reservoirs has been applied to thirty-four reservoir areas in Texas that have been surveyed by the Topographic Branch of the U. S. Geological Survey, co-operating with the Texas Board of Water Engineers. Some of the areas studied are mapped on a scale of 1 : 24 000, with a contour interval of 5 ft.; others are mapped on a scale of 1 : 48 000, with contour intervals of 10 and 20 ft. At some of these areas two or more locations for the dam were considered, making a total of fifty-five reservoir sites studied. The development of some of them would be impractical; only a few of them have been, or are being, developed. They merely represent some of the investigations that have been made by the Texas Board of Water Engineers, looking toward the development of the water resources of the State. In this investigation, some of the dams were carried to maximum height for the purpose of applying the author's method of study, and not as an indication of what might be practical in the economic development of these reservoirs.

The capacity curves of the reservoirs in Table 9 were drawn as straight lines on logarithmic paper, as shown by the author. For most of these reservoirs the plotted points showing capacity, fit closely the lines thus drawn. For some the plotted points give a uniform upward curve; while others give a uniform downward curve. Some of them give a decided curve at the lower heights, but soon develop into a tangent as the height increases. The extension of some of these lines to the 100-ft. height, in order to calculate the constants in the author's formula, give storage values that are probably not reliable and would affect the accuracy of the values of the constants, C_w, calculated therefrom.

In the arbitrary classification of the reservoirs into four types, the particular class into which a reservoir may fall depends upon the shape of the cross-section of its area, and somewhat upon the height of the dam considered, as the value of m may be varied considerably by changing the height of the dam. This classification may have little to do with the general topography of the surrounding country outside the stream channel. However, with the foregoing observations in mind, the classification as made and used by the author appears very satisfactory and should be useful.

* By author's Figs. 4 and 6, using values of m and C_w computed by using maximum depth shown in this table for the particular site.

comparison may be made of the values of m in reference to elevation on any particular stream. The computed values of the constants, m and C_w, for different heights of dam, are given in order that comparison may be made. In order to compute the value of C_w in Item No. 9 (Table 9) by Equation (3), it was necessary to extend the height-capacity curve from Height 40 to Height 100. This may have given a capacity for 100-ft. depth that would be considerably in error, which, in turn, would cause errors in the computed value of C_w and also in the capacities and areas taken from the diagrams.

The author's reservoir capacity diagram, Fig. 4, as well as the other alignment charts are very ingenious, and should often be found useful in the preliminary examination of reservoirs. Comparing the computed values of m and C_w with values taken from Fig. 4, by using intersecting lines from two known depths and capacities, quite a difference in values is often noted. Where such differences are found, capacities taken from the diagram for other depths may be considerably in error, as may be seen from Table 9.

Computing the value of the ratio, the average or mean depth divided by the maximum depth, to any given elevation for the fifty-five sites considered, the mean value is 0.3148, corresponding to $m = 3.18$. Most of the reservoirs fell into the "hill type" classification, which probably accounts for the smaller variation in the values of m.

Areas were computed for the sites in Table 9 and for different depths. These are plotted in Fig. 26. The plotted points have been connected by dotted lines for easier identification, no attempt being made to fit a straight line to them. Table 9 also shows a comparison of the computed values with the values taken from the author's diagrams for capacity, surface area, m, and C_w. In computing the site area it is sometimes found that there is a low sag at one side or the other, that will require the construction of a levee, spillway, or other structure. Whether or not to include this value in computing the site area is a problem that is not always easy to determine, because it may be a continuation of the main site area, adjacent to it, or widely separated from it.

Fig. 27 represents the curves of height plotted against capacity, height plotted against area, and area plotted against capacity for the San Saba Project as determined in this study. These curves are fairly well represented by straight lines on logarithmic paper for this particular site. The scale on which these values are plotted has much to do with the distance of certain points from a straight line drawn on the logarithmic chart.

A. J. GILARDI,[38] ASSOC. M. AM. SOC. C. E. (by letter).—The method of comparing and classifying reservoirs, dam sites, and the various types of dams described in this paper, is very useful, because, to a certain extent, it makes possible the visualization of their respective merits in comparison with such standards or "yardsticks" as those with which the hydraulic engineer may be most familiar.

Probably, the constant use of the charts given in the paper would overcome some difficulties which the writer has experienced in attempting to apply a few of them in his studies of dams. It would seem possible, however, to introduce a few simplifications and thus increase the facility and accuracy of application of the charts on the part of engineers.

---

[38] Cons. and Civ. Engr., Seattle, Wash.

In the course of his work of making numerous preliminary investigations of dam sites and reservoirs, the writer has prepared two simple and helpful charts to determine the approximate volume of dams for a wide range of sizes and types.

Fig. 28 gives directly, as abscissas, the total volumes of concrete required for gravity dams of a given height, $H_{\max.}$, and for a given distance between abutments, measured at the water surface. This diagram is based on the following assumptions:

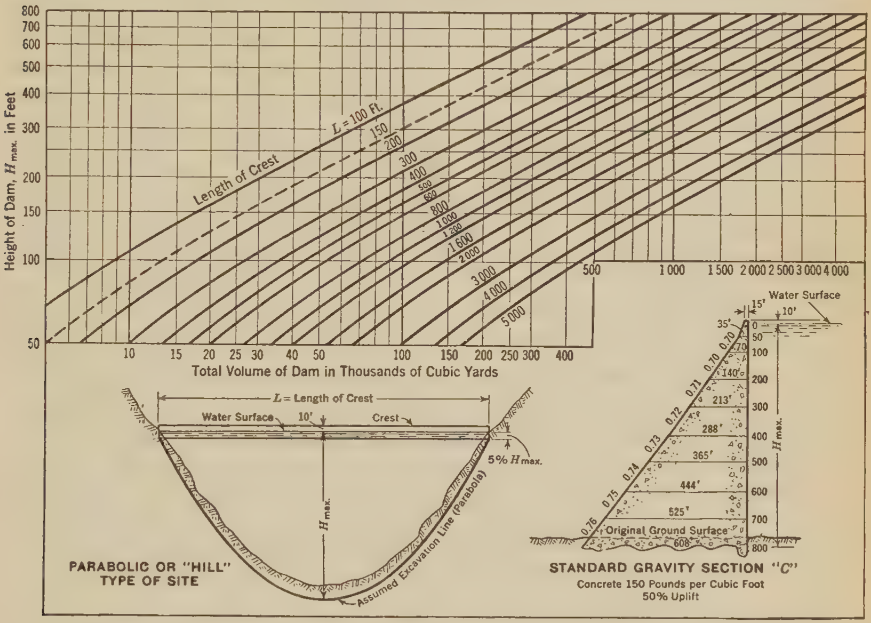

FIG. 28.—TOTAL VOLUME OF GRAVITY DAMS FOR STANDARD SECTION, *C*, AND PARABOLIC OR HILL TYPE OF SITE

(*a*) That the dam has a gravity section which will be designated as the standard section, *C* (see Fig. 28), and is designed for uplift of 100% on 50% of the area, or what is usually called 50% uplift. The weight of the concrete has been assumed at 150 lb. per cu. ft. The section has a top width of 15 ft. and a free-board of 10 ft., which would correspond to about the same volume as a top width of 20 ft. and a free-board of only 5 ft.

(*b*) That the actual dam site has such a shape as to be replaceable by a theoretical site of the parabolic or "hill" type. This assumption is similar to that suggested by Mr. Sutherland, with the exception that two modifications of a practical nature are introduced. The first is that the vertex of the parabola is at the deepest part of the excavation (estimated or actual, as the case may be), the vertical distance from this point to the water surface being designated as the height of the dam, $H_{max.}$. The second assumption is that the foundation of the dam or excavation line is assumed to follow a parabolic line and end at the abutments with a depth of excavation of 5% of $H_{max.}$.

Fig. 28 covers a wide range of sizes, from heights of 50 to 800 ft. and lengths of 100 to 5 000 ft.

Fig. 29 is intended for the purpose of modifying the volumes obtained from Fig. 28, whenever it is necessary to take into consideration sections and sites other than those used as a basis for that chart. This desirable result is arrived at by the introduction of factors, which will be designated as "section factors" and "site factors" (see Table 10).

TABLE 10.—SECTION AND SITE FACTORS FOR USE WITH FIG. 29.

Height, $H_{max.}$, in feet	SITE FACTORS			SECTION FACTORS			
	Hill type, standard	V-type	Gorge type	*A*, average arch	*B*, no uplift	*C*, 50% uplift (standard)	*D*, 100% uplift
50	1.00	0.76	0.58	0.50	0.96	1.00	1.04
100	1.00	0.71	0.49	0.50	0.94	1.00	1.05
200	1.00	0.67	0.43	0.50	0.93	1.00	1.11
300	1.00	0.66	0.42	0.50	0.92	1.00	1.15
400	1.00	0.65	0.41	0.50	0.91	1.00	1.17
600	1.00	0.64	0.40	0.50	0.90	1.00	1.18

The four typical sections of dams used in Fig. 29 are the following:

Section *A*, an average arch section for which the top width is reduced to 7½ ft. with a 10-ft. free-board;
Section *B*, a gravity section designed without any allowance for uplift;
Section *C*, a gravity section which has been designated as the standard section and is designed for 100% uplift on 50% of the base, or what is generally called 50% uplift; and,
Section *D*, an ultra-conservative gravity section designed for 100% uplift on 100% of the base.

For the sake of simplicity, all the sections used have a vertical up-stream face throughout and have practically a triangular shape. While it is probable that for the higher dams the triangular section would be replaced by a more complicated section, this would mean essentially that the masses would be distributed somewhat differently, although approximately the same total volume would be required.

The "section factors" in Table 10 are intended to be applied to the volume obtained from Fig. 28 for the standard section, *C*, the given $H_{max.}$, and length of crest, for the purpose of allowing for a change in section, such as the engineer may consider desirable in his particular case. For instance, a dam, 250 ft. high ($H_{max.} = 250$ ft.) with a crest length of 1 500 ft., on a site of the parabolic or "hill" type, would have a total volume of 685 000 cu. yd., as determined from Fig. 28 for a standard section designed for 50% uplift. A dam for the same site, designed without any allowance for uplift, would have a section factor of 0.925. Therefore, the corresponding volume would be reduced to 685 000 cu. yd. by 0.925, or 633 000 cu. yd.

Fig. 29 shows the three typical sites investigated, which are the parabolic or "hill" type, the V-type, and the "gorge" type.

The "site factors" are intended to be applied to the volume obtained from Fig. 28 for a site of the parabolic or "hill" type, for the purpose of determining the volume of a dam of the same crest length and height, $H_{\max.}$, but for a different type of site. For instance, a dam of standard section, C, 1 500 ft. long at the crest and with $H_{\max.} = 250$ ft., located on a parabolic or "hill"

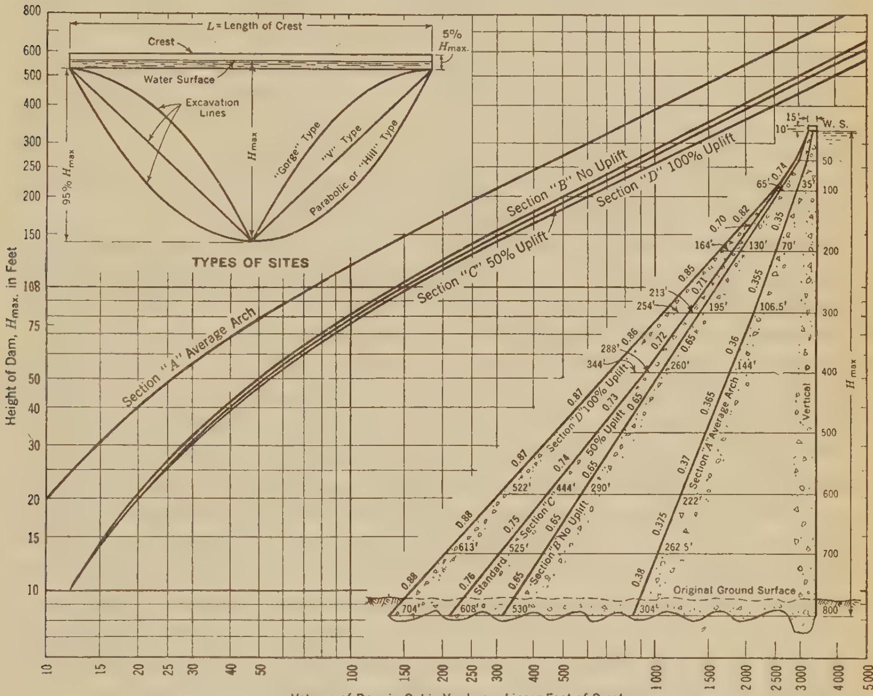

FIG. 29.

type of site, would have a volume of 685 000 cu. yd. A dam with the same height, $H_{\max.}$, and same crest length, L, and designed on the same basis, but located in a site of the "gorge" type, would have a site factor of 0.425 and, therefore, would require 0.425 by 685 000 cu. yd., or about 291 000 cu. yd.

Both section and site factors may of course be applied simultaneously to determine the desired volume when both the basis of design and the type of site are changed from those used in Fig. 28. It is also readily possible to interpolate for such intermediate types of sites and sections which are not shown directly in Fig. 29.

For trapezoidal sites, the volume of the dam can be determined readily by segregating into a V-type and adding to this volume that obtained by multiplying the volume per linear foot given in Fig. 29 by the length of the part of the dam which has the constant height, $H_{\max.}$. The same procedure of segregation and summation may be applied to such others for which the three typical sites may not be directly applicable. The diagrams presented herewith are intended, of course, to be used for preliminary purposes only, and as approximate checks in other cases.

The writer has not had the time required to prepare a detailed tabulation to compare the volumes obtained from the diagrams with those of dams actually constructed. However, a few comparisons have shown to his satisfaction that the diagrams give results which are sufficiently accurate for the purposes for which they are intended. For instance, in a preliminary investigation of a gravity dam, straight in plan, with a crest length of 1 545 ft. and a height, $H_{\text{max.}}$, of 252 ft., a detailed analysis requiring many hours of work resulted in a volume of 680 000 cu. yd., whereas Fig. 28 gave at a glance a volume of 720 000 cu. yd. Upon investigation, it was found that the small difference of 5½% was probably due to a "hump" on the right side of the actual dam site at about mid-height, which, of course, the parabolic or "hill" type of site had not taken into consideration.

Another example for which a comparison was made, was the Gibson Dam, an arched structure with a crest length of 960 ft. and a total height of 195 ft., corresponding to an $H_{\text{max.}}$ of 185 ft. As already mentioned, the actual volume of the dam alone, as constructed, was 160 700 cu. yd. Fig. 28 gives a volume of 250 000 cu. yd. for a standard gravity section, *C*. By comparison of the section of the Gibson Dam with the average arch section, *A*, on Fig. 29, it will readily be seen that the section of the Gibson Dam is considerably thicker at all points, the width at the top being 20 ft. against 7½ ft., and the depth, at a depth of water of 150 ft., being about 60 ft. against 50 ft. In addition, the Gibson Dam has a considerable mass of concrete added at the maximum section. In view of this, it is reasonable to interpolate between the section factors given on Fig. 29 for Sections *A* and *B* by adding 25% to the section factor for *A*. This results in a section factor of 0.625, which, in turn, determines the volume of the Gibson Dam at 0.625 by 250 000 cu. yd. = 156 200 cu. yd., or only 2.8% less than the actual volume as constructed. In using the diagrams for estimating the volume of arched dams, the developed length of the crest must be introduced.

The diagrams will sometimes be found useful in reversing the usual procedure of determining the volume from given dimensions. Assuming, for instance, that, for a given dam site, only a limited sum of money is available and that, therefore, the maximum volume of concrete is fixed, it is possible to determine in a few minutes what maximum height of dam could be constructed. The diagrams have been prepared for non-overflow sections of dams. However, they have been found quite useful also for overflow sections, with minor arithmetical adjustments. Diagrams similar to those presented herewith, could be prepared for earth dams, rock-fill dams, and other types.

In the course of the extensive computations and other work required for the preparation of the diagrams, the writer has had the valuable co-operation of Mr. L. S. Moore, of the U. S. Engineer Office, at Seattle, Wash., to whom thanks are extended herewith.

R. A. SUTHERLAND,[39] ASSOC. M. AM. SOC. C. E. (by letter).—The discussion by Mr. Eaton is particularly interesting in that it deals with problems similar in many ways to those met by the writer in Australia. The increase in flood severity and in the quantity of detritus carried, due to destruction of natural cover, as mentioned by Mr. Eaton, has become a problem of real gravity in many countries. The writer believes that in America this problem has been faced for many years by the reservation of immense areas of forest, with adequate provision for safeguard from fire. In most countries, however, the destruction of forest and other cover is allowed to go on far beyond a safe point before anything is done to prevent it.

Mr. Eaton has touched a vital point when he states that "the costs of the remaining dam sites in Los Angeles County mountain territory are relatively high." This is now becoming true for practically every country, and the increasing cost of storage has prompted the intensive study which has been given to economy in dams during the twenty years since about 1910. The writer's paper was developed and presented with the object of aiding in the study of how to obtain the greatest "value for money," having regard not only to the dam but to the reservoir itself.

Relative to the justified expenditure on a dam, there are, as Mr. Eaton points out, many factors to consider; looking at the dam as an insurance against either an excessive or a defective flow of water, it is obvious that the premium which can be afforded for such insurance will be in proportion to the risks to be guarded against. In the case of dams built solely or mainly to create head (and these form probably a growing proportion of the total), the value of such head is another factor to be considered, whether it is used to create power or to avoid pumping for water supply.

The method of comparing dams and storages, as described by Mr. Eaton, is of great interest and value, enabling a comprehensive preliminary survey to be made of a series of sites on any one stream or on adjacent streams. The increase of unit cost with increasing capacity as shown by Fig. 22, is characteristic of storages having a relatively low value of m. The cost of most dams varies with the height according to a power of from 2.5 to more than 4, depending on the site and the type of dam, while many storages have lower values of m.

The writer is gratified that his paper has been of interest in a district which he has always admired for its progressive water administration policy.

The writer agrees fully with Mr. Simonds as to the paramount importance of the geological aspect of water conservation. It is essential that a dam should form a stable and integral part of the landscape, or to use a mechanical analogy, that it should be a "weld" and not a "patch." Scarcely less importance should be attached to the geological properties of the reservoir basin. This phase of the subject is treated more thoroughly in the comprehensive manuscript from which the material for this paper was condensed.[40]

As Mr. Simonds points out, expenditure on diamond drilling is generally not only necessary, but is a true economy. The exploration of the dam site should not stop at the examination of the rock strata, but should be sufficiently extensive to enable the history and probable stability of the entire surrounding terrain to be visualized. The writer can cite a case in which the site of a large dam to be built for power generation was most excellently prospected by drilling and tunneling, but in which, nevertheless, the completed works had to be shut down soon after commencing operation, on account of unsuspected weaknesses in the adjacent terrain, under the altered conditions. Provision against this meant a large further expenditure in remedial works, in addition to heavy losses through idle plant.

---

[39] San Francisco, Calif.

[40] Bound copy on file at Engineering Societies Library, New York, N. Y.

The writer regrets that Mr. Simonds considers the curves to be of doubtful practical value. The topographic survey is essential when the project has reached a certain stage, and the writer has never suggested otherwise, but he has seen thousands of dollars wasted in careful surveys of projects which were never begun. In many cases this useless expenditure could be avoided by a common-sense application of the broad principles introduced in this paper.

Mr. Nimmo's able discussion of the reasons for the characteristic properties of different types of reservoir is very interesting, and appears to be founded on a scientifically correct basis.

Mr. Olberg considers that the classification of reservoirs into different types is of importance only as a means of definition and comparison. The original idea of this classification is due to Mr. Nimmo, and it has been fairly well established by theoretical considerations and from actual practice. It seems desirable to be able to recognize any given reservoir as belonging to a certain type, since each type has distinct characteristics of its own as regards seepage, evaporation, and flow-regulating properties. This aspect of the subject has been merely touched on in the paper, but might be considerably elaborated.

No mathematical legerdemain is required to prove that m is the ratio of maximum depth to average depth. The average depth equals $\frac{\text{capacity}}{\text{water-spread area}}$ $= \frac{C_w \; h_1^{m}}{m \, C_w \; h_1^{m-1}}$, and dividing this into the maximum depth, h_1, gives m. As regards the constant, C_w, this is the theoretical capacity at unit depth, but this fact is of no practical importance.

Mr. Olberg is correct in preferring the plotting of the logarithmic line to the use of the alignment charts (Figs. 4, 6, and 8) as a means of finding the correct constants for a reservoir or dam site. The alignment charts, however, are sufficiently accurate for practical purposes and give the desired result at a glance without calculation or the chance of arithmetical error.

Referring to the remarks of both Mr. Olberg and Mr. Nimmo regarding the use of the site-area and the site-width equations, the writer has evidently not made the fact sufficiently clear that the use of Equation (1) as the starting point in deriving the formulas for the volume of dams is purely empirical. It was found to give satisfactory results, and the use of the width of dam site was not found satisfactory. It should also be pointed out that

Equation (7), derived from Equation (1), really applies not to the site itself, but to the equivalent theoretical site as shown in dotted lines in Fig. 9. If the width is measured at a large number of short-height intervals (that is, making *dh* very small), and the logarithmic line is plotted, it should give exactly the same result as the plotting of site areas. In practice, it is easier to let the planimeter assist in striking the average, than to plot so many points.

Mr. Olberg's assumption that Equation (7) was derived from the capacity equation for the reservoir is in error. The writer has not endeavored to derive any relationship between the capacity and site-area equations. It is doubtful whether even a quantitative relationship holds between the constants of the two equations; and examples will readily come to mind of large storages being impounded at a narrow gorge, and, conversely, of long and costly dams being required for a relatively small storage. The fact is that the properties of dam sites are frequently determined by some rather local geological condition, while the properties of reservoir basins are determined by the geological and climatological conditions on a fairly extensive terrain.

Mr. Nimmo has pointed out the existence of a compound type of reservoir, as exemplified by Lake Cushman. The writer believes this to be very exceptional, and has never encountered a similar case. He is glad to note that Mr. Nimmo and Mr. Olberg have found his formulas to give results sufficiently accurate for preliminary investigations. For such purposes the data available are usually not sufficient to warrant the more laborious methods frequently used in computing quantities, and the accuracy of these methods is often more fictitious than real.

The volume of dams designed by the Cain formulas or by the trial-load method, might be found as a certain percentage of the volume of the corresponding plain arch dam having a given "cylinder" stress, such percentage being determined from experience. The writer has not sufficient data to enable him to indicate a coefficient for this use. Mr. Simonds has given the actual volume of the Gibson Dam as 160 000 cu. yd. The volume computed by the writer's method is 142 000, which indicates an error of 11 per cent.

Mr. Olberg suggests that an adjustment might be made in the formulas for "specific capacity," to allow for the crest and foundation margins. The difficulty is that by altering the arguments in the numerator and denominator of the expression, the possibility of deriving a simple expression is lost. The writer made an adjustment in the coefficient to allow for the average conditions and margins stated, and the formulas will be approximately correct under those conditions, but will be increasingly in error as the dam considered is very low or very high.

The method of determining the most economical size of installation, of which Mr. Olberg would like to have more information, depends on a use of the Rippl curve, or other means of determining the storage required to provide a given regulated flow. For various values of regulated flow, various sizes of dam are required, the quantity of material in which can be found approximately from the formulas given in the paper; and, by applying proper unit costs, the total cost of the different dams can be found. Dividing these costs by the values of the regulated flow, therefore, enables the point to be found, which will give the lowest cost per unit of regulated flow.

Data for developed and proposed storage in Texas for different purposes, as given by Mr. Pritchett, are of great interest. The large value of 2 500 000 acre-ft. being developed or approved for water power is remarkable. In view of the arid nature of Texas climate, it would have been of interest to have figures showing the acre-feet of storage considered necessary per acre of irrigated land, and the writer presumes that this figure would be relatively high. It is noted from Table 9 that the computed and diagram capacities for the larger storages generally agree fairly closely. The values of m also agree reasonably well, while those of C_w show wide discrepancies. Actually, it would be found that the computed values would give an exact agreement of capacity for one value of height, with greater or smaller errors at other values of height, and the object in selecting values of m and C_w should be to spread the errors so that they are nowhere excessive.

Mr. Gilardi's very useful and practical diagrams should be of great value in investigations of the cost of dams when the leading particulars, such as height, crest length, and type have been decided. They should give practically the same results in parallel cases, as the writer's Fig. 10, for any particular case. For example, consider a site for which $n = 1.5$, $C_A = 10$, and $H_{\text{max.}} = 100$. In that case, $L = 150$. This gives, from Mr. Gilardi's Fig. 28, a volume of 15 500 cu. yd. and from Fig. 10, 15 390 cu. yd. (total height = 110 and mean $K_g = 0.73$, as shown on Fig. 28).

The use of site and section factors, applied to the results obtained for a standard gravity section, is a distinctly useful artifice, although interpolation in two senses may not be always easy. For sites of the composite type, not covered by the writer's procedure, Mr. Gilardi's proposal to divide the site into its component parts and determine the separate volumes from his two diagrams, is a practical method of procedure.

It is necessary to correct the impression that the "gorge" and "hill" types of dam site mentioned by Mr. Gilardi, have any necessary connection with the classification of reservoirs into these types adopted by the writer. The type of reservoir depends on the average of the cross-sections of an extensive stretch of river, including any tributaries in the reservoir basin. Where these cross-sections are predominantly of the gorge type, the reservoir is a gorge type. In many cases the nature of the dam site may be determined by purely local geological conditions, and it may be of a different type as, for example, the hill type. In point of fact dam sites below reservoir basins of the gorge type are frequently of the hill type, and the gorge type of site may occur below a lake type of basin. For this reason the writer did not attempt to draw any connection between the type of basin and its dam site.

Regarding the writer's statement following Table 1 that in the cases examined by him, the value of m for reservoirs occurring on the same river was a function of the elevation, Mr. Nimmo has kindly pointed out a case in which a large number of reservoir sites on one river were investigated, and in which this relationship does not hold. This is the Umpqua and North Umpqua River, in Oregon. Fig. 30 and Table 11 were plotted by Mr. Nimmo from data supplied by the U. S. Geological Survey.[41] While it is true that the relationship does not hold in this case, Table 11 does show in a general manner that, for reservoirs of similar type, C_w varies with the catchment. For example, compare Sites 10 and 17; 16, 21, and 22; and 8, 23, and 24. Site 14 does not conform to this generalization.

TABLE 11.—CHARACTERISTICS OF PROPOSED RESERVOIR SITES ON THE UMPQUA AND NORTH UMPQUA RIVERS, OREGON

Dam Site No.	Mileage from Scottsburg, Ore.	Elevation, in feet	Value of C_w	Value of m
25	1	0	70.8	1.75
24	11.5	41.5	149.2	1.60
23	29.5	100	91.6	1.64
22	45	166	53.3	1.72
21	49.5	186	48.5	1.72
20	63	255	1.162	2.51
19	69	294.5	1.022	2.68
17	91	439	23.2	1.82
16	97.5	506	42.2	1.73
15	106	596	24.25	1.89
14	112	660	38.5	1.80
12	122.5	847	16.6	1.76
10	137.5	1 187	6.82	1.82
9	145.5	1 450	10.6	1.68
8	152	1 750	10.97	1.62

Referring to that part of the writer's paper, headed "Arch Dams," the following should be added: The Gibson Dam (Table 7, Item No. 12), was designed by the trial-load method and the use of Fig. 15 is not strictly applicable. The discrepancy between the actual and chart values of W_s shows that the actual volume of concrete is much more than when computed from the stress derived from the batter of the mid-section. This increase is due to the considerable thickening of the flanks of the dam and the excess section over the theoretical triangular section.

CONSTRUCTION OF LA OLA PIPE LINE, IN CHILE[1]

BY W. B. SAUNDERS,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. ERNEST B. NELSON, H. L. THACKWELL, WILLIAM E. RUDOLPH, AND W. B. SAUNDERS

SYNOPSIS

The purpose of building the pipe line described in this paper was to supply water to the Metallurgical Plant of the Andes Copper Mining Company, at Potrerillos, Chile. The line is 32.3 miles long and the pipe varies in diameter from 22 to 36 in.

The unique and outstanding features are as follows:

1.—The fabrication of riveted steel pipe in the field.

2.—The unusual method of field transportation for construction materials.

3.—The construction of a number of inverted siphons under very high pressure heads.

4.—The rapidity with which construction work was accomplished and the low unit costs obtained under difficult conditions.

INTRODUCTION

After several years spent in the development of its mining properties, and in experimental work on the metallurgy of its ores, the Andes Copper Mining Company, in January, 1925, started the construction of its Metallurgical Plant. The schedule called for the completion by January 1, 1927, of that part of the plant to be used for treating sulfide ores.

One of the major problems in connection with this project was to secure an adequate supply of water for use in the metallurgical processes adopted. The problem was difficult, because of the scarcity of water, the character of the country, and the high altitude of the plant.

The estimated requirements were 29 cu. ft. per sec., of which about 9 cu. ft. could be reclaimed.

Potrerillos is about 596 miles south of the northern boundary of Chile, and about 74.5 miles east of the Port of Chañaral. (See Fig. 1.)

[1] Published in September, 1930, *Proceedings*.

[2] Hydr. Engr., Andes Copper Min. Co., Barquito, Chañaral, Chile.

About 2 miles south of Chañaral, the Andes Copper Mining Company maintains its own port—Barquito—where its ocean-cargo handling facilities are located, a steam power plant of 30 000-kw. capacity, a warehouse, the Chilean Custom House, the railway terminal, and living quarters for employees engaged in port activities.

The Chilean Government maintains and operates a railway from Chañaral to Pueblo Hundido, a village 36 miles east of Chañaral. The Andes Copper Mining Company operates over this railway, under an agreement with the Government. It has constructed its own line between Pueblo Hundido and Potrerillos, a rail distance of 57.8 miles.

FIG. 1.—REGION OF LA OLA PIPE LINE.

Potrerillos, the site of the Metallurgical Plant, is the terminus of La Ola Pipe Line, described in this paper. The mine is connected with the Metallurgical Plant by an electrified railway, 6.2 miles in length.

DESCRIPTION OF COUNTRY

The Continental Divide of South America is formed by the main range of the Andes Mountains which parallels the Pacific Coast; the summit is only from 100 to 150 miles inland. This range of mountains is the highest in the Western Hemisphere, the peaks reaching more than 22 000 ft. in altitude.

From a point about 300 miles south of Chañaral to beyond the northern boundary of Chile, the Humboldt Current (extremely cold), touches the western coast of South America and tempers the climate of that area. This cold-water area coming in contact with cold air currents from the high mountains and with cold ocean winds from the south, creates a physical condition that eliminates all possibilities of any great precipitation of moisture. As a consequence Potrerillos and the entire area surrounding it, is almost entirely devoid of rainfall. This area is known as the Atacama Desert, and receives a smaller amount of precipitation than the Sahara Desert.

This arid condition has produced a marked effect on the country. Incomplete erosion has left a topography of extreme roughness with considerable variation in elevation. The entire area is practically devoid of vegetable growth, and consequently geological formations are strikingly exposed.

The Metallurgical Plant is at an altitude of about 9 500 ft. and the mine at about 10 500 ft. The plant and the mine are both in what might be classed as the foothills of the main Andes Range, the summit of which is about 50 miles farther east.

The area between Potrerillos and the Continental Divide is rough in the extreme; it is cut by "quebradas", or canyons, thousands of feet deep, which have created large areas inaccessible to any form of transportation other than by saddle or pack animals. Water holes are few and far between, and the entire area is incapable of supplying food of any character for either man or beast.

The Ola Pipe Line was constructed within this area during 1925 and 1926, under the direction of the writer.

WATER SUPPLY

There is only one possible supply of water lying within a reasonable distance and capable of furnishing a sufficient quantity for the metallurgical requirements. This is a small stream, known as Rio La Ola, about 25 miles east of Potrerillos. The Ola River traverses a large volcanic "pampa," or plain, for a distance of about 9 miles. This pampa, practically surrounded by mountains, is about 125 miles long by 10 miles wide, and lies at an elevation ranging from 11 500 to 13 000 ft.

The river has its sources in a series of "vegas", or meadows, which include a large number of springs and water-holes; the supply is probably from an artesian flow originating in the high mountains where there is sometimes heavy precipitation in the form of snow. The "vegas" cover an area of several thousand acres and are almost entirely surrounded by a water-bearing formation. (See Fig. 2.)

The Ola River flows north above the surface for a distance of about 9 miles and then gradually disappears into the loose sands and gravels of which the pampa is formed. The indications are that from its point of disappearance it follows an underground seepage course and again rises about 12 miles farther north in Pedernales Lake, which is at the most northerly end of this pampa. Pedernales Lake is a salt bed with an area of about 115 sq. miles.

Necessarily any diversion of water from the Ola River must be accomplished at some point within the 9 miles where the water flows above the surface. Only one site was found that was suitable for the construction of a diversion dam. At this place, the formation of the pampa changes from loose sand and gravel to a conglomerate which has the characteristics of a very fair grade of concrete. Through this formation the river cut a narrow channel, leaving a good site for a low diversion dam. This formation appears for only a short distance up stream and down stream from the dam site, and seems to form a cut-off or barrier that throws all the Ola River water to the surface at this point.

The Spanish word, "ola," means ocean wave or billow; so this stream very probably received its name from the fact that the water is slightly salt or brackish to the taste. It does not contain sufficient salt to be unpalatable, however, and it was used throughout the construction period for camp drinking water and construction purposes. An analysis of the water is given in Table 1.

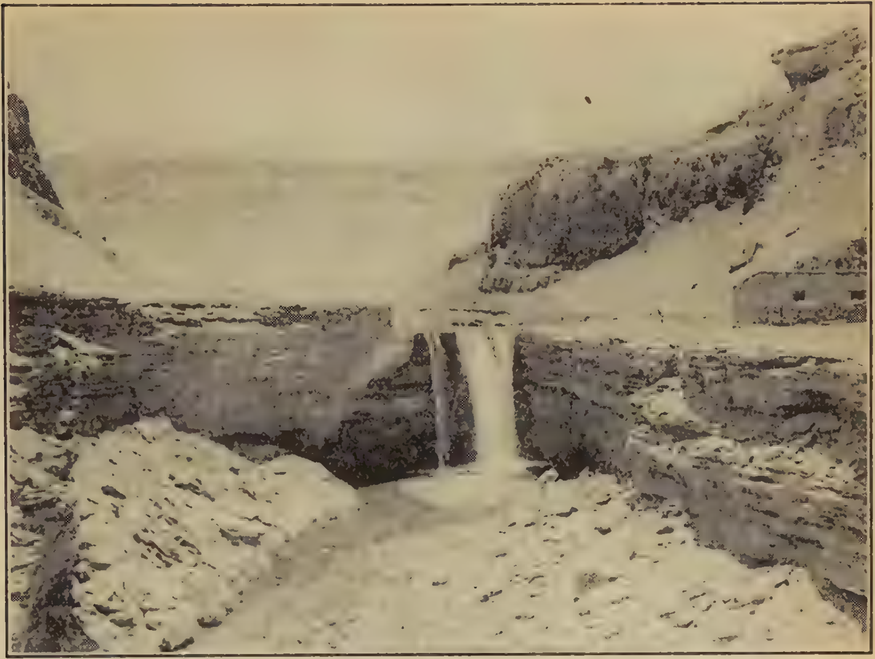

FIG. 2.—JUNCAL FALLS IN THE DRAINAGE AREA ABOVE LA OLA RIVER. THIS WATER DISAPPEARS BEFORE IT REACHES THE RIVER.

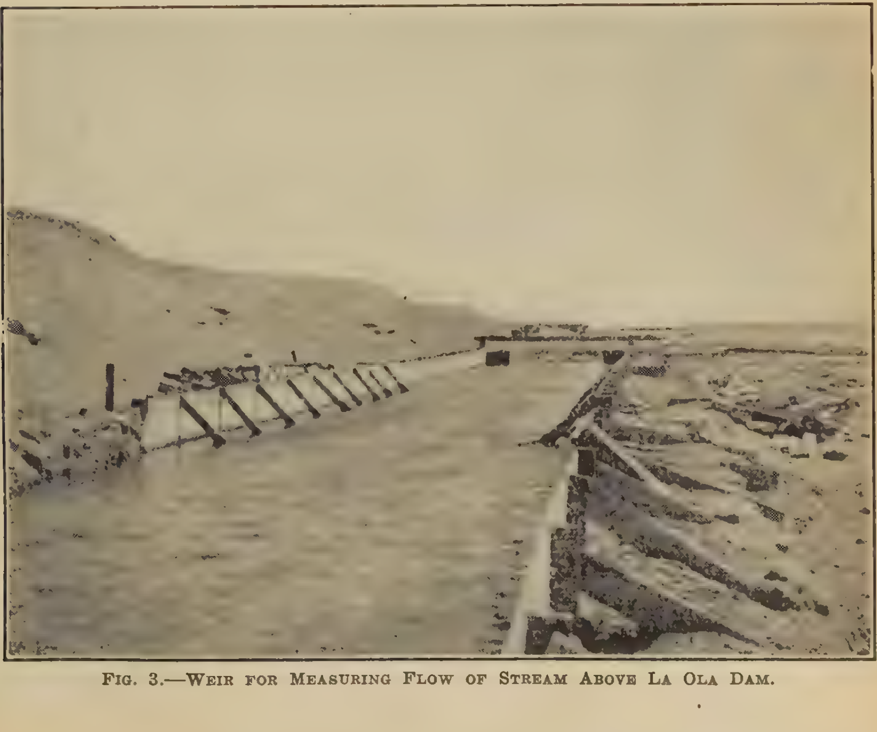

FIG. 3.—WEIR FOR MEASURING FLOW OF STREAM ABOVE LA OLA DAM.

During the period of investigation of the Potrerillos ore deposits, a weir was constructed in the Ola River a short distance below the present dam site (see Fig. 3), and when work was started in 1925, flow records were available extending from September, 1915, to November, 1920. Since February, 1925, continuous records of flow have been kept. (See Fig. 4.)

The 5-year hydrograph which was available at the time the pipe line was designed, shows the following characteristics:

1.—The average flow for the 5-year period was 27.87 cu. ft. per sec.;
2.—The minimum flow occurred in December, 1917, with a monthly average of 21.44 cu. ft. per sec.; and,
3.—The maximum flow occurred during July, 1916, with a monthly average of 55.50 cu. ft. per sec.

The 5-year hydrograph was considered to be too short a period on which to base calculations, but it indicated that the stream was one of fairly constant flow. This is reasonable when it is considered that practically all the water comes from underground sources and is subject to only slight variations, due to precipitation on the drainage area. The principal variations in flow are due to freezing during the winter months of June, July, and August, and to evaporation during the summer months.

Variations from freezing are characterized by daily peaks caused by the vegas freezing at night and thawing during the day. This variation often reaches 40% of the average flow of the stream; but it is easily controlled by the pondage up stream from La Ola Dam.

Climatic conditions in this area are such that a maximum of evaporation may be anticipated. The atmosphere is absolutely dry, the sun shines practically every day of the year, the air is brilliantly clear, there is no foliage and no grass, except in the vegas, and the wind reaches a velocity of about 20 miles per hour on practically every day of the year. During the warmer months, from November to April, these conditions have a marked effect on the flow of this stream, and it is believed that almost the entire seasonal variation is due to evaporation.

The annual variation, no doubt, is due to the precipitation on the catchment area that supplies the underground watercourses. However, since the rate of underground flow is undetermined and the catchment area is unknown, no approximations or calculations can be made regarding this factor.

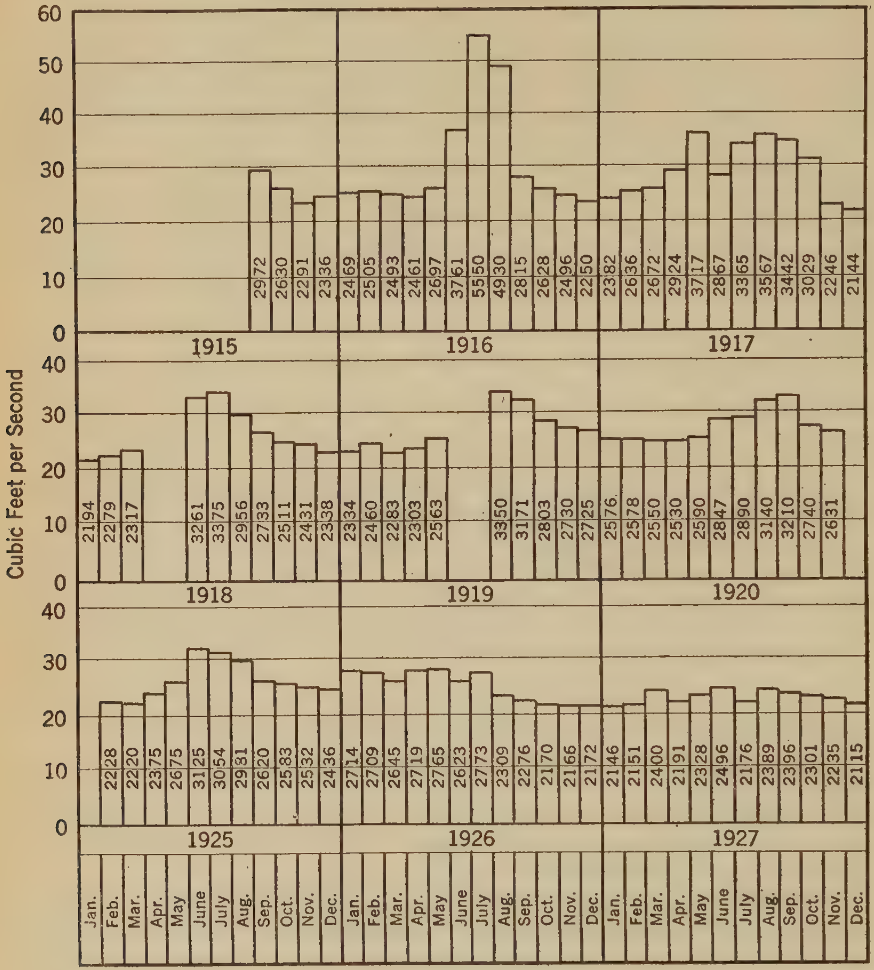

FIG. 4.—HYDROGRAPH OF LA OLA RIVER.

An excellent demonstration of this variation is shown by the hydrograph for 1927 (Fig. 4). During the early part of July of that year an unusually heavy snowfall occurred on the pampa and on the mountains surrounding it (see Fig. 1). The average depth of snow was more than 3.0 ft. on the pampa and undoubtedly reached a depth of many feet on the western slope of the main Andes Range; yet the month of June, just prior to this storm, shows a greater run-off than any following month of that year. A similar snowfall had not occurred since the winter of 1919. It is impossible, therefore, to forecast accurately the annual variations of flow. Hence, it was necessary to assume, from past performance, that the stream has a fairly consistent and constant flow and that it is not subject to sudden great increases or decreases.

From the 5-year period it may be seen that the stream flow is less than 25 cu. ft. per sec. for about 30% of the total time; that the duration of low flow extends each year over a period of from 3 to 6 months; and that it is more than 26.5 cu. ft. per sec. for 50% of the total time.

The storage capacity of the reservoir above La Ola Dam is only 1 025 000 cu. ft., which is not sufficient for any appreciable quantity of storage; but it will supply a regulation covering a reduction of flow of 40% for a period of 30 hours. This 30-hour regulation is more than sufficient to take care of all daily fluctuations.

With the plant requirements estimated at 29 cu. ft. per sec., of which 9 cu. ft. per sec. might be recovered by pumping, and with a flow of 26.5 cu. ft. per sec. recorded for 50% of the time, it was deemed to be economical to develop this project with the object of securing 26.5 cu. ft. per sec. for as much of the time as possible. Therefore, the pipe line was designed with that quantity in view.

Determination of Types of Pipe Line

Prior to 1925, various studies had been made to determine possible means of conducting water from La Ola River to Potrerillos. Three plans were considered: One for a high-pressure steel pipe line; one for a reinforced concrete pipe; and the third for a continuous wood-stave pipe.

The result of the preliminary work was a recommendation to construct a diversion dam about 1.5 miles up stream from the present site of the La Ola Dam and to use continuous wood-stave pipe for the pipe line. Through the greater part of the distance this line was to follow a location for light pressures, and the plan called for the use of lap-welded steel pipe at points of heavy pressure and in inverted siphons. This arrangement involved a line 39 miles long and was considered of sufficient merit to warrant the establishment of a definite location, and the driving of tunnels. A total of seven tunnels had been planned; two were more than a mile long and the others varied from 250 to 1 270 ft.

On January 1, 1925, the work of driving these tunnels had been in progress for several years and they had all been completed except about 2 000 ft. in Pedernales Tunnel which has a total length of more than 1 mile.

During the prosecution of this work, a considerable length of 6-in. wood-stave pipe failed. It had been laid in soil having a chemical content similar to that to be traversed by the Ola line. This resulted in a decision to use steel in the construction of the new line. The difference in ocean freight and customs duties on fabricated pipe and steel plates made it necessary to manufacture as much of the pipe as possible on the site of the work. This is illustrated in Table 2.

Factors recommending the use of riveted pipe in preference to electrically welded pipe were: (1) The class of labor available; (2) the speed of fabrication that might be maintained; (3) the quality of workmanship to be obtained with unskilled labor; and (4) the joining of pipe in the field where electric power would not be available. In order that the life of the pipe would be equal to the requirements of the plant, and in order to construct pipe of sufficient rigidity, for handling and transportation, it was deemed advisable to specify $\frac{3}{16}$ in. as the minimum thickness of metal.

TABLE 2.—Comparison of Costs Between Lap-Welded and Riveted Pipe.

Pipe.	Per foot.	Per ton.
Riveted pipe assembled on job	$ 4.33	$ 84.20
Light-weight lap-welded joint pipe purchased in United States	8.20	167.50
Heavy-weight lap-welded joint pipe purchased in United States	19.15	172.90

At the beginning of construction work the problem was encountered of using the tunnels which already had been driven at a grade laid down for the location of a wood-stave pipe line, and to adapt them to a hydraulic grade that would be consistent with the use of steel pipe. To complicate this problem the investigations made in 1925 indicated that the upper dam site, previously approved for use with the wood-stave pipe design, was unsuitable. This made necessary the use of the lower dam site where a previous structure had failed. This site was very close to the grade of the tunnels.

A bold location, therefore, was adopted. As few horizontal angles as possible were used; heavy pressures were taken in preference to unnecessary length; and the line was made as short as the topography would permit. This threw the line into a series of inverted siphons, some of which are under far greater pressure heads than any previously attempted in a pipe line of this character.

The line, as designed and constructed, therefore, is unique in two features: (*a*) It involved the use of heavy siphons; and (*b*) the greater part of the pipe was fabricated on the ground.

Available Labor

The Chilean laborer, when properly managed, compares very favorably with the laborer in the United States; but to obtain efficiency, certain expedients must be used in making work an object. With work on an hourly or daily rate of pay the results obtained are not satisfactory; but when placed on a piece-work system, or "contrato", the Chilean laborer works steadily and efficiently.

With these characteristics in view, methods of handling labor on the Ola Pipe Line were revised to suit the needs of the situation. Much of the work was done on a strictly piece-work basis. Often a "capataz", or foreman, would be given a contract and he, in turn, would divide his profits with the laborers. Special contracts were entered into with men or groups of men. In other cases bonuses were paid for certain work accomplished.

A separate and important class of labor on this work were the cartmen or "carreteros" who drove the mule carts which were used exclusively for transportation of pipe and supplies. These men are almost a distinct class, and their work is a profession among them, which is handed down through generations in the same family. They consider themselves superior to the ordinary laborer, and will not do his work. They are a tough, hardy set of men who provide their own meals on the road and sleep under their carts at night, regardless of the weather.

There are few rough-work, or form, carpenters in Chile, but high-grade carpenters are rather plentiful. They are especially adapted to cabinet-making or work of a similar nature. They are slow, but they turn out a splendid product.

Mechanics are not plentiful, and it became necessary to recruit men from the better grade of laborers and train them as riveters. These people are naturally quick and skilful with their hands, so that by confining them to one class of work and putting that work on a contract basis, they would quickly become efficient.

The higher class of engineers and foremen on this work were in some cases contract men brought from the United States, and the others were secured in Chile.

The money values quoted in this paper are reduced to United States currency at the various rates of exchange existing throughout the period that the work was in progress. For practical purposes 8.25 pesos equal $1.00. The average 8-hour daily wages paid throughout this entire work were as follows:

Blacksmiths and helpers	$1.41
Boiler-makers and helpers	1.61
Carpenters and helpers	1.47
Chauffeurs	1.38
Clerks	2.66
Cooks and helpers	1.53
Electricians and helpers	1.74
Engineers and draftsmen	8.36
Foremen	4.52
Harness makers and helpers	1.32
Iron workers and helpers	1.53
Laborers	1.22
Machinists and helpers	$1.69
Masons and helpers	1.44
Miners: Hand	1.28
Miners: Machine	1.54
Painters and helpers	1.40
Pipe-fitters and helpers	1.85
Rodmen and levelmen	1.71
Teamsters and stablemen	1.50
Tinsmiths and helpers	1.43
Watchmen	1.36
Welders and helpers	1.69
Wheelwrights	1.48

The average wages, including bonus on contracts, were $1.57 U. S., or 12.95 Chilean pesos.

When work began on the Ola Pipe Line there was a decided scarcity of labor, due to the fact that all the work, in and about Potrerillos, was being started at that time. The ultimate requirement for the Company's entire project was to be about 10 000 men. The isolated location, slow transportation facilities, and incomplete organization in the beginning made the mobilization of labor forces slow and difficult. The quality of labor secured in the beginning was also of a low order. There was no choice except to take all who came, many of whom were drifters, and men who had no intention of doing a day's work. This, combined with the high altitude which affected many, the severe climatic conditions, and lack of proper clothing, made the turnover of labor reach as high as 40% each month at the beginning of the work.

There was a continual demand for more labor on this work from its start until September, 1926, when the first necessary reduction of forces was begun. The maximum number of men on the job was reached in April, 1926, at which time the payroll showed 1 310 employed. Shortly after that date an epidemic of influenza made a considerable reduction in the forces, and that number was not reached again.

Pipe Assembly Plant: Steps in the Process

All riveted pipe and special shapes were fabricated at the assembly plant, which was located in the bottom of Pasto Cerrado Canyon where the pipe line intersects the Potrerillos Railway (see Fig. 1). This is the lowest point on the entire line and is about 2 000 ft. lower than the outlet.

The canyon is about 650 ft. wide at the bottom and has a gradient of about 4 per cent. The walls are 1 800 ft. high on the north side and 2 500 ft. on the south. The Potrerillos Railway runs along the northern edge of the canyon bottom, and a spur was run at the end of the plant in such a way that, by utilizing the 4% grade, tracks were dropped from this spur so that all materials could be transported through the assembly plant by gravity.

The plant equipment consisted of layout benches, punches, shears, drill-press, forges, rolls, air compressors, oil rivet-heaters, assembly platforms, dipping-tanks, and the necessary trackage, trolleys, and derricks for handling the materials through the plant.

Twelve distinct operations carried the steel plates through the plant and finished them into pipe of approximately 20-ft. lengths. Each operation was performed by men specially trained for that particular work. Practically every step was done on a piece-work basis and the gangs of men were so proportioned that the work ran through the plant at about an equal speed for each operation. The itemized costs given in Table 3 are the averages for the eighteen different classes of pipe manufactured.

Receipt of Materials.—All steel plates and other materials were received on railway cars, dropped into the assembly plant yard, and "spotted" at the proper unloading point. Many cars of plates contained loads of mixed sizes and thicknesses. Laborers were kept busy sorting this material but the size of the gang varied with the requirements. These men would work at any time, night or day, when cars were received for unloading. The pay for unloading and sorting plates and other material was from 40.00 to 60.00 pesos ($4.85 to $7.25) per car, depending on the class of material to be unloaded. (See Table 3, Item 4.)

Layout Work.—The second process consisted of transporting plates on push-cars from the stock piles to the layout tables and there marking them for the punches.

For straight pipe, pilot holes were first made with screw punches from a template which squared the plate. Later, these were used to hold the plate in proper position in the gang punches. This was done by drift-pinning the plate through the pilot holes to a corresponding hole in a spacing table erected in front of each punch. These pilot holes were placed in the regular position of rivet holes and, later, fell into the line and spacing of the regular punching.

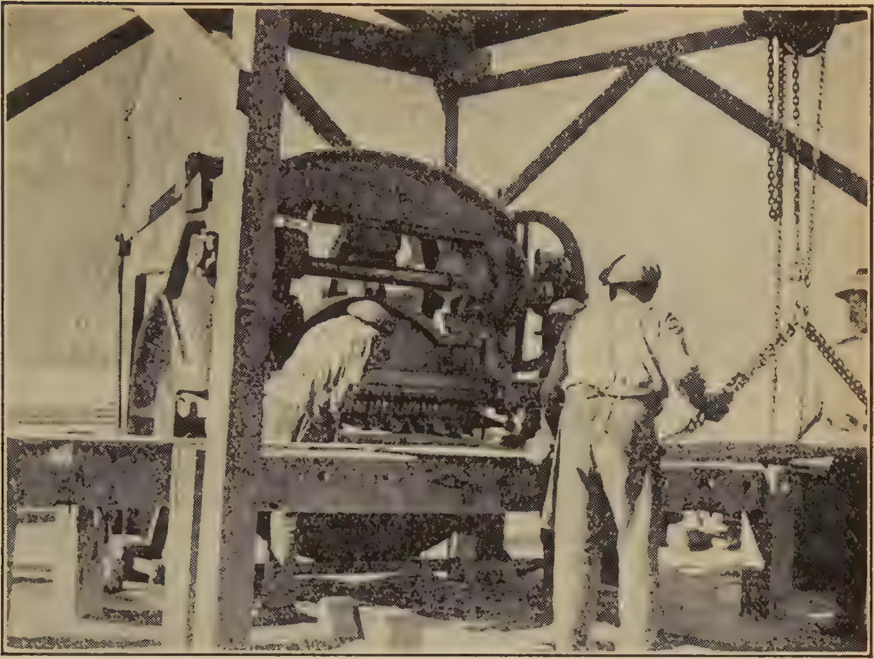

Fig. 5.—Punching Pipe Plates with Gang Punch.

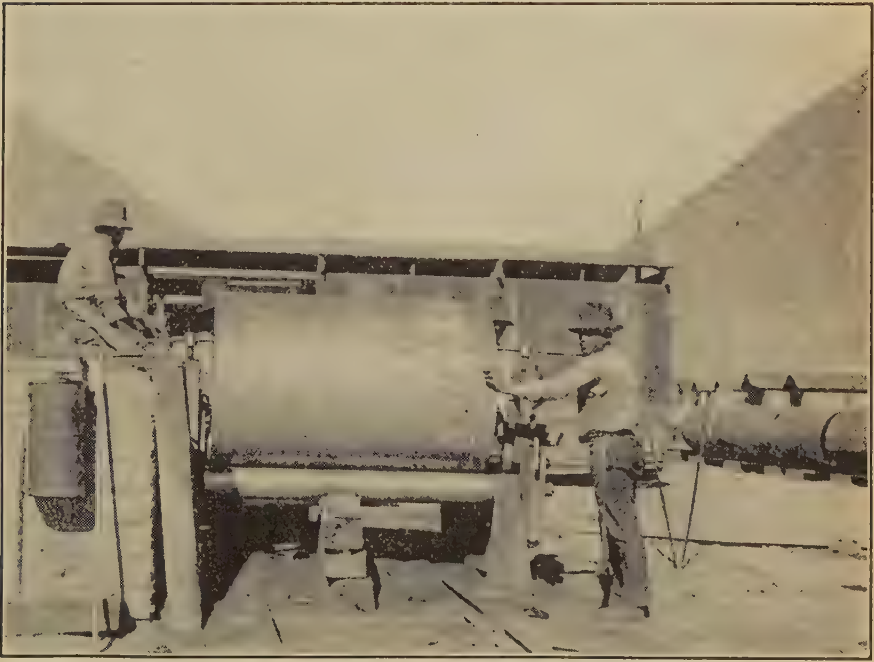

Fig. 6.—Rolling Plates in the Bending Rolls.

(See Table 3, Item 5.) The price paid for handling and pilot-punching plates for straight pipe was 0.60 peso per plate.

Special layout work for curved pipe, valve connections, flange connections, expansion joints, and special length pipe was not done by contract or piece work.

Punching and Bevel Shearing.—From the layout tables, plates were handled over chain-block trolleys to the two 62-in. gang punches. (See Fig. 5.) These punches had a capacity to make thirty-six $\frac{7}{16}$-in. holes through a $\frac{3}{16}$-in. plate when evenly spaced, or as many as nine $\frac{13}{16}$-in. holes through $\frac{3}{8}$-in. plate.

All the pipe designs were adapted to using male and female plates with no taper in the plate sections; double riveting was specified in the longitudinal seams and single riveting in the circular seams. Rivet spacing was designed to use the same size and spacing of rivets in both the longitudinal and circular joints so that one type of plates could be completely punched with one setting. One gang punch was always assigned to male plates and the other to female plates of the same type; and they were set so that the holes would correspond on the circular seams of the two plates. This method of punching proved to be fast and accurate, and scarcely any reaming of holes was necessary, except at the scarfed corners of the plates where the accuracy of the holes had been upset in the process of scarfing.

Four men could handle and punch about 8 plates per hour with this equipment. (See Table 3, Item 6.) Only plates $\frac{1}{4}$ in. thick, and more, were bevel-sheared for caulking. These plates went directly from the punches to the rotary bevel shears for cutting.

Scarfing.—From the punches and shears the plates were carried by trolley to the two scarfing forges. These were equipped with electrically driven blowers, and were placed so that each would heat one corner of the plate to be scarfed. After heating, the plates were drawn directly from the fires to two anvils where the scarfing was done by hand. Four men would scarf about 9 plates per hour at the rate of 0.50 peso per plate. (See Table 3, Item 7.)

Bending Ends of Plates.—Before being turned through the rolls it was necessary to bend the end of the plates to conform with the pipe radius; otherwise, the rolls would leave a flat section at each end of the plate. For doing this work, forms were constructed with the proper bend, upon which the plates were held by clamps. The ends were bent by hammering the plates cold over these forms with 12-lb. hammers. Four men could bend both ends of the plates at the rate of about 9 plates per hour. The piece-work price paid for this work was 0.50 peso per plate. (See Table 3, Item 8.)

Rolling.—The plant was equipped with a 5-ft., motor-driven, reversible bending roll for rolling plates to the pipe radius. (See Fig. 6). One operation through these rolls would bend the lighter plates to the proper radius, the heavier plates requiring two or three operations to bend them to shape. A force of four men could handle and roll an average of 9 plates per hour at the rate of 0.50 peso per plate. (See Table 3, Item 9.)

Assembling.—From the bending rolls the plates were rolled by hand to the assembly platforms. These platforms were constructed in such a manner that the pipe would rest on a system of disk rollers, on which the pipe could be turned without being moved from the platforms. Pipe of four plate lengths, or a laying length of 19 ft. 5 in., were assembled and bolted together on these platforms. Circular joints were made without belling and all joints were assembled, metal to metal, with no paint between. Such little reaming as was necessary at the scarf corners was done immediately after the assembly of the pipe, and this cost was included in the unit price. Four men would average the assembly of 1 pipe made up of 4 plates, per hour. The price paid for this work was 6.50 pesos per pipe of 4 plates. (See Table 3, Item 10.)

TABLE 3.—MANUFACTURE OF RIVETED STEEL PIPE IN THE FIELD.

Item.	Steps in manufacture.	Cost, U. S. Dollars.		Man-hours per mile.	Remarks.
		Per ton.	Per mile.

	Totals............................	$84.20	$22,902.40	10 156	....

Riveting.—Rivets, $\frac{3}{8}$ and $\frac{7}{16}$ in. in size, were driven cold and by hand, and the heads were snapped and finished to a reasonably smooth button. Those more than $\frac{7}{16}$ in. in size were driven hot with air hammers.

All rivets were bucked up from the inside of the pipes by means of a bucking iron held in place by a wooden lever. The weight of the man who sat on the end of the lever would provide the proper pressure to the bucking iron.

Air for rivet hammers and forges was provided by two motor-driven compressors with a total capacity of 550 cu. ft. per min. A gasoline-driven compressor of 250 cu. ft. capacity was used as a stand-by for times when no electric power was available. Rivets were heated in a series of oil forges distributed through the riveting sections of the plant.

The riveting gangs consisted of three men, and the average number of rivets driven was 65 per hour per gang. The prices paid ranged from 7.00 to 9.00 pesos per hundred rivets, according to size. (See Table 3, Item 11.)

Caulking.—All joints between plates heavier than $\frac{3}{16}$ in. were caulked with air hammers. In the beginning of the work and before the first hydraulic test was made in the field, all pipes, including those made of $\frac{3}{16}$-in. plate, were caulked at the scarfs. The first hydraulic test showed scarf caulking to be ineffective and many pin-leaks developed. Thereafter, all scarfs were electrically welded, which completely eliminated this defect. Caulking and welding were done on a "per day" wage basis because inspection of this class of work is difficult. (See Table 3, Item 12.)

Inspection.—General inspection of the work was made by the foremen in the plant and special inspection of rivets, caulking, punching, and assembly was made by men who also kept accounts on piece-work contracts. Test pipes were also made, with bulkheads in the ends, and these were subjected to hydraulic pressure to twice their working capacity. (See Table 3, Item 13.)

Dipping.—After they were riveted and inspected, all pipes were numbered and marked to show the type and were then placed in a storage yard. From this yard they were rolled by hand to the dipping tanks as they were required for use.

The two dipping tanks, with a capacity of four pipes each, were constructed of steel plates, surrounded with adobe. These tanks rested upon furnaces built of fire-brick; they were equipped with odometers and were heated by oil burners.

The pipe dip used was a high-grade asphalt. When this was heated, a special flux was added to an amount of about 2% of the asphalt. The temperature of the dip was maintained at from 375° to 400° Fahr. It has a flash-point of about 425° and caught fire twice, due to carelessness of the furnace operators. The first fire resulted in the loss of practically all the mastic in the tank as well as the pipe that was in the bath. Prior to the second fire a steel cover for the tanks had been constructed, and with this the fire was quickly smothered.

The pipe was dipped cold and allowed to remain in the tank about 20 min. to bring the temperature of the metal up to the temperature of the bath. This resulted in a very smooth, shiny coating, about $\frac{1}{32}$ in. thick, which had an excellent bond to the metal, was not brittle in cold weather, not too soft in hot weather, and withstood well the rough handling received in transportation. After almost four years of use this coating has now (June, 1930) resisted the abrasive and other effects of the water and is in excellent condition.

The two dipping tanks were served by a derrick which was used for placing the pipes in the tanks, for removing them, and for standing them on the drying platform. The pipes were held over the tanks until the drip had stopped and were then stood on end to cool. As soon as they reached the temperature of the air they were ready for use, because this dip required no further drying. The labor of dipping was paid for at the rate of 2.00 pesos per pipe. (See Table 3, Item 14.)

Special Pipe.—All special pipes were laid out and fabricated to fit the particular point for which they were made. Curves were limited to a maximum of a 5° angle for a single joint between 5-ft. plates; hence a length of pipe, of four plates, was enough for any angle up to 15 degrees. Angles of less than 5° were made in one joint. Angles between 5° and 15° were made in three equal joints, and those of more than 15° were extended to as many joints as were necessary to cover the angle. Field surveys and excavations followed these rules, so that when the Special Plant received an order for a curve of a certain degree angle, no further information was necessary to show how that pipe should be laid out to fit the ground.

Special lengths of pipe were required for making closures between sections of pipe-laying and for fitting curves of high degree to the ground. These had to be specified, together with the type of ends, whether male or female, and had to be turned out at the plant in a short time to prevent delays in the pipe-laying. Holes for air and drain valves were cut out with acetylene torches and all saddles were caulked after riveting. Expansion joints were manufactured in the United States and shipped to Chile with blind companion flanges. These flanges had to be punched to fit the type of pipe to which they joined, and were riveted at the plant, to one plate length of pipe.

The fabrication of "specials" was carried on in a manner similar to that of straight pipe except that the Special Department was equipped with a double-end punch and shear for cutting and punching curved joints, and with acetylene welders and torches for cutting and welding. All "specials" were tagged as they passed through the dipping tanks, and as soon as they cooled from the dip they were lettered with white paint with their line station numbers.

TABLE 4.—SUMMARY OF PIPE LINE COSTS.

	Item.	UNIT COSTS, IN DOLLARS (8.25 PESOS).			
		Materials and supplies.	Labor.	Expenses.	Total.
	Cost of Pipe, Including Specials:				
1	Assembly per foot	$ 2.88	$ 0.85	$ 0.27	$ 4.00
2	Dipping per foot	0.24	0.09	0.00	0.33
3	Total, Items 1 and 2	$ 3.12	$ 0.94	$ 0.27	$ 4.33
4	Total, Item 3, in dollars per ton	$60.60	$18.40	$ 5.20	$84.20
	Cost of Field Transportation:				
5	Per ton-mile	$ 0.37	$ 0.32	$ 0.08	$ 0.77
	Cost of Excavation and Back-Filling:				
6	Total per linear foot	$ 0.08	$ 0 61	$ 0.02	$ 0.71
7	Total per cubic yard	0.17	1.28	0.04	1.49
	Cost of Tunnel Driving (1 942 ft.):				
8	Total per linear foot	$13.72	$12.34	$ 0.54	$26.60
9	Total per cubic yard (3 100 cu. yd.):	8.59	7.73	0.34	16.66
	Cost of Tunnel Lining:				
10	Total per linear foot (7 196 ft.)	$ 2.87	$ 3 88	$ 0 38	$ 7.13
11	Total per cubic yard (5 300 cu. yd.)	3.83	5.27	0.52	9.68
	Cost of Pipe Laying:				
12	Total cost per foot	$ 0.12	$ 0.84	$ 0.09	$ 1.05

Approximately 8% of the total pipe fabricated was in "specials." In Table 4, showing a summary of pipe-line costs, "Expenses" include electric power, railway freights, railway passages, and various other small items.

Rate of Progress.—Activities began at the "Sifon Assembly Plant" in March, 1925, but such work as was possible at that time was confined to the construction of camp buildings, and the laying out and grading of the assembly plant and yard. At first, the shortage of labor and material retarded progress.

It was not until July, 1925, that the first of the equipment was received, and it was nearly the end of August before sufficient equipment had been received and erected to start assembly work on the pipe.

The total period of manufacture extended from August, 1925, to August, 1926. In that time 131 200 ft. of riveted pipe were fabricated, or an average of 360 ft. per day. This rate required the use of 75 plates and the driving of about 8 100 rivets per day.

The maximum rate of fabrication was reached in April, 1926, when the monthly average was 640 ft. per day, which required the daily use of 130 plates and the driving of 15 000 rivets.

TRANSPORTATION

The largest single item of labor cost for the construction of the Ola Pipe Line was that of transportation, and except for the cost of pipe material, it was the largest item of the entire work.

Those who are unfamiliar with South American and Chilean conditions can hardly realize the tremendous undertaking required to transport the 22 040 tons of materials and supplies that were used.

The Assembly Plant was the freight-receiving station for all materials and supplies for the entire job. At this point the general store house, and the yards with sufficient capacity for handling all materials, were located. It was 28 miles, by pipe line, from the intake at La Ola Dam, and 4.3 miles from the outlet of the pipe at Potrerillos. The distances by rail were 83.9 miles from the Port of Barquito and 12.4 miles from Potrerillos. As previously stated, the plant was built at the bottom of a deep canyon and at the point of lowest elevation on the entire pipe line, which meant an uphill haul from there to all parts of the line. The location chosen, however, was the best possible because railway facilities were necessary for incoming materials, and this location was at the only intersection of the pipe line and the railway.

Existing roads, which in reality were little more than trails, extended from the Assembly Plant down Pasto Cerrado Canyon to Jardin, a distance of 4.3 miles, and from there zigzag roads had been constructed up the canyon sides, one leading south to Potrerillos and the other going up the opposite canyon wall, and thence to Pedernales and La Ola. From the Assembly Plant to the rim of the canyon the vertical distance is 1 700 ft., and the haul by road is 12.4 miles, of which 3.7 miles is a switch-back road on a 10% grade. This haul is a full day's work for a mule cart. The construction of the inverted siphon across Pasto Cerrado Canyon required the construction of inclined tracks paralleling both legs. It was decided, therefore, to build the north leg track with the purpose of using it for hoisting all pipe and supplies to the top of the canyon wall.

This inclined railway was built with a vertical lift of 1 600 ft. in a horizontal distance of 2 950 ft. The average slope was 27° and the maximum slope, 46 degrees. The roadbed was cut through limestone and conglomerate throughout the entire distance. The lower end of the track began at a sloping trestle about 328 ft. long which made an overhead crossing over the railway and landed at the top of an almost vertical cliff of limestone. The track had a gauge of 39.37 in., which corresponded with the gauge of the Potrerillos Railway. The rails were laid on ties in the usual manner, but were anchored at each rail-joint to an eye-bolt grouted into the rock of the roadbed. On the trestle the ties were drift-bolted to the stringers.

This incline was equipped with a 10-ton electric hoist having a drum, 5 ft. in diameter, which carried 3 800 ft. of 1-in. wire rope. Flanged cast-iron rollers, 2 ft. long and mounted in bronze bearings, were placed at all points where the loaded cable would drag.

The car used on this incline was 20 ft. long and had a capacity of 12 tons. Its traction pull was from the center through a bridle that could be raised and lowered at the cable end to conform with the irregular grade of the track and to prevent lifting the front wheels of the car from the rails.

The hoist had a rope speed of 200 ft. per min. and the average trip, up or down, consumed about 20 min. With loading and unloading, a round trip of the car required about 1 hour. For much of the time this car ran night and day and handled as much as 2 314 tons in 1 month.

All the materials for the construction of the La Ola Dam, 27.9 miles of pipe line, the Montandon Power Station, tunnel lining, the stock feed, and camp supplies for all the work at the dam end of the line, passed over this incline.

Sifon Alto Camp was at the head of this incline railway on a sloping mesa or ridge about 0.62 mile wide which drops away to the north into another canyon of about the same depth as Pasto Cerrado. At this camp there was ample room for a large storage yard for pipe, corrals for mules, shops for blacksmiths, cart repairmen, and harness makers, and for the necessary camp buildings for housing the men.

Sifon Alto was headquarters for all the animals used on the job and for all cartmen. All cart and harness repairs were made here and all feed for the animals passed through this camp. The maximum number of animals in service was more than 600. All water for animals and men had to be hoisted to this camp from the Assembly Plant which was supplied with water from a pipe line constructed to serve the railway.

From Sifon Alto the cart road followed a ridge for about 4½ miles at about a 4% grade; then it meandered and zigzagged along side hills at about a 10% grade for a distance of 7½ miles to the top of Piñon Pass which has an elevation of about 13 000 ft. From Piñon Pass the road first drops and then rises a second time to Llanta Pass in a distance of about 2½ miles, and then drops abruptly to an elevation of about 11 250 ft. at Pedernales Camp, which is at the bottom of a deep valley between two mountain ridges.

Pedernales and Llanta Tunnels were driven through these two ridges. They were each more than 1 mile in length and were the destination of much trans-

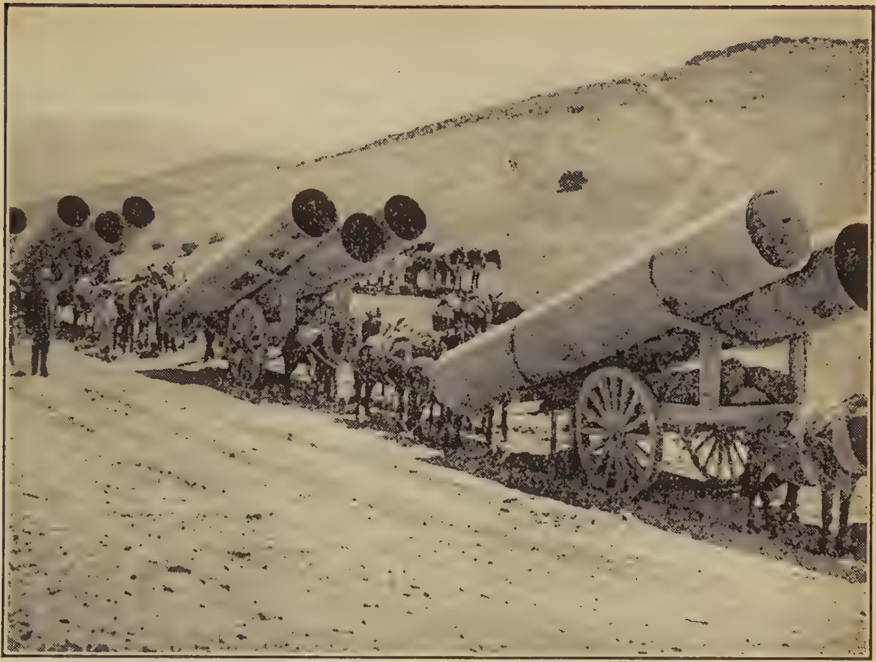

FIG. 7.—THE NOON STOP AT REFRESCO.

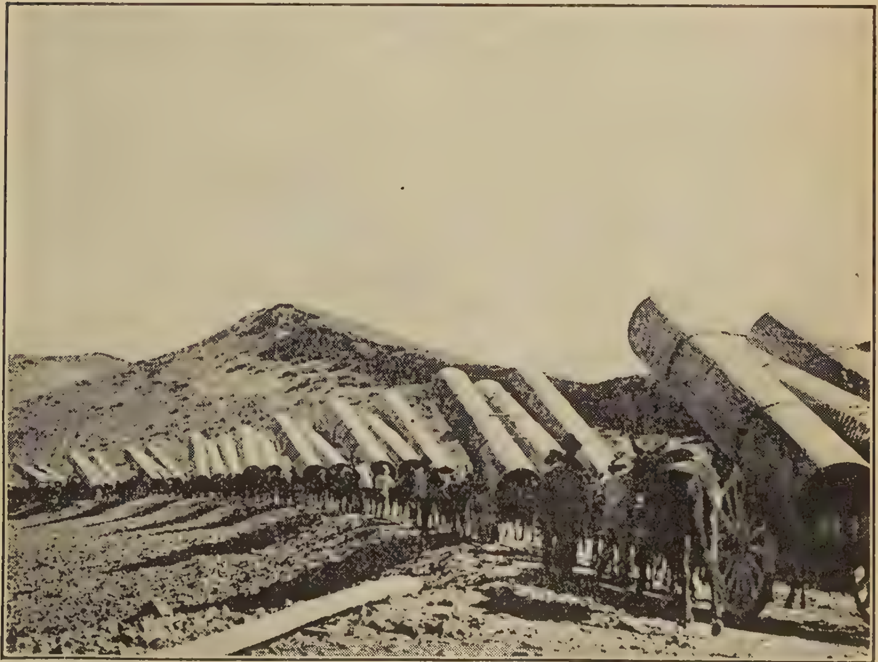

FIG. 8.—TRAIN OF PIPE CARTS RESTING ON PINON PASS. ELEVATION, 13 000 FEET (3 962 METERS), AND THE HIGHEST POINT ON THE ROAD.

ported material. The camp consisted of a staff house, bunk houses, store, warehouse, mess house, first aid station, corral, and blacksmith shop. Water in sufficient quantities to supply the corrals and camp, was available from shallow wells. A slaughter house was also located at this camp where all meat for the upper end of the line was butchered. Beef and mutton provided their own transportation to this point.

From Pedernales Camp the road followed down the course of Pedernales Canyon for about 3¾ miles, on about a 2% grade, and from there it led to the open La Ola Pampa, which is a flat valley 6 to 12 miles wide, with a sand and gravel floor. This pampa rises at about a 1% grade toward La Ola Dam and the intake of the pipe line. About 15.5 miles of this pampa had to be crossed to reach the dam and no attempt was made to maintain roads because the character of the country was such that carts could break new tracks as fast as the old ones became impassable. The pipe line was located along the western edge of this pampa and gradually reached the bounding ridge of mountains as the grade dropped away. The cart roads, therefore, followed the pampa as far as practicable, and then turned in to accessible points on the pipe line, with no attempt to follow any established trails.

The Chilean mule cart, which was used exclusively on the work of transportation of pipe and other materials, is at first glance a very inefficient piece of equipment. However, it has been developed through generations of use, and proved in this instance to be well adapted to the bad roads, steep grades, deep ruts, and sharp turns over which material had to be hauled. It is a heavy vehicle, with two wheels about 6 ft. in diameter, and a gauge of 5 ft. (See Fig. 7.) The tires are 5 in. wide and 1 in. thick. The hubs are of cast steel, and the axles are made of 3-in square metal. The car is so constructed that the load is balanced equally, fore and aft, on the axle. At the front and rear are two swinging props on which the cart is balanced while being loaded or when the team is resting on the road. A brake-beam with large wooden brake shoes operates against the rear of the wheels by means of a screw stem and large wing nut called a "mariposa," or butterfly. To operate this brake the driver has to run behind the car and turn up the screw. The brake is powerful and can be set at any tension desired.

When in motion the cart and load are balanced by one mule that is hitched between rigid shafts. This mule's harness consists of a heavy halter, a collar with chain traces hooked to the front of the shafts, and a padded saddle with a heavy cinch to which the shaft ends are bound in a manner to balance the cart by the weight of the mule. The mule also wears a heavy breeching which is attached forward to the shafts so that he is hitched firmly forward, back, up, and down. He acts as a flyball for the entire unit and is either carrying a heavy load on his back or is scratching for a toehold. The drivers are remarkably clever in balancing their loads, however, and the outfit performs better than might be expected. The mules are hitched three abreast to these carts, one on each side of the shaft mule.

The harness of each of the other mules in the team consists of a collar and chain traces which are held up by a padded saddle. The traces of the wheel mules are hitched to single-trees and no eveners are used. The traces of the lead mules are hitched to the traces of the mule behind at the saddle. No bits are used, and no lines, except a jerk-line to the lead mules' halters which is pulled to stop the team or when making a turn. The driver rides the left-hand wheel mule on a high saddle and drives his team with a whip. This hitch is ingenious and very flexible, providing for quick changes and additions to a team, and can be strung out to any number of animals. On this work as many as twenty-four mules were used on one hitch.

A driver will ordinarily handle six or seven animals and the best drivers, nine. In transporting pipe, with a load of about 5 500 lb., in addition to the weight of the cart, one driver and one helper were used for a 9-mule team. On this work it was necessary to have one man to handle the brake while the other drove the team.

Pipe carts were constructed with a rack in front, wide enough to carry three 36-in. pipes side by side. This rack raised the front end of the pipes and held them in a slanting position with the rear end high enough to clear the irregularities of the road. The pipes were bound to the carts with chains tightened with turnbuckles and were held from slipping back by chains hooked into the ends. The pipes, being about 20 ft. long, extended over the wheel mules and driver and produced such a teetering motion that an extra shaft was added to the right side of these carts so that two mules could be used in the shafts to balance the load.

Each cart carried its ration of hay and feed for the entire trip which, on the longest end of the haul, took four days to complete. The mules were allowed 15½ lb. of hay and 6½ lb. of grain per day; working seven days a week, they kept fat on this ration.

At some points of the line, particularly in the neighborhood of La Tabla and Huacho Tunnels, the road was as much as 1¼ miles from the line of the pipe. At these points the loads would be carted as far as possible along the ridges and from the point of unloading the pipes would be rolled to the line. At many points, it was impossible to deliver pipe by cart above the line, and at these places it had to be rolled uphill. Where any great number had to be handled in this manner the pipes were rolled with ropes and blocks.

Between the Assembly Plant and Potrerillos the pipe traverses the canyon side across the roughest and most inaccessible part of the line. To make deliveries throughout this section, pipe had to be loaded on railway cars and transported part of the distance by rail, and then hauled to the line on carts. In order to do this, 4½ miles of new, side-hill road had to be constructed through a steep and difficult country. This road had one main entry to the railway where the greater part of the pipe was taken from the cars, hoisted to the top of a ridge about 100 ft. high, and there loaded on the carts with a steam derrick. From this entry the road followed the top of a long ridge at a grade of about 10%, to a point above the pipe line where it branched in both directions, going at a level grade to Sifon Sur at one end and to San Augustine Canyon at the other.

San Augustine Canyon presented the most difficult problem for the delivery of pipe of any point on the line. A double siphon crossed this Canyon and the ridge between the two outside legs was inaccessible to any form of transportation except pack animals. It would have been necessary to construct about 3 miles of difficult road to reach the central ridge. The problem of delivering pipe to this section was solved by the use of a low two-wheeled cart. The pipe was balanced on the cart and was pulled to the top of the ridge with a hand winch. It required the work of 2 men for 16 hours to hoist 1 pipe to the top. The vertical lift was 325 ft. in a horizontal distance of about 500 ft. About 1 000 ft. of pipe were transported in this manner and it took about 30 days to make the delivery.

Trains of pipe and supply carts (see Fig. 8) were started each morning from Sifon Alto under the supervision of a leader who had complete charge of the train en route. These leaders were men who had been advanced from drivers, were thoroughly competent and reliable, proud of their responsibility, and who would take their trains through the trip and without delay under almost any circumstances. Each day's trip was laid out for the drivers, and if they completed that distance they were paid a bonus of 25% more than their regular pay. Regardless of the reason, the driver, unless he completed his trip, received no bonus. This made them care for their carts, harness, and mules, and assume entire responsibility for their outfits. The result of this bonus system was that very few drivers would fail to finish their trips.

The average day's haul, up grade and with a load, was about 15½ miles. Returning, down grade and with no load, the average was about 25 miles per day.

The haul to La Ola Dam and the upper end of the line required four days for the round trip. From La Cabra Tunnel the time was cut to three days and from Perro Muerto Tunnel, to two days. Train leaders would start from Sifon Alto at 7:00 A. M. with as many as twenty-four carts and would arrive at Pedernales at about 5:00 P. M.

Pipe carts were unloaded in the field by throwing off the binding chains and sliding the pipe to the rear until the ends rested on the ground. This would throw them out of balance so that the cart could be driven out from under them. Table 4, Item 5, includes the construction of 4.34 miles of road, the maintenance of 19.88 miles, the purchase of carts and harness, all maintenance of equipment, the loading, unloading, and operation of the incline car, and all regular transportation expenses.

TRENCHING AND BACK-FILLING

In the high altitudes where the Ola Pipe Line was constructed an extreme daily variation of temperature exists. To prevent freezing and to reduce expansion and contraction it was decided that the pipe would be placed in a trench and covered throughout its entire length, except across the Montandon Siphon, where it would be supported on piers and anchors.

On the Ola Pampa, where the line is exposed to extreme weather and violent winds, it was planned to cut a trench of sufficient depth to place the pipe entirely below the surface of the ground. In less exposed locations and at lower altitudes the depth of the trench was planned to be equal to about two-thirds the diameter of the pipe, and the excavated material was to be used for covering. Figs. 9 and 10 illustrate conditions along parts of the line.

All trench excavations were made by hand. The material was such that only very heavy excavating equipment would have sufficed, and the use of such equipment was prevented by the roughness of the country. The ground along about 50% of the line required blasting before it could be excavated, and much of the trench was through solid rock.

Practically all the excavation was done by contract, the men being paid according to the classification and quantity of material moved. The earth was classified as earth, hardpan, or solid rock, and measurements of the different classifications were made after the excavation had been completed. A gang or group of men would be given a contract for excavating the trench between certain stations on the line. They would be required to excavate and finish that section, and would receive no liquidation of their contract until the work was finally finished.

The proper width and shape of the trench was maintained by the use of light wooden templates which were marked along the sides in such a manner that the area of the cross-section could be read from them direct. By this method the quantities and classification of excavated materials could easily be recorded and checked.

Trench excavation was started in July, 1925, and was finished in August, 1926. During the greater part of this time two gangs of from 60 to 100 men, were employed.

Through the greater part of the work the back-filling was done by hand. The dirt was tamped under the invert of the pipe with shovels to prevent settling. Where the pipe followed side-hills, the fill on the down-hill side was maintained with dry rubble walls. On the pampa where the pipe was laid below the level of the ground, the top-fill was placed with teams and scrapers. The costs are shown in Table 4, Items 6 and 7. These items include the cost of constructing rubble walls.

La Ola Dam

A diversion dam was constructed in La Ola River during the summer season of 1925 and 1926, between the months of October and April. (See Fig. 1.)

The dam is approximately 160 ft. long between abutments and raises the water about 10 ft. above its natural level. It is a concrete structure of the gravity type, with a spillway 65 ft. long, an outlet chamber and head-gate, and one sluice-gate for drawing off sediment from the reservoir.

Tunneling

When work on the Ola Pipe Line was begun in March, 1925, 1 942 ft. of Pedernales Tunnel remained to be driven. This section was 1 190 ft. from the west portal and 1 670 ft. from the east portal of the tunnel. The completed portion at the west end was through a hard blue limestone which stood up well without timbering and required no lining to make it water-tight. The section of completed tunnel at the east end was through bad ground for 1 640 ft., but

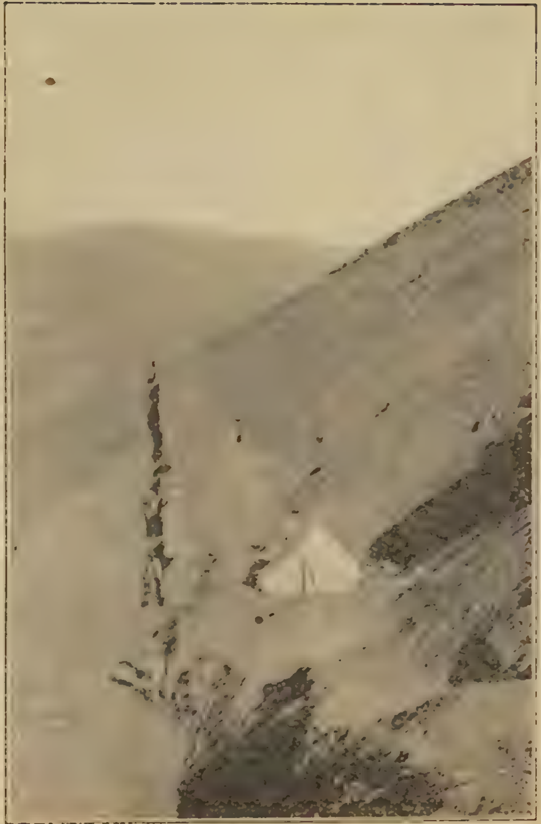

FIG. 9.—PIPE TRENCH EAST FROM PEDERNALES TUNNEL.

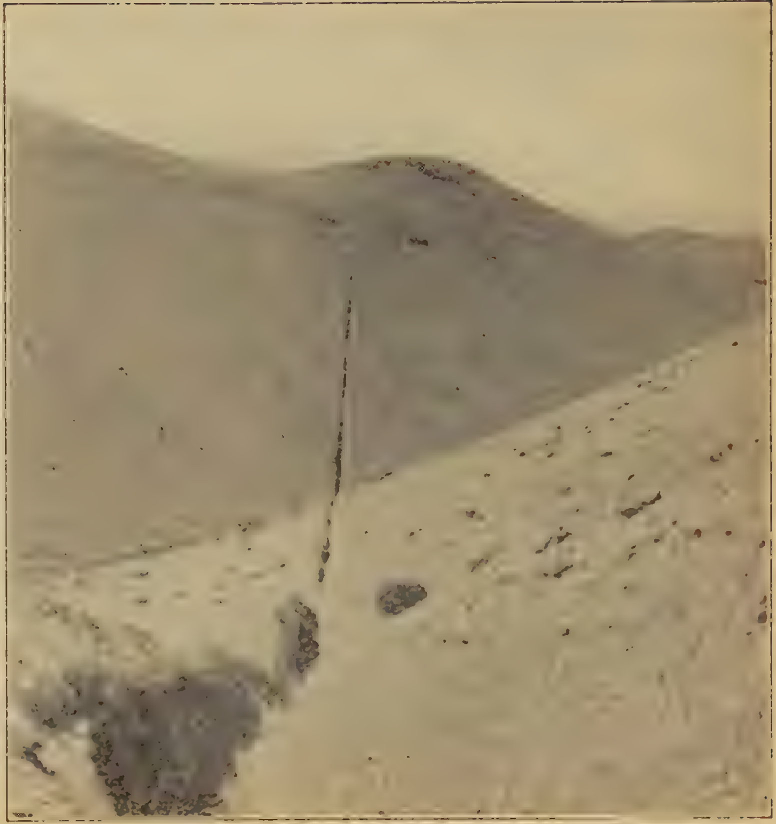

FIG. 10.—PIPE TRENCH BETWEEN PINONCITO AND LA TABLA TUNNELS.

ended in hard granite. The timbering in the first 1 640 ft. was in bad condition, which necessitated the lining of that section to make it safe. In order that the driving of the remainder of this tunnel should not conflict with the lining work, it was decided to complete all the driving from the west face.

The construction program called for the completion of the tunnel driving by January 1, 1926. In order to do this it was necessary to drive 220 ft. per month, with an average haul of more than 2 000 ft. for the material broken.

The section of tunnel was 6.56 ft. square, which allowed room for the operation of only one drill at the face. Two portable gasoline-driven air-compressors, one of 250 cu. ft. and one of 175 cu. ft. capacity, were installed at the west portal to provide air for drilling and for running a drill sharpener and forge. The efficiency of these compressors was only about 60%, because of the high altitude.

Ventilation was provided by a gasoline-driven blower, and fresh air was conducted to the face through canvas vent tubes; these were extended as the driving progressed. Broken rock was hauled by mules in 1-yd., side-dump mine cars.

Three 8-hour shifts were worked at the face. Holes were drilled to a depth of 5 ft. It required two shifts to drill a round of holes, to blast them, and to remove sufficient material to permit further drilling.

Chilean labor, on a contract basis, was used exclusively. The Company furnished the equipment, tools, air, timber, and powder, and paid 150.00 pesos per meter of tunnel completed ($5.53 per ft.), including all labor for drilling, drill sharpening, shoveling, and timbering.

Work was started March 1, 1925, by hand drilling. It was not until May 1 that the compressors were installed and ready for operation. During September, 1925, a fault plane was intersected which opened up quite a heavy flow of water. The ground was badly shattered and the tunnel opening was difficult to maintain. For about 820 ft. the tunnel had to be heavily timbered and, later, lined with concrete. This condition slowed up progress, but the tunnel was finished on December 29, 1925, two days ahead of schedule, and with a perfect closure.

The greatest progress made in any one month was during August when 376 ft. were driven. The total cost is shown in Table 4, Items 7 and 8.

TUNNEL LINING

The final location of the Ola Pipe Line with the necessary adjustments of grade to the completed tunnels, threw Pedernales and Llanta Tunnels below the hydraulic grade of the line, and, consequently, they are under a light hydraulic pressure.

Practically the entire length of Llanta Tunnel and 2 890 ft. of Pedernales Tunnel were in bad ground, composed of a shattered limestone through which were sloping layers of soapstone. Some water seeped into these tunnels; the timbering was old, and several falls of rock had occurred in Llanta Tunnel which had blocked the entries and flooded it for almost its entire length.

As a concrete lining seemed better adapted to inspection and maintenance than the process of running the pipe through these tunnels, it was decided to line the bad sections. On account of the small size of the tunnels it was necessary to use concrete forms that would not obstruct the passage in any manner to prevent the placing of concrete, or the removal of forms from the completed sections. To accomplish this, forms were developed that needed no center bracing, and that left the tunnel bore entirely open between the form ribs. This was done by making the ribs in three sections, consisting of an invert section and two side sections.

A concrete floor was first laid to grade, and upon this, while the concrete was still green, the invert ribs were placed, held in position by bracing against the roof, and then lagged. Near each end of these invert ribs were holes which held a ¾-in bolt. The bolts were fitted with nuts and O. G. washers which were embedded in the invert concrete when the forms were filled. Upon removal of the invert forms the bolts would be tapped lightly and then unscrewed, leaving holes with the nuts and washers embedded in the concrete. After the invert concrete was set and the invert forms were removed, the side forms were erected and held in place at the bottom by screwing back the bolts through corresponding holes in the upper ribs. The two side ribs were held in position at the top by a wedge, which when dropped would loosen the ribs for removal. The lagging for the upper ribs was built up as the sides were filled with concrete. The top lagging was put on in 5-ft. sections, and the concrete was shoved and spaded back from the end until the top was thoroughly filled.

The concrete in these tunnels was reinforced with a ⅜-in., round, reinforcement placed on 12-in. centers both ways and short ⅜-in., round, bars were used for bonding at the construction joint between the invert and the sides.

Sand and gravel were available at the portals of nearly all these tunnels, but had to be separated and screened by hand. Water for concrete was available from the inside except for about one-half the east end of Pedernales Tunnel. For this work the water had to be hauled about 2 miles up a 15% grade. The cement was carted from Sifon Alto to Llanta Tunnel and to Pedernales Camp, and packed from there on burros to both ends of Pedernales Tunnel.

All the concrete for the latter was mixed by hand inside the tunnel and shoveled from the mixing platforms directly into the forms. The concrete for Llanta Tunnel was mixed in a steam mixer at the east portal, and hauled by mules in end-dump cars to the forms.

All the work was done on a contract basis and was paid for at the rate of 80.00 pesos per lin. m. ($3.00 per ft.) This price included the removing of timber, cleaning up the tunnels, screening sand and gravel, placing and removing forms, cutting and placing reinforcement, and mixing and placing concrete.

The progress of the work was more rapid in Llanta Tunnel where the concrete was mixed outside. In Pedernales Tunnel a delay was caused by bad air from the setting concrete. This was before the tunnel had been holed through, and there was no ventilation until a canvas vent-tube and a blower were installed.

The 1 640 ft. of tunnel lining in Pedernales, East, was started in May, 1925, and completed in August. During July, 853 ft. were completed, which was the best monthly average on that work.

The Llanta Tunnel lining was started in August and completed in November. The length of tunnel lined was 4 308 ft., and the best run was made in November, during which 1 801 ft. were finished.

Pedernales, West, was lined in January and February, 1926, the best run being made in February when 1 014 ft. were completed by the 20th of that month.

The moist cool air of these tunnels retarded the setting of the concrete to some extent; but it contributed in producing a splendid lining.

Due to the cheap labor and to the fact that salvaged steel transmission-line cable was used for reinforcement, for which no charge is included, the costs of this tunnel lining are very low. These costs include all labor and material, but do not include transportation. (See Table 4, Items 10 and 11.)

PIPE LAYING

The laying and jointing of the pipe in the field were the final steps in the construction of La Ola Pipe Line, and required the co-ordination of all the work up to this stage of the construction. This co-ordination included preparation of the ground, the receipt of materials and supplies (including expansion joints, saddles, air and drain valves, and those sections of lap-welded pipe which were purchased in the United States), the proper order of assembly, and the transportation of material from the Assembly Plant.

The pipe-laying work extended over so much territory that, even when material was ready for shipment from the Assembly Plant, it often would take two days, or more, to make deliveries to the points where the materials were needed. This part of the work included the laying of eighteen different classes of riveted pipe, fabricated at the Assembly Plant, and seventeen different types of lap-welded pipe, purchased in the United States. Much of the latter was pipe that had to be joined in its proper order because each joint had been manufactured to fit its special location. The delivery of this pipe from the United States was erratic, and a delay in the receipt of a few sections held up the work of laying for about two months. This co-ordination proved to be the most difficult problem with which the field organization had to deal.

Pipe-laying started at the intake end of the line with 36-in. riveted pipe. The first part of the work was across the flat pampa where there were no horizontal and very few vertical curves. The system of laying adopted was to rivet together several 20-ft. sections of pipe outside the trench, and to join such a section to the last that had been laid. As shown in Fig. 11, the end of the finished section and the section being joined to it were held up in the trench with tripods and chain-blocks until the joint had been riveted, and then were lowered into place with the chain-blocks. It was found that a long string of this pipe had sufficient flexibility to permit the use of this method without putting undue strain on the rivets. After riveting and caulking, all field joints were painted inside and outside with hot mastic.

In the beginning of this work more than 12½ miles of pipe were laid before the expansion joints and valves were received. Consequently, the laying was done in sections leaving openings at points where the expansion joints were to be placed. Saddles for air and drain valves had been received in time to be connected to the riveted pipe at the time of fabrication, and the valves were bolted in place after the pipe was laid. Inability to install expansion joints and valves at the time the first pipe was laid, delayed the hydraulic tests on the line until the construction had reached Pedernales Tunnel, a distance of 14¼ miles from the intake.

The first test included the section between La Ola Dam and La Cabra Tunnel, a distance of about 5 miles. This disclosed no breaks in the line and no faulty pipe, but showed a large number of pin-leaks, particularly at the points where the plates had been scarfed and lapped. After this test all the pipe assembled at the plant was electrically welded at the scarfs and much greater care was used in caulking all field joints.

In the rougher country it became necessary to decrease the number of lengths of pipe connected together outside the trench, and it was found that, in very rough sections and on steep grades, better progress could be maintained by handling only one length of pipe at a time.

When expansion joints were finally installed it was found that the openings, which had been left between pipe sections, varied considerably in length, due to expansion and contraction. In practically all cases of installing expansion joints special lengths of pipe had to be provided to produce a proper fit. It was by this method, and at expansion joints, that all closures were made between different sections of pipe laying. Four gangs were necessary to keep this part of the work up to schedule.

Two types of lap-welded pipe were used: (*a*) Bell and spigot pipe with leaded joints was used in sections of lower pressure; and (*b*) Van Stone flange-joint pipe was used at points of high pressure on the line—in general, for pressures greater than 400 lb. per sq. in. Angles in this latter pipe were made either with curved sections for the higher degree or with wedge-shaped "Dutchmen" for the low-degree angles. As much of this pipe was laid in the Montandon Siphon, where the slopes exceeded 45°, the fitting of the joints required much care and accuracy.

Each second joint was supported on a concrete pier (see Fig. 12), and anchors were spaced about 164 ft. apart, with an expansion joint near each anchor. Reinforced concrete anchors were used where solid-rock footings were available. The reinforcement was extended into the rock foundations by being grouted into drill holes, and concrete anchors of the gravity type were used where solid-rock footings were not available.

A special cross-casting, equipped with high-pressure drain-valves, was installed at the invert of Montandon Siphon where the working pressures were 1 000 lb. per sq. in. This drain is equipped with two high-pressure 10-in. valves in tandem, which are interconnected by a by-pass pressure relief. Two men can operate them by hand under the full pressure head.

When hydraulic tests were put on the lap-welded pipe sections it was found that the leaded joints would not withstand the combined effect of expansion

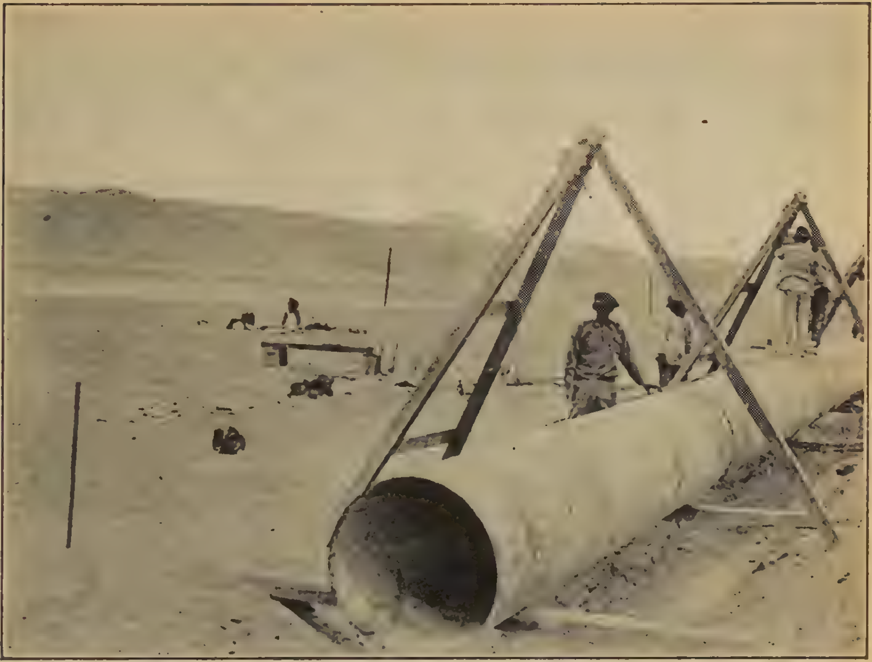

FIG. 11.—LAYING PIPE ON LA OLA PAMPA; SHOWING METHOD OF SUPPORTING PIPE WHILE MAKING FIELD JOINTS.

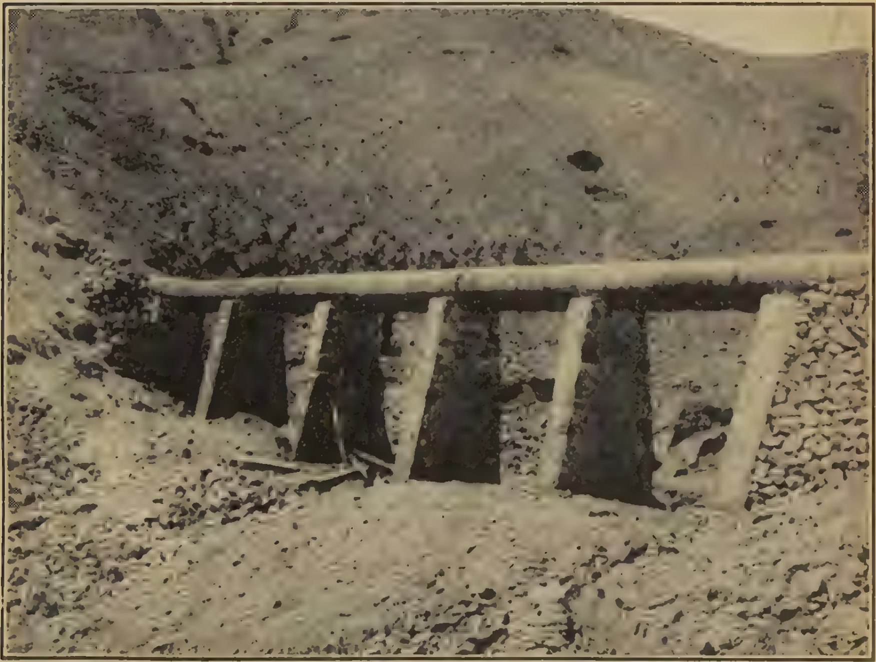

FIG. 12.—PIPE LINE CROSSING A CANYON; SHOWING METHOD OF SUPPORT FOR DRAINAGE.

and contraction of the pipe, and the high working pressures. The first test caused a joint on the south leg of Montandon Siphon to open and four lengths of pipe blew out. Two of these went to the bottom of the siphon 1 500 ft. below the break. This was followed by several breaks on the north leg of the siphon.

These leaded joints were designed with only a small bead of lead in the spigot end to prevent movement. An analysis of the trouble disclosed the fact that the movement of the pipe from expansion and contraction had sheared this bead of lead, and subsequent movements had worked it loose in the joint. The high pressures then blew it from the joint. This analysis showed that any process that might be used to hold the lead in place would remedy the difficulty. It was found that the quickest and simplest method was to construct reinforced concrete collars. Three rings of ⅜-in. reinforcement were made, one to lie in front of the lead, one behind the bell of the joint, and the third around the bell. These three rings were laced together with heavy wires of sufficient cross-section to withstand a stress equal to that exerted on the lead joint. This reinforcement was held in place by pouring a concrete collar around it. About 1 100 of these collars were made to protect leaded joints. To date (June, 1930), none of these joints has broken and only one has shown necessity for repair.

Only four of the Van Stone joints in the entire line showed leaks, and these required only a slight taking up on the bolts to make them tight. No leaks have developed at these joints to date (June, 1930).

Pipe laying was started on November 22, 1925, and the last pipe was laid November 21, 1926. The average rate of laying was 3 280 ft. per week; the maximum laid in any one month was 6.52 miles, or 1 150 ft. per day; and the maximum laid in one day was 1 312 ft. The cost items are shown in Table 4, Item 12.

MONTANDON POWER STATION

The original construction plans and estimates made for the Ola Pipe Line did not contemplate the construction of the Montandon Power Station, although it had been considered. It was only after the arrival of the construction forces in Chile, and the financial possibilities of the plant being presented by them, that the construction of this plant was authorized.

The idea of locating a hydro-electric plant in the middle of a desert is at first thought rather fantastic, and would not be practical unless the water was brought to it free of cost. In this case 1 250 ft. of head were available in the line, in excess of the required pressure head necessary to deliver the water to Potrerillos. This excess head and hydraulic drop occurs between the points where the line is tunneled through the mountain range which intervenes between La Ola Pampa and Potrerillos, and the head of Montandon Siphon; that is, in a distance of 4.40 miles beginning at Piñoncito Tunnel and ending at a point 525 ft. in elevation above the Potrerillos outlet of the line.

Piñoncito Tunnel was used as a forebay for the penstock and was provided with a spillway to care for any overflow of the line which might occur during a shut-down of the plant. The penstock between Piñoncito Tunnel and the Montandon Power Plant consists of 1 mile of 36-in. riveted pipe, 2.4 miles of 26-in. riveted pipe, 0.6 mile of 26-in. Matheson joint lap-welded pipe, and 0.3 mile of 26-in. Van Stone joint lap-welded pipe. The latter is used on the lower end of the line. This penstock contains a total of twenty inverted siphons, the greatest of which is under a pressure head of 430 ft.

As the primary purpose of the pipe line was to furnish water to Potrerillos, the power station was a secondary consideration and therefore was designed to by-pass water when the plant was shut down. Provision for this feature was made by governing the plant with a deflector which cuts the jet at the nozzle, allowing the water to pass, but deflecting it from the wheel. The plant is also provided with a by-pass for diverting the total stream away from the wheel. The needle-valves of both wheel and by-pass nozzles are hand-operated and interconnected in a manner to close one valve while the other one opens.

The hydraulic equipment in the plant consists of a single-nozzle, overhung, impulse wheel, 53 in. in diameter, propelled by a 4½-in. jet. This wheel is designed to operate under 1 132 ft. of head, at a speed of 514 rev. per min. It is mounted on the end of the generator shaft which runs on 9 by 15-in. bearings. The exciter unit is direct-connected to the other end of the generator shaft through a flexible coupling.

The tail-race and by-pass flumes discharge into a steel tank 25 ft. in diameter in which baffles have been constructed to check the velocity of the water. This tank is provided with a spillway and an outlet gate that discharges into the pipe line to Potrerillos. When closed, this gate diverts the flow over the spillway into a canyon which takes the water entirely away from the pipe line. The capacities of this plant for corresponding quantities of flow, are as follows:

Quantity of flow, in cubic feet per second.	Capacity, in kilowatts.	Quantity of flow, in cubic feet per second.	Capacity, in kilowatts.
21	1 575	26	1 950
22	1 650	27	2 025
23	1 725	28	2 100
24	1 800	29	2 175
25	1 875	30	2 250

Excavation for the foundations of this plant was started on March 15, 1926, and was completed by the end of that month. During April, all the substructure concrete was poured up to the level of the operating floor. During May, the work was delayed for lack of the superstructure steel and plant equipment, but during that month a permanent building for housing operators was constructed. By the end of June all the building steel had been received and erected, and the equipment had been transported to the site. On July 27, 1926, the plant was completed, and has been in continual operation since that date, except for minor interruptions.

The only difficult part of this work was the transportation of the plant equipment from the assembly plant yard to the power plant site. The heaviest piece to be transported was the generator shaft and rotor, which weighed more than 10 tons and was of a very difficult shape for handling because the rotor was mounted on the shaft. The weight of the piece taxed the capacity of the incline railway and was of such shape that the crate had to be bridled ahead to the haulage cable of the car, in order to prevent it from tipping over backward. From the top of the incline the transformers and other heavy pieces were carried in a four-wheeled wagon drawn by eighteen mules.

Conclusion

The difficulties attending this construction make a story in themselves. The organization of the necessary supervising staff, the selection and training of a large number of men in all departments of the work, the effect of climatic conditions at high altitudes, the difficulties in getting together and organizing the transportation facilities, and last, but not least, the delay in the receipt of necessary material were the disturbing factors encountered on this work. To appreciate the task, it is necessary to see the country traversed. The last pipe was in place and all work completed on November 21, 1926. To date (June, 1930), La Ola Pipe Line has demonstrated its fitness to serve the purpose for which it was built.

DISCUSSION

ERNEST B. NELSON,[3] ESQ. (by letter).—The author is to be commended for this very interesting description of La Ola Pipe Line and especially for the valuable unit construction costs presented. These low unit costs indicate a very efficient organization, as is likewise evident from the rapid progress of the work which was carried out in the face of many adverse and difficult conditions far from the source of supplies. As is the case on many construction jobs, transportation proved to be a major problem in maintaining progress to the required schedule.

The original design for this pipe line (1917-18) called for continuous wood-stave pipe for the low-pressure portions, about 80% of the total length, with lap-welded steel pipe at points of high pressure, including of course the Pasto Cerrado (now Montando) Siphon. Conditions at that time, with the World War in progress, made it necessary to reduce to a minimum the use of steel in all units of the projected plant development, since deliveries of steel plate, structural shapes, etc., were very slow and uncertain. During this period, due to the fact that steel construction had to be virtually abandoned, the last 20 km. of the railroad from Pueblo Hundido to the plant at Potrerillos—a difficult section in the mountains—was relocated in order to eliminate several proposed steel bridges. Four additional tunnels were thus introduced, making a total of eleven in this portion of the line, but the work was continued without serious interruption so that the railroad was completed and placed in operation early in 1919, a few months after the signing of the Armistice.

Work on the tunnels for the pipe line had been discontinued. Later, it was resumed, another tunnel having been introduced in the meantime by an alternate location through Pedernales Ridge. Late in 1920, with six tunnels completely driven and the Pedernales Tunnel 60% through, a general shutdown of construction put a stop to further activities.

When the work was opened up again early in 1925, the change to steel pipe throughout had been adopted, and the project was carried through to completion as described by the author. Steel pipe besides being more dependable and less likely to give trouble in operation than either wood-stave or concrete pipe, has the further advantage of a minimum loss or waste of water. Everywhere in a desert region, such as Northern Chile, water is scarce and inadequate, and in this case the entire flow of the Ola River is utilized during half the year, or more.

For a wood-stave pipe line of the size and length here considered, leakage, including seepage and evaporation losses due to saturation of the staves, may reasonably be taken at about 4% of the total flow, or well over 1 cu. ft. per sec., which would have meant just that much less water available for use at the plant. It is apparent that for conditions in which the supply of water is strictly limited and possibly insufficient for the demands, this item of leakage may be a determining factor in the selection of the type of pipe to be used.

---

[3] Supt. of Concrete Constr., Anglo-Chilean Consolidated Nitrate Corp., Tocopilla, Chile.

The author may have some data from observations of the carrying capacity of this line, which would be of general interest for comparison with some of the accepted formulas. If the writer remembers correctly, at several points in the line, provision was made for measuring the flow by means of a sharp-crested weir in a short section of open canal.

H. L. THACKWELL,[4] ASSOC. M. AM. SOC. C. E. (by letter).—The local conditions, trials, and labors of constructing a bold and daring water-supply project in the high pampas of Northern Chile, has been ably presented in this paper.

The casual reader can better appreciate this work by comparing it with a similar undertaking, such as crossing the Grand Canyon of Arizona with a pipe line, except that in Chile the "quebrados", or canyons, do not have running streams.

The transportation problem is particularly difficult to solve. All foodstuffs must be imported due to the arid climate, which is unsuitable for agriculture. This very lack of vegetables has made the Northern Chilean a meat eater, and largely a protein feeder.

As stated under the heading, "Water Supply", the "atmosphere is absolutely dry"; in fact, it is so much so that the mucus membrane in one's nostrils dries up, and will crack and bleed unless greased with vaseline or similar ointment. The statement that "the air is brilliantly clear" can be better understood by the study of photographs taken of mountains 25 and 40 miles away, which clearly show geographical demarcations and variations in texture and conformity. The only fuel is the root of a small "wind-blown" bush somewhat similar to the sagebush found in the Western United States.

The wind not only "reaches a velocity of about 20 miles per hour * * * every day", but it carries sand and small pebbles which cut like emery. Facing a high desert wind on La Ola Pampa is veritable torture; even burros turn their backs and seek shelter. Engineers' stakes have been eroded by the pampa winds to a depth of 0.25 in. in a year's time, erasing all marks of identification.

Chilean laborers are strong and capable and, in many ways, remind one of the Japanese; they are short, stocky, and able to carry large loads easily without tiring. The "rotos" are a distinct class of labor, and when recruited from the desert districts they become efficient workmen. Chilean miners working by hand in the tunnel headings, make as good progress as the average Western miner of the United States, using the same tools and methods.

The water supply from the Rio Ola is fairly constant as can be seen from Fig. 4. It is quite possible to obtain 29 cu. ft. per sec., provided a storage of 4 000 acre-ft., is available. A study of Fig. 13, will show that a maximum possible draft is available with adequate storage, and that if the pipe line is designed for 26 sec-ft., there will be periods every year when the mill will have to reclaim several second-feet of water. A mean draft of 22.5 cu. ft. per sec. is practical with a storage of 100 acre-ft. at the mill site, near Potrerillos. In

---

[4] Cons. Engr., Jacksonville, Tex.

Fig. 13, the hatched area below 26 cu. ft. per sec. indicates used water that should be reclaimed at the mill. Water flow will fall below the requirements about one-half the time.

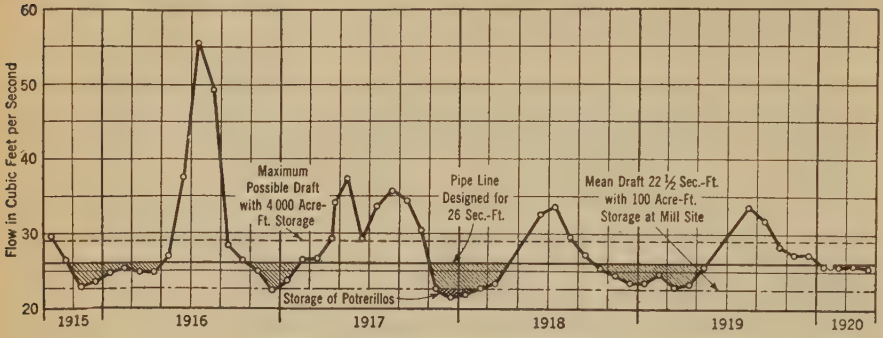

FIG. 13.—HYDROGRAPH OF RIO OLA.

The author is to be congratulated for the excellent manner in which the final construction work was completed, and, in particular, he should be commended for the difficult organization work and effective training of inexperienced labor and the economical results obtained by skillful supervision.

WILLIAM E. RUDOLPH,[5] M. AM. SOC. C. E. (by letter).—Some costs compiled by the writer might be of interest in comparison with those tabulated by Mr. Saunders. This particular undertaking was not a new pipe line, but concerned the construction of looping lines to increase the capacity of an existing water supply line.

The line in question was 55 miles long, 47 miles of which was 9-in. pipe and the remainder, 6-in., with all screw couplings. Its capacity had been impaired about 30% by nodular incrustations, and at one section the hydraulic grade had fallen below the level of the pipe. The measures taken to regain a portion of the lost capacity consisted of substituting a section of new 9-in. pipe for the 6-in. pipe at one location and a section of new 12-in. pipe for the 9-in. pipe at another. In each case the pipe that was removed was relaid beside the existing line in the adjoining section, this division of the flow between two parallel lines further reducing the flow friction losses.

Unit costs on this work are shown in Table 5. The following notes are in explanation of certain units in the tabulation:

Item 1.—The cost of housing and feeding a laborer in camp was about equal to the average wage paid. As this expense was considered part of the general overhead, it has not been charged against the various units. However, it can be distributed by doubling the units for labor under each of Items 3 to 10, inclusive.

Item 2.—The unit cost of pipe would appear high as compared to costs given by Mr. Saunders. This was partly due to the large number of specials required. On work of greater magnitude, and on which larger sizes of pipe were used, it would undoubtedly have been advantageous to assemble the pipe in the field as described by Mr. Saunders.

TABLE 5.—UNIT COSTS OF CONSTRUCTING "LOOPING" LINES FOR INCREASING CAPACITY OF TOCONCE PIPE LINE, SUPPLYING CHUQUICAMATA, CHILE, APRIL TO SEPTEMBER, 1927

No.	Item	UNIT COSTS, IN DOLLARS (8.18 PESOS)			
		Materials	Labor	Expenses	Total
1	Cost of maintaing men in camps per man-day:				
	(a) Camp supervision		$ 0.03		$ 0.03
	(b) Food and water	$ 0.62	0.11	$ 0.01	0.74
	(c) Fuel	0.03	0.01	0.01	0.05
	(d) Camp maintenance, including depreciation of equipment	0.14	0.06		0.20
	(e) Transportation of camp equipment		0.03		0.03
	Total	$ 0.79	$ 0.24	$ 0.02	$ 1.05
2	Cost of new pipe, unloaded from cars per foot	$ 3.65	$ 0.04	$ 0.03	$ 3.72
	Cost of new pipe unloaded from cars per ton	158.95	1.75	1.30	162.00
3	Cost of uncovering old pipe per foot		0.01		0.01
4	Cost of taking up old pipe per foot		0.03		0.03
5	Cost of motor-truck haulage per ton-mile	0.18	0.02	0.04	0.24
6	Cost of haulage by mule and by hand per ton-mile	3.21	8.00	0.93	12.14
7	Cost of excavation per foot	0.02	0.14		0.16
8	Cost of pipe-laying per foot	0.01	0.05		0.06
9	Cost of covering pipe per foot		0.06		0.06
10	Cost of building road per mile		381.25		381.25
11	Engineering and supervision, percentage				9

Item 5.—The trucks hauled average loads of 2 tons on outgoing trips and returned empty.

Item 6.—The average length of haul for each pipe, after being unloaded from a truck, was 0.65 mile, of which about one-third was accomplished by mules and two-thirds by hand. This hauling was in rugged country, on steep slopes of canyon enclosures for the greater part. The cost of hay and grain for the mules was $0.51 per animal day.

Item 10.—Motor-truck haulage on this work effected large savings, but it did involve considerable road construction. Such roads were build in large part by merely driving a truck over the barren pampa to consolidate the surface materials, and by removing projecting rocks. Grades as steep as 15% were used. At a dry canyon crossing the new road showed a tendency to become blocked by snow drifts, and it was found to be cheaper to relocate the road than to shovel snow from the earlier location.

High labor turnover was experienced. Little difficulty was encountered in recruiting men at the start, because although it was late April (the beginning of the winter season), Chilean workmen sought employment where lodging and board were free, even if it did involve living in tents at an elevation of 13 000 ft. In most cases, such enthusiasm lasted only until the first pay day. Later, the depleted ranks of workers were in part filled with native Bolivians, or more exactly, Indians, from the small farming centers of the mountain slopes. These "pueblos" exist upon the community system as in the days of the Inca, and they have little, if any, connection with the outside world. It was necessary to obtain permission from the head of each village to give employment to his men.

One would have expected that native Indians, accustomed to the altitude and the severe climate of the Andean highlands, would prove far superior to the average Chilean laborer. Such was not the case. Generations of inbreeding had worked its effects upon the Indians. The Chileans averaged 25% and more bonus on their contracts, the Indians scarcely earned their day's pay. As the job neared completion, it was the Chilean laborers who had remained through devastating snow and wind storms, constructing pipe lines on exposed mountain slopes. The Indians had returned to the less rigorous life of repairing their irrigation ditches, down in the valleys.

W. B. SAUNDERS,[6] M. AM. SOC. C. E. (by letter).—Since the completion of La Ola Pipe Line in November, 1926, operating history over a period of five years has answered in part the discussions by Messrs. Nelson, Thackwell, and Rudolph.

The general interest which would be accorded data concerning the carrying capacity of La Ola Pipe Line is mentioned by Mr. Nelson. For purposes of efficient operation and observation daily weir readings have been recorded at two different points on the line since December, 1926, from which some interesting data have been accumulated and, without going into minute details, the following observations have been made.

The section of pipe from the intake at La Ola Dam through to La Cabra Tunnel is that best adapted for experimentation and observation. In this section the hydraulic grade is 1.5 per 1 000 when the reservoir is full, and the pipe is of a uniform diameter throughout, with an average of 36.83 in. between male and female plates.

At the beginning of operation, when the pipe was new and the asphalt coating was very smooth, the records show a capacity of 28.5 cu. ft. per sec., but this capacity fell off rapidly at the beginning of operation to about 27.0 cu. ft. per sec. By July, 1929, the discharge had decreased to 25.5 cu. ft.

---

[6] Hydr. Engr., Andes Copper Min. Co., Barquito, Chañaral, Chile.

per sec., and an examination of the inside of the pipe showed a nodular incrustation forming, which materially increased the friction and reduced the inside diameter of the pipe.

After some experimenting a "go-devil" was devised which successfully cleans the pipe. The main frame of this apparatus is of wood, bound at the joints and contact points with steel plates, to which are attached steel brushes. The total weight and displacement is such that it will just float in water. It is moved through the pipe by the pressure head of water exerted on the circular disks. These disks are of such size, and their lengths are such, that the "go-devil" will easily pass through the flat curves in the pipe line. In theory, the disks form sufficient obstruction to allow the building up of about 10 lb. per sq. in. pressure head over their areas before the openings around them will pass the full flow of the pipe line. In practice, it is not fully known what pressure is exerted to move this apparatus, but when in use, the flow capacity of the line is reduced about 22%, and the "go-devil" moves at an average rate of about 2.5 ft. per sec., which approximates the velocity of the water at the reduced flow capacity.

In operation, this apparatus takes a rotary motion and successfully brushes out the incrustations from the line. By using it every six months the line capacity is maintained at 27.0 cu. ft. per sec., or more.

The coefficient of roughness, *C* (Hazen and Williams' formula), as applied to this pipe line and its operation, has been observed to be as indicated in Table 6.

TABLE 6.—QUANTITIES, VELOCITIES, COEFFICIENTS, AND CONDITIONS OBSERVED AND COMPUTED FROM LA OLA PIPE LINE OPERATION

Observed quantity of flow, in cubic feet per second	Computed velocity, in feet per second	Coefficient (Hazen and Williams), *C*	Condition
28.5	3.83	115	New pipe
27.5	3.73	112	Immediately after cleaning
27.0	3.66	110	60 days old and after cleaning
26.5	3.59	108	2 years old
25.5	3.46	104	2½ years old
24.5	3.32	100	Not yet reached

Mr. Thackwell presents a hydrograph (Fig. 13) which indicates the possibility of obtaining a continuous flow of 29 cu. ft. per sec. of water, provided 4 000 acre-ft. of storage might be made available at the head of the pipe line. The topography of the country and the available dam sites do not permit the use of such a hydrograph, within a reasonable cost. The present (1931) storage or regulation at La Ola Dam is about 25 acre-ft., and the site of the dam does not permit this quantity of storage to be increased at that point. The character of the country is such that an appreciable quantity of storage at any other available point would be prohibitive in cost. However, after two years of operation, additional water was added to La Ola supply by the construction of 4.2 miles of pipe line, ranging in diameter from 14 to

18 in., which diverts 12 cu. ft. per sec. of water from the Juncal River (see Fig. 2) and puts this water into a small stream leading into the head of La Ola Vega. After losses from seepage and evaporation, which are very large, this quantity of water is sufficient to regulate the flow of La Ola River at the intake of the pipe line so as to release a larger quantity than that which will pass through the pipe.

Mr. Rudolph's discussion and tabulated costs are interesting and show efficient management of that work. It is apparent that living and labor conditions must have been very similar on the two jobs and that the cost of labor was much the same.

A direct comparison of other costs between the two jobs is difficult, except between the cost of steel pipe purchased in the United States. The small difference in cost for this pipe is easily accounted for by a probable difference in ocean and rail freight charges and a different date of purchase. The comparison of these costs with those of riveted steel pipe fabricated on the Ola Line are all in favor of the local fabrication. On the large tonnage of pipe used in this line the saving effected by local fabrication was approximately $500 000.

THEORY OF SIMILARITY AND MODELS[1]

By Benjamin F. Groat,[2] M. Am. Soc. C. E.

With Discussion by Messrs. H. Bateman, W. P. Roop, A. V. Karpov, Jasper O. Draffin, Ed S. Smith, Jr., F. J. Eisner, and Benjamin F. Groat.

Synopsis

The paper aims to present a complete, concise treatise on the theory of similarity and models. Newton's theorem, which is not generally understood, is shown to cover every possible type of dynamic model. A misconception which has been unduly propagated, is disclosed and traced to its source. It is shown that models can be built to specification, as to materials and their properties, so as to perform with theoretical exactness. It is suggested that materials, including fluids, should be sought, made, or arranged, so as to adapt them especially for service in models, thus opening a new field in engineering. The theory is based upon data given in a previous paper by the writer.[3]

Introduction

Every engineer should know and understand that a model, constructed in accordance with Newton's theory of similarity, is not only the means for reproducing the complexities of flow, or other mechanical action, on a small scale, but that such model may be made the best means of designing works of great magnitude. In the present state of knowledge, a properly constructed and properly tested model will answer the difficult questions of hydrodynamics much more quickly and accurately than the most profound mathematical analysis.

Engineers and other groups of society incline too little toward making the most of past experience. It is about 250 years since Newton enunciated the principles of similarity and the theory of models; yet it is only during the last very few years that engineers have made any use of models, as a reliable means for determining a design, especially in hydraulics.

The cause of this inertia in the advancement and dissemination of science and truth, is the tendency to place a blind reliance upon the authority who makes a statement, instead of basing belief on analysis of what is said. Civilization should be standardized on the basis of reason; it should not be allowed to develop along a mere line of natural social evolution. Were it not that Lincoln said it, the slogan, "Government of the people, for the people, and by the people," would be a forgotten generalization to-day. It is "harped" upon because a great man said it, but, in reality, too little has been done toward a sufficient application of this, one of the greatest generalizations of all time. Is not the Engineering Profession best prepared to overcome inertia of every kind all along the front?

NOTATION

The following notation will be used consistently in this paper and its discussion:

$\propto$ = varies as.
g = acceleration due to gravity; also, acceleration in model generally.
V = velocity in prototype, or ratio of homologous velocities according to context.
D = diameter, or ratio of diameters, according to context.
l = linear magnitude in model.
p = pressure.
μ = absolute coefficient of viscosity, usually in centimeter-gramme-second units.
ρ = density in model, or ratio of homologues, according to context.
P = property of a material, or ratio of such. In Appendix I, it is ratio of homologous pressures.
T = time corresponding to a. (Stokes.)
T = time dimension, or ratio of homologous times. Sometimes as $[T]$.
W = specific weight in prototype, or ratio of homologues.
L = linear dimension, or ratio of such homologues. Sometimes as $[L]$.
F = force dimension, or ratio of such homologues. Sometimes as $[F]$.
$\nu = \frac{\mu}{\rho}$ = kinematic coefficient of viscosity of the fluid.
R = scale ratio.
G = acceleration in prototype, or acceleration ratio.
N = kinematic coefficient of viscosity of the fluid in the prototype.
E = ratio of homologous elastic moduli.
k = elastic spring constant.
Δ = density in prototype.
M = mass ratio.
M = absolute coefficient of viscosity in prototype, or ratio of homologues.
f = sign of functionality.
P = pressure of gas. (See, also, previous definition.)
c = gas constant in Appendix I.
w = specific weight of a gas.
θ = absolute temperature, in degrees centigrade.
K = a constant. Reynolds' number in Equation (9).
ϕ, ϕ' = signs of functionality in Equations (20) and (21).

HISTORIC BACKGROUND

History may now be recited to show how the theory of models and similarity made its appearance, and what the situation is at present (1930) relative to the use of models. It was more than 100 years after the greatest natural philosopher, Sir Isaac Newton, adduced the theory—in fact, the whole idea—expressed in true scientific simplicity, before any use was made of it. Most individuals fail to remember that the entire theory of terrestrial mechanics was given by Newton in three simple rules, or "laws," which can be written in about as many lines. The entire basis of celestial mechanics was delivered by that same philosopher in a statement of two or three more brief lines. Newton propounded the theory of models in a single paragraph, and nothing has since been added to any of these theories, other than their natural consequences.

In his "Principia Mathematica" (original in Latin), Newton published the theory of similarity[4] as follows:

> "Suppose two similar systems of bodies consisting of an equal number of particles, and let the correspondent particles be similar and proportional, each in one system to each in the other, and have a like situation among themselves, and the same given ratio of density to each other; and let them begin to move among themselves in proportional times, and with like motions (that is, those in one system among one another, and those in the other system among one another). And if the particles that are in the same system do not touch one another, except in the moments of reflexion; nor attract nor repel each other, except with accelerative forces, that are as the diameters of the correspondent particles inversely, and the squares of the velocities directly, I say that the particles of those systems will continue to move among themselves with like motions and in proportional times."

The term, "accelerative force," means the intensity of a force per unit mass acted upon by the force. The most common example is the acceleration of gravity, g, which is the acceleration of a freely falling body at the earth's surface. If this is multiplied by the measure of the mass acted upon, the result is the total force acting upon the mass.

Hence, Newton's Law of Similarity supplies the fundamental equation of similitude, namely,

$$g = \frac{V^2}{D} \qquad \text{(1)}$$

in which, the symbols relate to ratios of homologues.

Two systems of forces in space are dynamically similar if the lines of action of the forces (produced if necessary) form similar geometrical figures in space, while the measures of the two individuals of every pair of homologous forces in the two systems are in a fixed ratio (called the "force ratio of the homology"). Thus it is clear that proportionality of homologous forces, and geometrical similarity of the figures formed by the systems of lines representing their magnitudes and loci, are both involved in the idea of dynamical similarity.

Every engineer is familiar with the force diagram and the space diagram of graphical statics. Proportionality of homologous forces in dynamically similar systems corresponds to similar force polygons, while similarity of applications of forces to masses, similarly situated in two similar systems, corresponds to similar space polygons. Thus, two geometrically similar framed structures, bearing proportional loads similarly distributed, would sustain similar internal stresses, any two homologues of which would be in the force ratio. One such frame, so analyzed, would be the solution of all such similar frames bearing similar systems of loading.

---

[4] Book II, Proposition XXXII, Theorem XXVI.

Correspondingly, the term, "mass similarity," may be used to express the idea that two systems of masses occupy space in such configurations that the measures of homologous masses are in a fixed ratio called the "mass ratio of the homology", while the loci of the homologous masses are similarly situated in the two systems.

The complete notion of mechanical similarity embraces the idea of "similar motions," in addition to the ideas of dynamical similarity and mass similarity. Similar motions require that the paths described by homologous masses be geometrically similar, and that the velocities of homologous masses be in a fixed ratio, which may be called the "velocity ratio."[5]

Newton's law simply states the conditions which are necessary and sufficient to establish and maintain dynamic similarity, including geometrical similarity of both form and motion. It is to be emphasized that any one of these conditions must be satisfied in order to have similarity, but any one of them alone would not be sufficient without the others. For example, it is necessary to establish initial similarity, or the theorem would not apply at all. This means, furthermore (taking a practical example), that if a model of a section of a river is built, it is necessary that the water enter and leave the model with motions and levels exactly similar to the homologues in the actual river. This condition is as necessary as any of the others. Observe, in particular, that accelerative forces must be proportional to the squares of velocities directly and to the linear dimensions (diameters, for example) inversely. This part of the conditions relates especially to similar motions. However, the theorem does not require that accelerative forces be constant throughout any given system. Indeed, they may vary discontinuously from point to point. They may be concentrated at a point, for example. The theorem does require that the ratios of all pairs of homologous accelerations be the same.

This relation between accelerative forces and velocities has been erroneously called "Froude's law," because of his use of it in the celebrated tests of "skin friction" on boards (sides of ships), and especially in his tests of ship models to determine the wave-making resistances to their motion through the water. Froude's law has been written in the form of a dimensionless number, $\left(\frac{V^2}{l\,g}\right)$. The statement that it is constant is nothing more or less than Newton's law, $g \propto \frac{V^2}{D}$ (see Equation (1)). Note that l may be inserted in the formula in the place of D, since the ratio of similar dimensions is constant, regardless of what dimension is used.

Newton's law should be distinguished from the law of skin friction, which states that resistances per unit area vary as the squares of velocities. Equation (1) expresses the relation between model and prototype, while the frictional resistances may follow another law; for example, they may vary directly as the velocity. This last relationship is quite consistent with Equation (1). When the common law of friction (V^2 law) holds, the model may be of any size, but when friction varies with a power of the velocity different from 2, the scale of the model ceases to be arbitrary.[6]

---

[5] "Ice Diversion for St. Lawrence River Power Co.," by B. F. Groat, M. Am. Soc. C. E., *The Canadian Engineer*, November 25, 1920.

Newton's law of similarity was stated so as to cover models in general, independent of size, shape, and materials. To make this sweeping statement, its originator was careful not to permit the possibility of unknown reactions between the moving bodies. Consequently, he excluded every contactual influence except instantaneous contact of the moving particles, not because of any fundamental necessity for such restriction, but to emphasize that the forces of dynamic similarity must be proportioned so as to cause, or develop, the accelerations specified by him in the law, as he stated it.

It was not until 1850 that Stokes,[7] in the course of his investigations, noticed certain important mathematical relations involved in the theory of similarity and models. Through a slight oversight, however, he rendered an account of similarity involving viscosity which has led a number of investigators into the same error.

As its title shows, Stokes' paper was primarily concerned with viscosity. This is a special type of force which Newton wisely did not mention specifically, although his theorem, or law, does include any force which can be made to conform to it.

Stokes was an able pioneer investigator in hydrodynamics, a subject full of fundamental mathematical forms devised by him. He essayed to study the laws of similarity in viscous fluids, since it was necessary to ascertain the effect of changing the sizes, shapes, and conditions of bodies moving in a viscous fluid, such as air. He showed that the sizes of bodies did not change the mathematical treatment. In other words, the same differential equations would represent each of two, or more, similar linear systems.

His paper includes one of the most remarkable contributions touching upon similarity and models since Newton's great generalization. It covers the entire question of viscosity; but its author did not make his account of similarity in the presence of viscous fluids as complete as this part of the investigation can be made, as will appear after considering his very simple equations relative to similarity in the presence of viscous fluids.[7] This part of Stokes' paper requires some knowledge of coefficients of viscosity, which has been previously explained by the writer.[8]

ANALYSIS OF STOKES' REMARKS UPON SIMILARITY

Consider any number of similar systems, composed of similar solids oscillating in a similar manner in different fluids or in the same fluid. Let

---

[6] This follows from the writer's article in *Engineering Record,* September 25, 1915, p. 377.

[7] "On the Effect of Internal Friction of Fluids on the Motion of Pendulums," *Transactions,* Cambridge Philosophical Soc., 1850, p. 19, Section 5.

[8] In his discussion of the paper entitled, "Experiments on Discharge over Spillways and Models, Keokuk Dam," by Floyd A. Nagler and Albion Davis, Members, Am. Soc. C. E., *Transactions,* Am. Soc. C. E., Vol. 94 (1930), p. 833, *et seq.*

a, a', ..., be homologous lines in the different systems; T, T', ..., corresponding times, such, for example, as the times of oscillation from rest to rest. Let x, y, and z, be measured from similarly situated origins, and in corresponding directions, and t, from corresponding epochs, such, for example, as the commencements of oscillations when the systems are beginning to move from a given side of the mean position.

If any dynamical equations (including differential equations, of course) are satisfied for one system they will be satisfied for all the systems provided $u \propto v \propto w$; $x \propto y \propto z$; and $p \propto \frac{\mu u}{x} \propto \frac{\rho u x}{t}$, when passing from system to system. Stokes did not say that $p \propto \frac{\rho u x}{t}$ is the statement of Newton's law. The variations, $x \propto y \propto z$, merely signify that similarly situated points must be compared in inferring, from the circumstance that equations are satisfied for one system, that they will be satisfied for all the systems. If c, c', . . . , are the maximum displacements of similarly situated points of the fluids, then $u \propto \frac{c}{T}$; $x \propto a$; and $t \propto T$.

Quoting Stokes,[7] "the sole condition to be satisfied, in addition to that of geometrical similarity, in order that the systems should be dynamically similar, becomes" $\frac{a^2}{T} \propto \frac{\mu}{\rho}$, or $\frac{a^2}{T} \propto \nu$. This condition being satisfied, similar motions will take place in the different systems; therefore, $p \propto \frac{\rho a c}{T^2}$.

It follows from equations that might be written down by symmetry, that the pressures, such as normal or tangential, vary in the same manner as p; whence it appears, from the relation, $p \propto \frac{\rho a c}{T^2}$, that the resultant or resultants of the pressures of the fluids on the solids, acting along similarly situated lines, which vary as $p\,a^2$, vary as $\rho\,a^3$ and $\frac{c}{T^2}$ conjointly. In other words, these resultants in two similar systems are to one another in a ratio compounded of the ratio of the masses of fluid displaced, and of the ratio of the maximum accelerating effective forces belonging to similarly situated points in the solids.

Stokes' relation, $u \propto v \propto w$, means simply that (if capitals relate to the first system and minuscules to the second),

$$\frac{U}{u} = \frac{V}{v} = \frac{W}{w}$$

or, as Stokes writes it, $u \propto v \propto w$, in which the u's relate to x components of velocity, and the v's and w's, respectively, to the y and z components. The simplest way to see this is to note generally that the "dimensions" of velocity are, in all cases, $\frac{\text{distance}}{\text{time}} = \frac{L}{T}$. Thus, if the two systems are geometrically similar, and the times of motion over homologous distances are proportional, $u \propto v \propto w$ is satisfied for all the motions in two similar systems; that is, for all the homologous motions.

This is a general truth. If any two or more quantities have the same "dimensions" in F, L, and T, then, if every ratio of two homologues measured in a given simple dimension, L, F, or T, is in a given ratio which depends upon the type of the dimension, the quantities themselves are also in a determinate ratio, and that ratio is found by calculating the product of the known powers of the fixed ratios of their dimensions. Thus, the ratio, $\frac{V}{v}$, equals the product, $\left(\frac{L}{l}\right) \times \left(\frac{T}{t}\right)^{-1}$, and it will be constant from molecule to molecule if each of the factors is constant. Hence, one may substitute the sign of equality for the sign of variation when the symbols relate to ratios of homologues, as will frequently be the case hereafter.

In passing, it is well to call attention to the fact that confusion of ideas results from two distinct uses of the word, "dimension." One use relates to architectural dimensions, so familiar to all engineers; the other, to "dimensions of units," which is much less common. The first use relates to a measure in terms of a unit; the latter to the nature of the unit. Both the magnitude and its unit have the same dimensions (latter use). The measure of a magnitude is, therefore, a pure number (no dimensions). The measure of a fixed magnitude varies inversely as the magnitude of its unit, that is, of the unit employed in the measure. The complete specification of an architectural dimension consists of a measure followed by a specification of the unit, as 200 ft. Correspondingly, N ft.^{2}[9] names the unit as 1 sq. ft.; $N\,\frac{\text{ft.}^9}{\text{sec.}}$ names the unit as 1 ft. per sec.; etc. The dimensions (latter use) just specified are, respectively, feet, square feet, and feet per second. To avoid naming the unit along with a specification of its dimensions (latter use), the following forms are used, respectively, for the three cases mentioned, L, L^2 and $\frac{L}{T}$, or, $[L]$, $[L^2]$, and $\left[\frac{L}{T}\right]$. It is unfortunate that the word has been used in the latter sense, because architectural dimensions are measured in terms of units of certain dimensions. Thus, two different meanings of the word may occur in the same sentence.

If the three fundamental units, for measurements in the model, are so chosen as to bear the same respective magnitudinal ratios to their homologues as do corresponding homologous magnitudes, then the measurement of any quantity in the model will be precisely the same numerically, as in the prototype. One-twenty-fourth full size gives measures equal to those in full size when the scale is "½ in.=1 ft." Homologous ratios are merely cases of "conversion factors." In the example just mentioned the conversion factor is unity, by reason of the choice of the model unit.

---

[9] This is the correct form in which the unit should be specified; it shows just how the unit is constituted. The notation is now universal when the nature of the unit is involved in the analysis.

To illustrate the nature of dimensions, take Stokes' requirement that $p \propto \frac{\mu u}{x} \propto \frac{\rho u x}{t}$. The respective dimensions of the individual quantities are:

$$p = \frac{F}{L^2} \qquad (2)$$

$$\mu = \frac{F\,T}{L^2} \qquad (3)$$

$$u = \frac{L}{T} \qquad (4)$$

$$x = L \qquad (5)$$

$$\rho = \frac{F\,T^2}{L^4} = \frac{M}{L^3} \qquad (6)$$

$$t = T \qquad (7)$$

$$\nu = \frac{\mu}{\rho} = \frac{L^2}{T} \qquad (8)$$

Supplying these dimensions to all the terms, it may be shown that each one has the dimensions of pressure; that is, $p \propto \frac{F}{L^2}$, if L, F, and T are considered the fundamental dimensions of units, length, force, and time. Of course, it would have been found that all the terms were of the same dimensions, had mass been utilized as a fundamental unit, instead of force. Therefore, all that is required to insure these equal proportions is that forces be proportional to the areas upon which they act, the dimensions of area being L^2. This applies to shearing stress (viscosity) as well as to normal pressure.

It is clear generally, without further discussion, that since all the terms of any equation must necessarily have the same dimensions (apples cannot be added to peaches, so to speak), any equations expressing relations between homologous quantities in two similar systems will be the same for either system, except for a common constant factor in all its terms, which factor, of course, may be removed. If homologous units are suitably chosen the factor will be unity, as previously explained.

The relation, $\frac{a^2}{T} \propto \nu$, is the principal one for present purposes, since it imposes a new condition resulting from the introduction of viscosity into the calculation. It may be written in the form:

$$\frac{V\,L}{\nu} = K \qquad (9)$$

in which, the constant, K, is a dimensionless number since $V = \frac{L}{T}$, and ν is defined as the ratio of μ to ρ, which is the kinematical coefficient of viscosity (see Equation (8)).

Of course, the constancy of Equation (9) is maintained only for homologous values in similar systems, as model and prototype. It expresses the well-known Reynolds' number, which, as it appears, was first recognized by Stokes; in fact, it was defined by Stokes, before Reynolds made any use of it. It would seem more appropriate to call it "Stokes' number." In this relation, the real debt of science to Reynolds is for his discovery of "turbulence," as compared to stream-line flow, and for his additional discovery of the "critical velocity" and its relation to Stokes' number as the criterion of the existence of turbulence.

The reason why Equation (9) (or its equivalent, Equation (10)) puts a new limitation on models is that the introduction of viscosity demands a new, and additional, relation (Equation (9) or Equation (10)) between two of the three fundamental ratios of the homology, *L, F,* and T, or *L,* M, and T, if preferred. These ratios are considered fundamental because they relate to the three units which are chosen as the "fundamental" units of the system of measures involved. Briefly, viscous fluids in similar systems require that,

$$\nu = \frac{\mu}{\rho} = \frac{L^2}{T} = \frac{a^2}{T} \ldots, \text{etc.} \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

The symbol, ν, is the kinematic coefficient of viscosity. It is clear why this coefficient is called "kinematical," since, in finding the ratio of μ to ρ (see Equation (10)) the dynamical dimension, "force" (or "mass," when mass is one of the three "fundamental" units, or dimensions), is cancelled, leaving the ratio dependent upon "length" and "time" only, and, therefore, "kinematical."

While the writer has the greatest admiration for Stokes' valuable analysis, he can find no justification for the statement[7] that Equation (10) as derived by Stokes, is "the sole condition to be satisfied, in addition to that of geometrical similarity, in order that the systems should be dynamically similar."

If Stokes had said: "It is the sole condition to be satisfied in addition to those of geometrical and dynamical similarity in the absence of viscous fluids, in order that the systems shall remain geometrically and dynamically similar after introducing viscous fluids," there could have been no reasonable objection. His analysis conforms exactly with this statement, and it is probably what he intended to say, "geometrical similarity", doubtless including geometrically similar motions, which latter condition demands dynamical similarity.

In other words, Stokes' systems were dynamically and geometrically similar, in accord with Newton's law $\left(g \propto \frac{V^2}{D}\right)$. This condition is also expressed in Equation (12), before introducing viscous fluids, or, what is the same thing, before causing the fluids to become viscous. His principal equations (which need not be discussed here) show this, as they correctly determine geometrically and dynamically similar systems without the terms involving viscosity, and without those involving "extraneous forces" (gravity). Introducing viscosity may, or may not, change ratios of homologues, but the similarity continues, provided the conditions of Newton's theorem (law) are imposed throughout the entire time.

Consequently, Equations (9) and (10), are not essentially criteria of dynamic similarity at all, but are merely necessary conditions that must be satisfied by any viscous fluids in the systems. They are conditions appurtenant to viscosity, not to similarity.

Were this a matter of opinion there would be little hope of interesting the engineer and analyst; but it is not a matter of opinion. It is a matter of mere mathematical relations, and it is the writer's purpose to show that, although these relations were plainly visible in Stokes' paper, they were overlooked by him in giving an account of his investigation. This was doubtless due to his greater concern with the more intricate mathematical analysis of the pendulum problems in the remainder of his paper, which need not be examined here.

FORMAL THEORY OF SIMILARITY

Let two systems be constructed with the requirement that they shall be merely geometrically similar. Clearly, the sole requirement for this is that homologous linear dimensions be proportional. Stokes writes this in the form, $x \propto y \propto z$, or more formally, it may be written:

$$L = R \qquad \text{(11)}$$

in which, R simply indicates the constancy of the ratio, $\frac{L}{l}$ (which is represented by L) of any pair of homologous linear dimensions, as $\frac{A}{a}$ for example. The value of the scale ratio, R, is perfectly arbitrary until the two systems are chosen; but Equation (11) shows, further, that one does not destroy the validity of any correct equation in one of the geometrically similar systems by applying it to any of the others, independent of the value of R. That is what Stokes says so far, and it is evidently quite correct; and with general application to all manner of quantities which have a characteristic constant ratio between their homologous dimensions (whether linear, or otherwise) in the two systems.

Suppose it is now required that there shall be similar motions, in addition to the similarity of forms as required by Equation (11). (This equation is supposed to be applied to all homologous linear dimensions, thus representing an infinite number of equations, but it will be referred to as one equation hereafter.) This is specified by adding Newton's general theorem of similarity, $g \propto \frac{V^2}{D}$ (see Equation (1)). These necessary and sufficient conditions for simultaneous geometrical and dynamic similarity require that Equation (11) shall be satisfied and that,

$$\left(\frac{V^2}{L} = \frac{L}{T^2}\right) = \frac{G}{g} \qquad \text{(12)}$$

in which, the notation used on the left relates, respectively, to the ratios of homologues, and of homologous "dimensions" of the homologues, in accordance with the notation on the left of Equation (11). For example, either of the terms, $\frac{V^2}{L}$, and, $\frac{L}{T^2}$, indicates that the ratios of homologous accelerations are equal to certain functions of the ratios of the simpler dimensions, V, L, and T.

Equations (11) and (12) state simply, that Newton's theorem of similitude puts no restriction upon the scale ratio of two similar systems, nor upon the respective values of the homologous accelerations in the two systems, whether such accelerations arise from "extraneous forces" (gravitation, say), or from forces within the system, or from both combined. Relative to these equations, furthermore, Newton's theorem states that, if the experimenter takes care to establish similar motions initially, the similarity will continue. This is entirely independent of the presence or absence of viscous fluids. If Newton's law is satisfied, the systems must be similar, whether viscous fluids are present, or otherwise.

Observe that the extraneous forces may be eliminated, or annihilated, but that there must be left a ratio of homologous accelerations, just as there must be a constant ratio between any two homologues of any other type in similar systems. Stokes makes this necessary assumption, by providing for it in the form, $\frac{c}{T^2}$, and also in his equation,

$$p = \left(\rho \frac{u\,x}{t}\right) \quad \text{.........................(13)}$$

all of which arise from terms which do not contain the viscosity. In order to make the situation perfectly clear, Equation (13) may be expressed in the form:

$$\frac{p}{x} = \frac{\rho\,u}{c}\left(\frac{c}{t}\right) \quad \text{............................(14)}$$

or, substituting for $\frac{c}{t}$, its equivalent, u, and transposing:

$$\frac{p}{\rho\,x} = \frac{u^2}{c} \quad \text{............................(15)}$$

In other words the ratio, force to mass, varies as $\frac{u^2}{c}$.

Equation (15) is nothing more or less than Newton's law of similarity, $g \propto \frac{V^2}{D}$, or Equation (12), since Stokes intends it to be applied to homologues, and since the ratio of force to mass (left-hand member of Equation (15)) has the dimension, acceleration.

Equation (11) and Equation (12) involve the ratios, L and T, in terms of the two quantities, R and $\frac{G}{g}$, the respective scale ratio and accleration ratio of the two systems. Clearly, these ratios may be chosen arbitrarily without interfering with the consistency of the equations, since the first equation contains only L and does not contain T. In other words, geometric and dynamic similarity may exist regardless of the particular values of the scale ratio and acceleration ratio in the two systems.

Newton went farther than this in demonstrating his theorem. In the briefest possible language he says (see the theorem as quoted previously) that, if the two equations (Equations (11) and (12)) hold, and the mass ratio is properly adjusted, initial geometrical and dynamical similarity will continue as a necessary consequence.

It is important to emphasize that nothing less than this will do, for the similarity must exist initially (as expressly required by the theorem) so that Equation (11) and Equation (12) are not only sufficient, but necessary; that is, they must hold throughout the entire time and throughout the systems.

For example, if the systems are similar initially, as in the case of Stokes' two pendulums at the points of maximum displacement, the subsequent motions of surrounding frictionless fluids will be similar; or, the motions of surrounding viscous fluids will be similar, if the viscous forces can be adjusted so as to satisfy Newton's theorem, or law of similarity, or, more formally, Equation (11) and Equation (12). One cannot disregard Newton's absolute, necessary, and sufficient condition to sustain dynamical and geometrical similarity.

The only way to explain Stokes' silence on this point is to assume that he really did not mean just what he said, being more immediately concerned with his pendulum analysis than with similarity. However, there can be no doubt that he made the oversight and that it has caused many to repeat his remark. Others, less fortunately, based formulas and calculations of a practical nature upon a misconception. Such oversights are frequently made by writers of unquestionable authority. For example, Rankine has stated[10] that the coefficient of elasticity of a gas has the form:

$$A = \frac{d\,p}{d\,w} = \frac{\gamma\,p}{w}$$

The slightest consideration shows that this cannot be, since A and p have like dimensions (those of pressure), γ is an abstract number, and w, the specific weight of the fluid (Rankine calls it "density"). The nature of the correction is obvious.

This error has been running for the last seventy-five years without correction, apparently without notice, but, thanks to analysis of what is said, rather than reliance upon authoritative literature, the error is self-disclosing by inspection. No better textbook was ever written and none more carefully edited.

Proceeding further, take Stokes' limitation on ratios of homologues, Equation (10), as the additional (not the "sole") condition that systems containing viscous fluids shall be both dynamically and geometrically similar. Then, the three conditions may be represented by Equations (10), (11), and (12). This gives three equations between two unknown ratios, L and T; but only one of the unknowns appears in Equation (11).

---

[10] Rankine's "Applied Mechanics" (any edition including that current in 1930), p. 563. See, also, the footnote in *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 836, for another such error by another author.

Equations (10) and (12), therefore, present two conditions in terms of two unknowns, L and T. These two ratios, consequently, become determined; so that the condition defined by Equation (11), is no longer arbitrary. Thus, the three ratios, R, $\frac{\mathrm{N}}{\nu}$ and $\frac{G}{g}$, are not entirely independent, but any one depends upon the other two.

Solving Equations (10), (11), and (12):

$$L^{\frac{3}{2}} = R^{\frac{3}{2}} = \frac{\frac{\mathrm{N}}{\nu}}{\left(\frac{G}{g}\right)^{\frac{1}{2}}} \qquad \text{(16)}^{11}$$

and,

$$T = \frac{\left(\frac{\mathrm{N}}{\nu}\right)^{\frac{1}{3}}}{\left(\frac{G}{g}\right)^{\frac{2}{3}}} \qquad \text{(17)}$$

The conditions of Equations (10), (11), and (12) (all of which are present in Stokes' paper) determine the necessary scale-ratio and time-ratio (Equations (16) and (17)), between the two similar systems in terms of the physical properties of the fluids and the physical conditions existing at the places of the two systems. There can be no dynamically and geometrically similar systems (model and prototype) without all these restrictions, when viscous fluids are present.

This is probably what Stokes intended to read from his paper, but he accidentally overlooked the fact that Newton's theorem must be applied, whether or not the extraneous forces (gravitation, say) are eliminated.

The practical difficulties which arise in constructing models are apparent from Equations (16) and (17). If it is attempted to use the same fluids in model and prototype, the ratio of the coefficients of viscosity is then unity, and it is found that:

$$L = \left(\frac{G}{g}\right)^{-\frac{1}{3}} \qquad \text{(18)}$$

In this case it is theoretically wrong to test model and prototype at the same place on the earth's surface, for then $L =$ unity, and the model should be of the same size as the prototype, which would rarely be useful. If the same fluid is present in the two systems, but at different temperatures, such as to change the coefficient of viscosity, then the two conditions are equivalent to two different fluids, and should be so regarded.

On the other hand, if instead of $L =$ unity, $\left(\frac{G}{g}\right) =$ unity (testing at the

---

[11] These results were obtained by the writer in studies leading up to his paper entitled "Ice Diversion, Hydraulic Models, and Hydraulic Similarity," *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1138. The results of an application to large ice diversion works on the St. Lawrence River, and to the construction of other features, were also described by the writer under the title, "Ice Diversion for St. Lawrence River Power Co.," *Canadian Engineer*, November 25, 1920. See, also, *Engineering Record*, September 25, 1915, p. 377, and *Canadian Engineer*, February 14, 1918, p. 139.

same place on the earth's surface, say), then,

$$L^{\frac{3}{2}} = \left(\frac{N}{\nu}\right) \dots\dots\dots\dots (19)$$

in which, N and ν are, respectively, the kinematic coefficients of viscosity of the two fluids in prototype and model. Therefore, the two fluids must be different or, if they are the same fluid, then it must be at different temperatures in the model and prototype. Of course, one may have a model of the same size as the prototype with the same fluid at the same temperature in the model and prototype; but that again might not be very useful.

Thus, in this case, the conclusion is reached that, to have the model as small as possible, the ratio, $\frac{N}{\nu}$, should be as large as possible, and the ratio, $\left(\frac{G}{g}\right)$, as small as possible.

Examining Equation (19) more closely, the rule to secure a small-sized model evidently is to select a fluid having as small a kinematic coefficient of viscosity as possible, and also to test the model where the value of g is as large as possible (see Equations (16) and (17)).

Air would not likely make a small-sized model because, owing to the very small value of its density, which occurs in the denominator of the kinematical coefficient, the value of the coefficient is relatively large. Water would serve better, and mercury still better, owing mainly to their increasing densities. Hence, one reaches the astonishing conclusion that an airplane propeller might be tested in a small-sized model in mercury.[12]

As another example, consider a ship and its model. At corresponding speeds—whether greater or less than critical velocities—the total resistances to a ship and its true model of proper scale in true "model" fluid (say, mercury) would vary exactly as the respective densities, wet areas, and squares of corresponding velocities. This relation between ship and model would hold for all velocities of the ship and model at corresponding speeds (constant-velocity ratio). It would no longer be necessary to treat the skin friction and wave-making resistances separately. This truth illustrates perfectly the real advantage of a true model, namely, that it reduces the entire problem to a comparison of simple ratios, whereas, in general, for arbitrary sizes and shapes, the ratios are not simple. If they were, there would be no need for models.

SUMMARY OF EQUATIONS OF SIMILITUDE

Properties of Materials.—Thus far, nothing has been said of the force ratio, or mass ratio. The truth is that both have been determined by the method of making the problem kinematical, which is another process of elimination that has obscured the true relations and added to the confusion previously discussed.

---

[12] As suggested in the paper on "Ice Diversion, Hydraulic Models, and Hydraulic Similarity," *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), footnote, p. 1187. It is shown that the model would be one-twenty-fifth full size and would run at one-fifth full linear speed.

As is well known, ordinary mechanics involves only three "fundamental" units, in terms of which all quantities of that science may be measured. At least three equations will be available connecting ratios of homologous quantities in similar systems with the ratios of homologous measures in each of the three fundamental units, L, F, and T (any three independent units may be taken as fundamental, but here, length, force, and time are selected). Procedure in sciences of more than three fundamental units is the same, there being simply an additional equation for each such unit beyond three.

Summary.—Hence, summarizing the equations of similitude, the four necessary conditions for dynamic similarity among ordinary mechanical systems are:

$$L = R \qquad (11)$$

$$\left(\frac{V^2}{L} = \frac{L}{T^2}\right) = \frac{G}{g} \qquad (12)$$

(first property equation),

$$f_1 (L, F, T) = \phi' (P') \qquad (20)$$

(second property equation),

$$f (L, F, T) = \phi (P) \qquad (21)$$

To illustrate the use of the property equations it may be explained that, if P' in Equation (20) is to represent the density, this equation would reduce to the form:

$$\frac{F\,T^2}{L^4} = \rho$$

since the left-hand member expresses the dimensions of ρ. In Equation (21), P denotes the ratio of pertinent homologous properties, such as elastic moduli, electrical constants, etc. If more than one property, or material, must satisfy Equation (21) separately, suitable bodies must be found, made, or arranged, so to do, before similarity can be sustained. If a property (density, or load, say) satisfies the third equation (Equation (20)), then the fourth equation (Equation (21)) is free, as to that property, and may be used with some other property or properties. Thus, P may denote the ratio of homologous viscous, or elastic, pressures, or both, if they should have the same ratio, either by chance or by artifice.

Thus, the ratios L, F, and T, can each be found in terms of the conditions and properties of systems and materials by solving the equations. Conditions and properties include: Terrestrial gravity, internal accelerations, density, viscosity, elasticity, capillarity, mass attraction, electrical forces, etc. Therefore, solving Equations (11), (12), (20), and (21):

$$L = R = \phi_1 (G, \rho, \text{and } P) \qquad (22)$$

$$F = \phi_2 (G, \rho, \text{and } P) \qquad (23)$$

$$T = \phi_3 (G, \rho, \text{and } P) \qquad (24)$$

From these equations, the ratios of homologues of any kind can be found, since any such ratio can be "derived" from its dimensional equation. The specifications for the model may be written from this analysis. Then, if the model is caused to move with motions similar to those of the prototype, the similarity will continue, because all conditions of Newton's theorem are satisfied.

Example 1.—Write the conditions for dynamical similarity in a model elastic structure. Besides Equations (11), (12), and (20) (see illustration given after Equation (20)), Equation (21) takes the form,

$$\frac{F}{L^2} = E \text{ .... } (25)$$

in which, E is the ratio of homologous elastic moduli. If shear as well as extension is taken into account, both E's must satisfy Equation (25). Engineering will be required. True models must be built to specification. They are not more likely to be picked up by chance than is a well-designed structure. If factors of safety enter, still more moduli must satisfy Equation (25). It is as great a mistake to use the same materials, or fluids, in a model and prototype, as it would be to use the same scale. Therefore, solving these simultaneous equations, and assembling relations,

$$L = R = \frac{E}{\rho\, G}$$

or,

$$\frac{R\, \rho\, G}{E} = 1 \text{ .... } (26)$$

$$F = \frac{E^3}{\rho^2\, G^2} \text{ .... } (27)$$

and,

$$T = \frac{1}{G} \sqrt{\frac{E}{\rho}} \text{ .... } (28)$$

Then, also,

$$L = T \sqrt{\frac{E}{\rho}} \text{ .... } (29)$$

$$F = E\, L^2 \text{ .... } (30)$$

and,

$$V = \frac{L}{T} = \sqrt{\frac{E}{\rho}} \text{ .... } (31)$$

These equations conform exactly to the dimensions of factors of safety given in the paper on "Ice Diversion, Hydraulic Models, and Hydraulic Similarity" (page 1188), previously mentioned. Equation (26) may be called the "characteristic."

Equations (26) to (31) include the velocities of sound in the solids as well as the velocities of oscillations. In Equation (31), V denotes the ratio of maximum velocities (components) due to vibrations alone; but it is the correct velocity ratio.

These results give great generality for elastic models of suitably selected, made, or arranged materials; but, if model and prototype are of the same materials, the model not only becomes non-representative (elastic properties change in small sizes of given material), but of limited utility, as may be seen by making $E = 1$ and $\rho = 1$, giving:

$$L = R = \frac{1}{G} \dots\dots (32)$$

$$F = \frac{1}{G^2} \dots\dots (33)$$

$$T = \frac{1}{G} \dots\dots (34)$$

$$L = T \dots\dots (35)$$

$$F = L^2 \dots\dots (36)$$

$$V = 1 \dots\dots (37)$$

or,

$$V = v \dots\dots (38)$$

This latter method ($E = 1$, $\rho = 1$) is to elastic models what "Reynolds' Model Law" is to fluid models; both methods lead to undesirable conditions for model tests. Notice in Equation (26) that $RG = 1$ is the characteristic, since $E = 1$ and $\rho = 1$ (see, also, Equation (32)).

Example 2.—Construct two similar systems, each combining mechanical, elastic, and viscous actions. Suspend a weight by a spiral spring, also making a similarly suspended weight to a smaller scale, such that all manner of oscillations and motions of solids and fluids will be similar. Equation (21) must satisfy two properties (forms two equations):

$$F = k\,L = \mu\,\frac{L^2}{T} \dots\dots (39)$$

Letters refer to ratios of homologues, unless considering one system separately, when they refer to indicated measures. The elastic spring constant and density are, respectively, k and ρ, the former being of the dimensions, pounds per foot. Then, since $R = L$, solve Equations (11), (12), (20), and (21), as follows:

$$\frac{k^3\,\rho}{G\,\mu^4} = 1 \dots\dots (40)$$

$$L = \frac{k^5\,\rho}{\mu^6\,G^2} = \left(\frac{k}{\rho\,G}\right)^{\frac{1}{2}} = \frac{\nu^{\frac{2}{3}}}{G^{\frac{1}{3}}}, \text{ etc} \dots\dots (41)$$

$$F = \frac{k^6\,\rho}{\mu^6\,G^2} = \frac{k^3}{\mu^2\,G} = \frac{\mu^2}{\rho}, \text{ etc} \dots\dots (42)$$

$$T = \frac{\mu^7\,G}{\rho^2\,k^5} = \frac{k}{\mu\,G} = \frac{\nu^{\frac{1}{3}}}{G^{\frac{2}{3}}}, \text{ etc} \dots\dots (43)$$

There are four equations involving the three quantities, L, F, and T. The solution demands that these equations be consistent, that is, that they apply simultaneously. The condition is found by eliminating L, F, and T, which gives Equation (40), the "characteristic." Had there been five equations instead of four, there would have been two characteristics instead of one. In fact, a superabundance of properties may introduce any number of characteristics according to the circumstances. It will be seen that some of the quantities involved are arbitrary, as the mass, or weight, of spring, or model;

and this is the case with the elastic constant, which may be assumed at 10 lb. per ft. for the model; or, after testing the full-sized spring, the model must be made to have a constant conforming to the ratio, k. The characteristic (Equation (40)) is equivalent to,

$$\frac{k_1^3\ \rho_1}{G_1\ \mu_1^4} = \frac{k_2^3\ \rho_2}{G_2\ \mu_2^4}$$

each member being dimensionless, and it contains all the properties involved—G, ρ, μ, and k. It corresponds to characteristics in other homologies, Reynolds' number, Froude's number, etc.

Adopting air as the fluid, the following data, in centimeter-gramme-second units, may be found in physical tables, such as International and Critical Tables, and those by Landolt and Börnstein, for the large scale and small scale, respectively. The values used in the problem are merely approximations:

Air temperatures, in degrees centigrade = 260 and 20
$10^7\ \mu$ = 2 800 and 1 830
$10^7\ \rho$ = 6 000 and 12 000
ν = 0.467 and 0.1526

Then, by slide-rule,

$$\frac{\mathrm{M}}{\mu} = 1.53 \pm ;\ \frac{\varDelta}{\rho} = \frac{6}{12} = \frac{1}{2} \pm ;\ \text{and}\ \frac{\mathrm{N}}{\nu} = 3.06 \pm$$

In this case, the density for air determines the density ratio for the homology, as all such ratios must be the same throughout for homologues. It will not be difficult to make springs and weights to satisfy this requirement, if the maker can grasp the idea that he is not making springs, but models. The centimeter-gramme-second ratios are the same as the English. The springs are to oscillate under the action of gravity, as well as by reason of their elasticity. Therefore, all homologous accelerations are equal, although they need not necessarily be the same, numerically, as gravity. Thus, the ratio, $G = 1$, and the characteristic gives:

$$k^3 = \frac{\mu^4}{\rho} = 10.96\Big]_{G=1};\ k = 2.22;\ R = L = \left(\frac{k}{\rho}\right)^{\frac{1}{2}} = \left(\frac{k}{\mu}\right)^2 = 2.104\Big]_{G=1}$$

and, since $G = 1$, the mass ratio is,

$$M = \frac{T^2\ F}{L} = \rho\ L^3 = 4.675\Big]_{\rho=\frac{1}{2}} = F$$

Now, make, calibrate, and adjust, the similar springs. The larger may be of spring steel and the other a model, such that its length, effective density, and elastic constant will be in the proper proportions, L, ρ, and k. The weight (arbitrary) on the smaller spring is 10 lb.; then, on the larger spring, it must be 46.75 lb., the respective masses being $\frac{10}{32.2}$ and $\frac{46.75}{32.2}$ slugs. Thus, to check the calculations, 1.5 ft. being an extension (to one side) of the larger spring,

$$G_1 = \frac{k\ L}{M_1} = 22.9\ \text{ft. per sec.}^2$$

and,

$$G_2 = \frac{10 \times 0.731}{M_2} = 22.9\ \text{ft. per sec.}^2$$

The final check is by Equation (16) thus:

$$\frac{L^3\ G}{\mathrm{N}^2} = \frac{9.35 \pm \times 1}{9.36 \pm} = 1$$

which checks.

Of course, Reynolds' equation will now be satisfied, thus:

$$\frac{V\,L}{\mathrm{N}} = \frac{v\ l}{\nu} = 18.9$$

This checks exactly, although it is not expressed entirely in English units. It is evident, however, that these results could not possibly have been attained, had Reynolds' equation been considered the sole requirement in addition to geometrical and elastic similarity, as, in that case, Newton's theorem would have been ignored, whereas, it must always be effective in every case of dynamic similarity.

If, now, the springs are extended in proper ratio, R, at any angle to the vertical, and if they are released simultaneously, in their properly tempered atmospheres, the motions will be similar, although compounded of various types of oscillation. By properly proportioned side impulses on the sides of the springs, flexural vibrations may be introduced, as well as longitudinal and pendular oscillations, without destroying the similarity, provided shearing has been introduced into the equations, as mentioned. The springs must be confined in similar spaces.

To attain this result means, of course, that the material, or form (without destroying theoretical similarity, both external and internal), of the model spring must be devised so as to develop an effective shearing modulus of elasticity, or, if necessary, an artificial "modulus", such as will satisfy Equation (21), simultaneously with k. An illustration is given by Equation (39), in which, k and μ are connected.

The resulting motions of the two springs are not synchronous (time scales being different), and would gradually subside unless maintained by some device (clockwork). It should be noticed, however, that if time is reckoned according to the model time-scale (as by a "model" watch), the motions would be synchronous in the sense of similarity. The elastic motions need not be, and probably are not, isochronous.

The problem has been solved by postulating that the air will act as an incompressible fluid. This is accurate for most motions of solids in air, such, for example, as the motions of ordinary machinery, automobiles, and airplanes. If fluid elasticity is to be involved (sound effects, cavitation, etc.), the ratios of corresponding elastic moduli must be made to satisfy Equation (21), just as E does in Equation (25) which is merely a form of Equation (21). In this way, sound, cavitation, etc., should be reproduced in the model.

It is worthy of notice that, whether the cubic strains are isothermal, adiabatic, or whether they vary according to an arbitrary law, the ratio of homologous moduli is the same as the ratio of the homologous atmospheric pressures. This assumes that the ratio of the ratios of the specific heats is equal to unity. In the case of gases, exhibiting a variance in this respect, the ratio of the ratios of the specific heats must be introduced into formulas.

By "specific heat" is here intended the general specific heat, isothermal and adiabatic conditions being merely special cases.

Whether it will be permissible to modify the natural atmospheric pressure, or introduce an artificial "atmosphere", in a model, depends upon conditions in the prototype. If the normal pressure in the prototype nowhere falls below p lb. per sq. ft., then the atmospheric pressure in it may be reduced by p lb. per sq. ft. without otherwise changing materially the dynamic action of the prototype. In such cases the model atmosphere may be adjusted to correspond to such hypothetically reduced atmosphere on the prototype, without making any actual change of the atmospheric conditions in the prototype.

Under these circumstances, there would be a point, or points, in the model at which the pressure would be nil. This last condition determines the least possible pressure of the model atmosphere, for there is no such thing as a negative pressure. It is only a difference in pressure, or its direction, which may be considered as being negative.[13] Such difficulties are not problems of theory. Among many problems, they are merely some which must be solved in the field by the Newtonian model engineer, a type of engineer yet to be developed, of whom much may be expected. A problem involving atmospheric pressures is treated in Appendix I.

Herein lie possibilities for creating a new department of engineering design, that of "model engineering", concerned with the technical methods of constructing models which will perform with theoretically exact similarity. In this way, the most difficult problems of mechanics may be solved by making and shaping materials (including fluids) so as to have desired properties and qualities. This care is especially necessary in designing important structures when the mathematical difficulties render solutions impracticable. This does not necessarily mean difficult constructive problems in making the models, since, in many cases, properly constituted materials and fluids are at hand, or may be made easily.

Many ordinary kinds of forces are properly constituted so as not to interfere with theoretically exact model operation.[14] Among these may be mentioned all those similar forces which are proportional to homologous areas and to the squares of homologous velocities, such as: (1) Pressures; (2) ordinary skin friction under the V^2 law; (3) reactions of moving masses; (4) "adjusted viscous forces"; (5) static and dynamic effects due to heads of water and of water falling over a spillway; (6) effects of wind on running ice; (7) transportation of detritus and carriage of floating ice; (8) time on a "model" watch; and (9) measurements in "model" units. Time given by the model watch will agree with the actual time. Weighings and measurements by the model weights and measures agree with actual weights and measures for the prototype. Even factors of safety for structures may be included, if models are properly constructed and properly tested. Moreover, if materials are found, made, or arranged to satisfy Newton's theorem of similarity, as many as may be so provided can be used in the model.

---

[13] See Lamb's "Hydrodynamics," Third Edition, p. 18, where such pressure changes are mentioned, but without notice of the limitation.

[14] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1171.

The effect of varying values of g may be obtained by rotating the model about a vertical axis, if care is taken to place the model in a proper position relative to that axis. This has the effect of increasing g and may be desirable when the properties of the model leave the size to be determined by the acceleration ratio of the homology. Theoretically, when above the surface of the earth, the model should be nearer the earth's center than the prototype, supposing viscous forces to be present. When below the earth's surface, the reverse would be the case. Other conditions than viscosity also affect the size of the model, if similarity is to be obtained. (For effect of pressure, see Appendix I.)

It may be desirable to know the significance of "Reynolds' number." That dimensionless number occurs in many formulas for the flow of viscous fluids;[15] its form is given in Equation (9). It occurs also in Equation (10). It occurs implicitly in Equations (16) and (17). If L is calculated from Equation (16), then, upon forming $\frac{L\,V}{\frac{N}{\nu}}$, the latter will be found equal to unity. That will mean that Reynolds' number is constant as between similar systems, or, $\frac{V\,L}{N} = \frac{v\,l}{\nu} =$ constant. This may also be calculated from Equation (10) by simple division, having regard to the dimensions of velocity. Therefore, if similarity exists throughout the systems, Reynolds' number will be constant throughout.

It cannot be inferred from this, however, that the systems will be similar if Reynolds' number is constant. In order that this latter state of affairs may hold, the scale of the model relative to the scale of the prototype must be determined so that it will satisfy the three equations, (10), (11), and (12), which is the real reason why Reynolds' number is constant in Equations (16) and (17).[16]

Example 3.—Let it be supposed that a tank furnishes water to a 5-in. horizontal discharge under 25-ft. head, and that it is desired to make a model of the plant one-fifth of the full size to be operated with water. By Newton's theorem,

$$G = \frac{V^2}{D} = \frac{V^2\,D^2}{D^3} = \frac{1}{D^3} \dots\dots\dots\dots\dots (44)$$

since Reynolds' number is to be taken constant, and because of the use of water in the model. The velocities are: $V = 8.02\sqrt{25} = 40$ ft. per sec.; and $v = 5 \times 40 = 200$ ft. per sec., since $VD = vd$. Thus, the effective test head is $\frac{200^2}{64.4} = 625$ ft. This head is altogether out of proportion. Reynolds' number does not here prove to be an infallible criterion. However, if the horizontal model discharge, alone, is supplied with water from a main under a head of 625 ft., it is supposed that the flows in the discharges will be similar, although the systems are not similar throughout. Thus, $\frac{G}{g} = \frac{200^2}{1} \div \frac{40^2}{5} = 125$, or the value of the acceleration in the model discharge is 125 times normal g, by Newton's theorem.

---

[15] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), pp. 839 to 841, Equations (8) to (13), inclusive. The friction factor, F, in Equation (12), for example, has been shown by experiment to be a function of Reynolds' number; "Similarity of Motion in Relation to the Surface Friction of Fluids," by Stanton and Pannell, Collected Researches, British National Physical Laboratories.

[16] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1187, first two paragraphs relative to Equation (20), where this important admonition is given by the writer after careful theoretical studies followed by several years of experimental investigation.

Now, try a model with mercury at 80° cent., the water in the tank being at 15° cent. The values of the kinematical coefficients are, respectively, $\nu_m = 0.00097$, $\nu_w = 0.0114$, (centimeter-gramme-second); giving $\frac{N}{\nu} = 11.76$. Then, by Equations (16) and (17), $R = 11.76^{\frac{2}{3}} = 5.18$, so that a scale ratio of 1 : 5.18 is correct for the mercury model. Hence, $h = \frac{25}{5.18} = 4.82$ ft.; and $d = \frac{5}{5.18} = 0.965$ in. — the respective head and diameter of discharge for the model plant, which is a perfect model in all respects. The velocity ratio is $1 : \sqrt{5}$, or the velocity in the model discharge is less than one-half that in the larger discharge. No calculations have been made for friction, because the mercury model will reproduce it perfectly; nor does the friction head need to be proportional to the square of the velocity in creating the friction heads in the separate systems, because the similarity will exist between the systems at all corresponding velocities, including pure viscous flow. However, the friction heads, as between model and prototype, will vary as the squares of homologous velocities, also including pure viscous flow.

There are other ways by which to satisfy Newton's theorem, and to adapt the apparatus to viscous fluids. One may assume that the scale ratio and acceleration ratio are known; and then adapt the viscosity ratio to suit the requirements, if suitable fluids can be found, or made. If limited to certain fluids, as in the first part of Example 3, one may let the acceleration ratio be determined from Equations (16) and (17) by introducing the properties of the fluids and the chosen scale ratio, R. In every case, it is necessary to satisfy Equations (16) and (17), and to see that conditions conform to Newton's theorem, in order to have similarity. It is the adjustment of values to satisfy Newton's theorem that suffices to establish a model, and not solely the constancy of Reynolds' (Stokes') number.

In the last case mentioned (first part of Example 3), when the acceleration ratio is determined in terms of R and N, it may be necessary to use two given fluids, or one and the same fluid, in model and prototype. In either of these events, the force ratio is,

$$F = \rho\, \nu^2 = \frac{\mu^2}{\rho} \dots\dots\dots\dots\dots\dots\dots\dots (45)$$

which, of course, is intended to refer to homologues throughout. This force ratio may be found by the general process outlined in connection with and by Equations (20) and (21), as exemplified by Equations (25) to (31) inclusive;

or, that which is the same thing, by solving Equation (20), and the equation formed by the first and third members of Equation (39), for F. In the latter case the result is reached quickly by dividing μ^2 by ρ.

When the two fluids become one and the same fluid, the density ratio and viscosity ratio each become unity, thus also reducing the force ratio (Equation (45)), to unity. This means that the actual total operating force on the model must be the same as the total force operating upon the full-sized prototype. This is an awkward and unnecessary situation, for it frustrates the entire object of a model, in which it is desired to reduce the measures to moderate values. This difficulty has been commented upon by other writers,[17] and it is a little surprising that none of them has pronounced it an absurd extreme, for the purpose of designing by models. The parallel with elastic models was mentioned in connection with Equations (32) to (38), inclusive, in which the velocity in the elastic model was the same as in the full-sized structure.

Furthermore, the ideas have long been current in scientific and engineering literature that the method of allowing the acceleration ratio to adjust itself to the velocity ratio, is equivalent to "eliminating gravity"; and that the motion of the fluid is "non-accelerated," as in the case of steady flow along a pipe. It is true that the mean velocity of steady flow along a cylindrical pipe is uniform, but the fundamental idea of similarity has nothing directly to do with the nature of the flow in any separate system. The idea concerns itself only with a comparison of homologous conditions in two, or more, distinct systems. Thus, homologous velocities must be in fixed ratios, whether those velocities are uniform or variable, as to time or place, in any given system. The similarity applies to the motion of fluid particles, such that every eddy or irregularity of flow is to be repeated in the model. If this were not true, there would be no such thing as comparing two systems, for it is this elemental similarity which causes like actions. All these eddies and irregularities of flow are the vital agencies which produce the principal friction losses—the main resistances with which it is usually necessary to deal. Consequently, instead of being non-accelerated, the motion is highly accelerated, both longitudinally and transversely, to say nothing of the initial acceleration to introduce the flow, and to maintain it at joints, fittings, and bends. It seems to the writer that the theory of probability might be applied to the flow of water in a manner somewhat similar to that used in the kinetic theory of gases. The study of the nature of such flow (turbulence included) offers one of the great fields for hydraulic and hydrodynamic research.

The use of the same materials in model and prototype leads to certain limiting cases of models. Weber has tabulated[18] five such cases which compare the operations of models of gravity, mass attraction, viscosity, elasticity, and capillarity.

The writer prefers not to consider these cases as separate types of similarity, but merely as special forms of more general cases due to the operation of models of different types, when made of materials identical with those of the prototype. Mathematically, this amounts merely to assigning particular values to the parameters in the equations of each general type of model. This was illustrated when placing E and ρ, each equal to unity, in Equations (26) to (31), inclusive, to reduce them to Equations (32) to (38), inclusive. The latter condition corresponds exactly with Weber's elastic model, but, as shown, is merely a limiting case of one more general.

---

[17] "Model Experiments and the Forms of Empirical Equations," by Buckingham *Transactions*, Am. Soc. Mech. Engrs., Vol. XVII (1915), Paragraph 30; see, also, "Dimensional Analysis," by Bridgman, pp. 85 and 86.

[18] Jahrbuch der Schiffsbautechnischen Gesellschaft, 1919, p. 414.

Taking this view, it would seem better to compare general types of models, rather than special cases of those types. To make such comparison, it is not necessary to go beyond the use of three dimensions, since all homologous ratios may be derived from any three. It will be sufficient to indicate such a general synopsis by comparing the two types which have been previously treated. (See Table 1.)

TABLE 1.—COMPARISON OF ELASTIC AND VISCOUS MODELS.

Ratio.	Symbol.	Elasticity.		Viscosity.	
		Dimensions.	Equations.	Dimensions.	Equations.
Scale (linear)	L	$\frac{E}{\rho G}$	(26)	$\frac{\mu^{2/3}}{\rho^{2/3} G^{1/3}}$	(16), (41)
Force........................	F	$\frac{E^3}{\rho^2 G^2}$	(27)	$\frac{\mu^2}{\rho}$	(39), (42)
Time	T	$\frac{E^{1/2}}{\rho^{1/2} G}$	(28)	$\frac{\mu^{1/3}}{\rho^{1/3} G^{2/3}}$	(17), (43)
Characteristics: General case.............	....	$\frac{R \rho G}{E} = 1$	(26)	$\frac{R^3 \rho^2 G}{\mu^2} = 1$	(16)
Special case: Same materials in model and prototype; values of constant ratios.....	....	$R G = 1$ $E = 1;\ \rho = 1$	(32)	$R^3 G = 1$ $\mu = 1;\ \rho = 1$	(16), (18)

In some instances the special cases of characteristics can be associated with the names of celebrated investigators. For example, $R^3 G = 1$ indicates the constancy of Reynolds' (Stokes') number, as shown by linear scale ratio and acceleration ratio, thus,

$$R^3\,G = L^3\,\frac{L}{T^2} = L^2\,\frac{L^2}{T^2} = (L\,V)^2 = 1 \ldots\ldots\ldots\ldots\ldots (46)$$

which is the same as $V L = 1$, or $V D = 1$; that is, respectively, $V L = v\,l$, and $V D = v\,d$, the usual form of statement that Reynolds' number (Stokes' number) is constant for a given fluid. For purposes of definition, it seems better to state such dimensionless numbers in terms of the constants of the particular problem involved; that is, in terms of given data. This has been done in Table 1.

It is instructive to notice that the dimensions of L, F, and T, are given in terms of the "dimensions"—acceleration, density, viscosity, elasticity, etc.—

in which, by making the problems kinematical, the number of arbitrary dimensional ratios may be reduced to two, the least possible number. As an example, the dimension, L, in viscosity may be expressed in the two dimensions, N and G, each being necessary dimensions in a viscous model. Theoretically, there are three dimensions, μ, ρ, and G. In elastic models the three dimensions are, E, ρ, G, etc. In this last case, to secure similarity, E must be the same for all types of moduli involved. Observe that in each case the ratio, E, is that of two similar moduli.

It will be noticed, of course, that the general case of the characteristic for viscous models, in Table 1, is precisely the form expressed by Equations (16) and (17).[19] Reynolds' number is a special case of this general characteristic of viscous models. It may be worth while to emphasize that this characteristic, and also that Equations (10), (11), and (12), are satisfied by straight-line viscous flow, as well as by turbulent flow, when similarity holds.[20] There is no essential difference in these two types of similarity; both of them conform exactly to Newtonian, which alone is dynamic similarity. If one will substitute the dimensions of N and ν in Equations (16) and (17), either of the two forms of Newton's theorem may be made to appear. When this criterion is satisfied throughout systems containing viscous fluids (model and prototype), and only then, can similarity exist throughout the systems.

It seems to be somewhat of an open question, whether similarity will establish itself, as in a pipe, but Stanton and Pannell's experiments, previously mentioned, go a long way toward showing that it will. These experiments, properly interpreted, are to hydraulics what Stokes' investigations were to hydrodynamics. It is hoped that experiments of the same nature will be made for differing degrees of roughness, and for differing shapes of channel boundary.[21] Every hydraulic engineer should study Stanton and Pannell's paper on "Similarity of Motion, in Relation to the Surface Friction of Fluids."[22] The word "similarity," in the title of this paper, is used in a somewhat different sense from that adopted in the writer's present paper unless the conditions of the test were such as to satisfy Newton's theorem.

Of course, Reynolds' number was satisfied in Stanton and Pannell's experiment, so that theoretically exact dynamic similarity may have been in operation; but it is certain that Newton's theorem must be shown to hold in any case, before an inference to that effect can be sustained.

Relative to the significance of Reynolds' number, the functional relation between the coefficient of hydraulic friction and the value of that number, as exhibited in the experiments of Messrs. Stanton and Pannell, shows that all hydraulic friction, of whatever nature, including turbulence, depends primarily and ultimately upon viscosity.[23] This is not a common view. It is, in fact, one that has been rejected by numerous writers of profund attainment,[24] but the writer clings to the affirmative for the reasons cited in the former reference.[23]

CONCLUSIONS

It is concluded that the present usage of models is not wholly consistent with sound theory. Newton's theorem for conditions of dynamical similarity has been gradually fading from view, while the fallacious idea that there are differing kinds of similarity has been unduly propagated. Nothing can be farther from the truth than the idea of differing kinds of similarity. All the variously designated "laws" of similarity reduce immediately to Newton's one unique definition and theorem. When that theorem is fully satisfied, Reynolds' number will be satisfied. Even in the absence of fluids of any kind, if Newton's theorem is satisfied under the conditions of acceleration in Equation (44), Reynolds' number will be satisfied ($V\,D = 1$), but that number may be satisfied without the existence of similarity. Moreover, except as just stated, and in the case mentioned, Newton's theorem may hold and similarity may exist, when Reynolds' number is not satisfied (for example, when, in the absence of viscous fluids, $v\,d$ is not the same in model and prototype).

Besides the establishment of initial similarity, the necessary and sufficient conditions to establish a model are, that the size of the model, the coefficient (kinematic) of viscosity, and the acceleration ratio, shall all be determined so that Equations (10), (11), (12), and (16)—in the general case Equations (11), (12), (20), and (21)—shall be satisfied. If this is not done, it is not known exactly what errors result, and one must rely upon the supposition that the effects of viscosity (and any other properties) in distorting the model are not great. Perhaps the important conclusion is that a thorough investigation should be made to ascertain what materials and fluids will serve best as materials for models, and to synthesize, if possible, materials which are capable of having their "physical properties" adjusted. By "physical properties" is meant, not only the usual properties of materials, but artificial properties produced in a practical way so as to serve in the manner desired. It is not improbable that, in due time, the stream lines and eddies of flowing water will be produced by mechanisms in the absence of fluids altogether.

There is a great field for the development of a corps of specialists to build models to the specifications indicated by the Newtonian theory, which is the only sound theory for models.

The final paragraph of Appendix I shows that an homology of elastic solids and incompressible fluids is mathematically identical with an homology of elastic fluids and incompressible solids. More generally, any homology of solids, liquids, and gases of varying (constant) characteristics (properties), will remain a homology, in the sense here used, providing the physical properties of the constituents and the other internal and extraneous conditions, instantaneously adjust themselves (or remain constant, as adjusted) to the requirements of Newton's theorem.

(1915), p. 281, "Model Experiments and the Forms of Empirical Equations," by Buckingham; Encyclopædia Britannica, Eleventh Edition, Vol. 27, p. 736; "Dimensions of Units," by Larmor; "Dimensional Analysis," by Bridgman, p. 85; and "Hydrodynamics," by Lamb, Third Edition, 1906, p. 593.

APPENDIX I

As further illustration of the nature and use of the dimensional forms for *L, F,* and *T,* given in Table 1, and as illustrating the method of treating compressibility of fluids, such as mentioned after solving Example 2, involving Equation (39), it will be interesting to examine the possibility of testing an airplane propeller in air under pressure as has been suggested.[25] This, of course, would increase the density and, consequently, diminish the kinematic viscosity, so as to admit of an accurate test of a model of reduced scale, assuming that the viscosity is not seriously affected adversely by an increase of pressure. It will then be of additional interest to see if the conditions of test can be improved by substituting a different gas in the model. The method of substituting a liquid (mercury, say) to represent the air, has been mentioned in the remarks following Equation (19). The question of "slip" is discussed in treatises on the kinetic theory of gases, and is also referred to by Lamb.[26]

The specifications of a gas should always relate to standard conditions of pressure and temperature, usually 1 atmosphere, and 0° cent. Then the gas equation, $P = c\,w\,\theta$, determines the pressure for any other conditions, the standard conditions being indicated by $P_s = c\,w_s\,\theta_s$, assuming that c remains constant. Whence,

$$\frac{P'}{P_s'} = \frac{w'\,\theta'}{w_s'\,\theta_s'} \quad\text{.........................(47)}$$

and,

$$\frac{p_m}{p_s} = \frac{w_m\,\theta_m}{(w_s)\,\theta_s} \quad\text{.........................(48)}$$

in which, the primed symbols may relate to the prototype, and the other symbols to the model. The subscript, *s,* refers to standard conditions of pressure and temperature. The symbols, *w,* refer to the specific weight, or to the density, indiscriminately, as long as the acceleration of gravity has its standard value. In either case, *w* is the reciprocal of the specific volume of the gas, the volume in terms of which the gas equation is so frequently written. Observe that the model and prototype may contain either the same, or different, gases.

Then, the ratios of homologues, prototype to model, become:

$$P = \frac{P'}{p_m} = \frac{w\,\theta}{w_s} \left| \begin{array}{l} P_s' = p_s \\ \theta_s' = \theta_s \\ \theta = \dfrac{\theta'}{\theta_m} \\ w = \dfrac{w'}{w_m} \\ w_s = \dfrac{w_s'}{(w_s)_m} \end{array} \right. \quad\text{...................(49)}$$

and,

$$\rho = w = P\,\frac{w_s}{\theta}\Bigg]_{G' = g_m = g} \quad\text{...................(50)}$$

---

[25] See *Transactions,* Am. Soc. C. E., Vol. LXXXII (1918), footnote, p. 1187.

[26] "Hydrodynamics," Third Edition, p. 594.

In Equation (50), the equality of the specific weight ratio, w, to the density ratio, ρ, refers to the comparison of conditions in the prototype and model as affected by standard gravity (equality of g in model and prototype). If the acceleration is really different in the model, then the specific weight ratio, referred to the resulting different acceleration ratio, is not the same as the density ratio. Of course, the density ratio is unaltered. Thus,

$$\bar{w} = \rho\, G = w\, G \quad \text{(51)}$$

in which, $\bar{w}$ indicates the new specific weight ratio. It may be represented by $w\, G$.

If it is assumed, as usual, that the viscosity of the gas is independent of the pressure,[27] then, for fixed temperatures in model and prototype, the absolute viscosity of each gas will be determined by its temperature. The resulting constant viscosity ratio will be indicated by μ, which, accordingly, becomes a constant of the problem.

Bearing in mind the foregoing relations, and recalling the solution of Equations (11), (12), (20), and (21), (Newton's conditions of similitude), as indicated in Table 1, the following simultaneous equations may be written:

$$R^3 = \frac{\mu^2}{\rho^2\, G} \quad \text{(52)}$$

$$F = \frac{\mu^2}{\rho} \quad \text{(53)}$$

$$T^3 = \frac{\mu}{\rho\, G^2} \quad \text{(54)}$$

$$\rho = \frac{P\, w_s}{\theta} \quad \text{(55)}$$

$$F = P\, R^2 \quad \text{(56)}$$

Equation (56) represents a very obvious equality.

As mentioned in the text, any quantity of ordinary mechanics can be expressed in terms of any three "fundamental" dimensions. Let these three dimensions be the most important three constants of the problem, say, R, μ, and $\frac{\theta}{w_s}$; or, P, μ, and $\frac{\theta}{w_s}$, if the pressure is more important than the scale ratio. Hence, in the former case, eliminating ρ, G, and P, the dimensions L, F, and T, are expressed in terms of the former set of dimensions, as follows:

$$L = R \quad \text{(11)}$$

$$F = \mu\, R \sqrt{\frac{\theta}{w_s}} \quad \text{(57)}$$

$$T = R \sqrt{\frac{w_s}{\theta}} \quad \text{(58)}$$

from which the ratio of any pair of homologues may be found. Thus, for example,

$$G = \frac{L}{T^2} = \frac{1}{R} \left(\frac{\theta}{w_s}\right) \quad \text{(59)}$$

---

[27] "Hydrodynamics," by Lamb, p. 536.

$$\rho = \frac{T^2 F}{L^4} = \frac{\mu}{R}\sqrt{\frac{w_s}{\theta}} \quad \text{.....................(60)}$$

$$P = \frac{F}{L^2} = \frac{\mu}{R}\sqrt{\frac{\theta}{w_s}} \quad \text{.....................(61)}$$

$$V = \frac{L}{T} = \sqrt{\frac{\theta}{w_s}} \quad \text{.........................(62)}$$

If it is desired to have a small model, R will be chosen, necessarily, as large as practicable, numerators of ratios relating to the prototype. This would tend to make the ratio, P, smaller, or the pressure in the model would be increased as the size of the model is decreased. This puts a practical limitation on the size of the model. However, by taking θ as large as possible, and w_s as small as possible, that is, keeping the temperature of the model atmosphere low, and selecting a fluid for the model with as great a density (under standard conditions) as practicable, the conditions of operation will be improved. If air is used in both model and prototype, the density of the air in the model may be increased by increasing its pressure. There does not appear to be any great changes in μ for ordinary changes of temperature, but one should use a model gas having as little viscosity as possible. Notice that diminishing θ (in case of most gases) has a like effect upon μ. In following the discussion, the text shows when a symbol relates to a ratio, and when it relates to a quantity in one of the systems only (model or prototype).

The investigator is now in a position to examine any homology which contains either the same, or different, fluids, especially for the purpose of determining the suitability of a particular fluid for use as a "model" of another fluid. Thus, let it be required to examine air for use as a model of itself, say, for the purpose of testing a model airplane propeller of small size in an atmosphere of modified air.

For this case, $w_s = 1$, since the specific weight of air is always the same for standard conditions; but θ may be modified, say, from 40° cent. (hot summer weather) to 0° cent., in the model; thus $\theta = \frac{313°}{273°} = 1.146$ (slide-rule), while μ, for these conditions, will be about $\frac{190}{170} = 1.118$; therefore, the dimension, $\sqrt{\frac{\theta}{w_s}}$, becomes 1.070. The size of the model may be tried at one-sixteenth the full size of the propeller, $R = 16$. Theoretically, the space in which the model is tested should be indefinitely large, all near-by objects being carefully made to scale, yet, for convenience, the model may be tested in a tunnel, or in a large pipe, provided the model is sufficiently small, relatively thereto. Equations (11), (57), and (58) then give, $L = 16$; $F = 19.14$; and $T = 14.94$, which, substituted in the first forms of Equations (59), (60), (61), and (62), or, if desired, the values of μ, R, and $\frac{\theta}{w_s}$, directly substituted in the second forms of Equations (59), (60), (61), and (62), give $G = \frac{1}{13.95}$; $\rho = \frac{1}{15.34}$; $P = \frac{1}{13.36}$; and $V = 1.07$.

Thus, the greatest difficulty with an air model is caused by the relatively high pressure in the model (about $13.36 \times 14.7 = 196.5$ lb. per sq. in.); but this would operate nicely if it were practicable to use such pressure.

In order to ascertain whether it is possible to improve the pressure condition in the model, another fluid, different from air, may be examined. An improvement in this respect will be made, if a gas can be found (it has been shown previously that a liquid such as mercury might serve) having a greater standard density than that of air. There are several such gases and vapors, which should be thoroughly investigated.

For present purposes, it will be assumed that a suitable gas can be found of viscosity (absolute) 1.111 times that of air under the actual conditions of the test. (It would be better to have its viscosity less, but it is assumed greater, for illustration). Thus, μ is about 0.9, which will be considered as the value applying for the temperature conditions of the test, since, as mentioned previously, the viscosity of the gas is independent of the pressure. The density ratio under standard conditions will be taken as $\rho = w_s = 0.133 = \frac{1}{7.525}$. The scale ratio, R, will be 16, as before.

With these three constants (μ, ρ, and G) fixed, the problem becomes determinate by Equations (11) and (57) to (62). Then, by introducing the numerical values of the constants, making the calculations as suggested, and as illustrated in the previous calculations, and by assembling all the formulas and results obtained in this Appendix, Table 2 may be compiled as shown.

A further improvement can be made if μ is reduced in the model. This suggests the idea of devising a method of synthesizing, or treating, a fluid in such manner as to secure a decreased viscosity without altering seriously the value of the density ratio. This makes the molecules of the gas (regarded as a homogeneous fluid) more "slippery," or, perhaps it would be more accurate to say, rendering the molecules less "coherent," so as to admit of rapid shearing distortion with less resistance.

Hence, it appears, that a different gas for the model may admit of reduced pressure in the testing pipe and, also, approximately, in the case examined herein, less than one-half the pressure required in the prototype, in this case, air. Moreover, the velocity in the model, for such change, is reduced to about one-third the velocity in the prototype; it is reduced to about one-third its value for the test of the model propeller in air.

The acceleration ratio, G, is not here due directly to gravity (terrestrial), but relates to homologues in the form of eddies and turbulence generally, as well as to centripetal accelerations at bends, etc. In fact, only the portion of space surrounding (and including) the model propeller, and along the testing pipe, or tunnel, forms the model. Whether the restricted dimensions of the pipe will have a material effect upon the action of the model, is a question which must be considered by the engineer.

TABLE 2.—CONDITIONS FOR TEST OF MODEL AIRPLANE PROPELLERS IN GASES UNDER PRESSURE (STUDY OF POSSIBILITIES).

	μ, ρ, and G.	μ, R, and $\frac{\theta}{w_s}$.	μ, P, and $\frac{\theta}{w_s}$.	$w_s = 1$; $\theta = 1.146$; and $\mu = 1.118$.	$w_s = 0.133$; $\theta = 1.146$; and $\mu = 1.111$.
L.........	$\frac{\mu^{2/3}}{\rho^{2/3}\,G^{1/3}}$	R	$\frac{\mu}{P}\sqrt{\frac{\theta}{w_s}}$	16	16
F.........	$\frac{\mu^2}{\rho}$	$\mu R\sqrt{\frac{\theta}{w_s}}$	$\frac{\mu^2}{P}\left(\frac{\theta}{w_s}\right)$	19.14	42.3
T.........	$\frac{\mu^{1/3}}{\rho^{1/3}\,G^{2/3}}$	$R\sqrt{\frac{w_s}{\theta}}$	$\frac{\mu}{P}$	14.94	5.45
G.........	$\frac{L}{T^2}$†	$\frac{1}{R}\left(\frac{\theta}{w_s}\right)$	$\frac{P}{\mu}\sqrt{\frac{\theta}{w_s}}$	$\frac{1}{13.95}$	$\frac{1}{1.856}$
ρ.........	$\frac{T^2\,F}{L^4}$†	$\frac{\mu}{R}\sqrt{\frac{w_s}{\theta}}$	$P\,\frac{w_s}{\theta}$	$\frac{1}{15.34}$	$\frac{1}{52.20}$
P*.........	$\frac{F}{L^2}$†	$\frac{\mu}{R}\sqrt{\frac{\theta}{w_s}}$	P	$\frac{1}{13.36}$	$\frac{1}{6.056}$
V.........	$\frac{L}{T}$†	$\sqrt{\frac{\theta}{w_s}}$	$\sqrt{\frac{\theta}{w_s}}$	1.07	2.94
Gauge pressure in model (14.7 lb. less than absolute pressure)				182.3	74.3

* Since PR is a constant in these similar systems, the bursting stress on the sides of pipes (or testing tunnels) of homologous thickness is constant; thus, the pipe may be made safer as the size of the model (including the pipe) is decreased. This favors small models.

† In terms of L, F, and T; may be used to reduce to results of the following columns.

It can easily be shown that Equations (11), (57), and (58) and their various forms as indicated in Table 2, are identical with Equations (40), (41), (42), and (43) in the problem of the elastic pendulums oscillating in gases, or fluids, of an incompressible nature. For example, observing that $k = PL$, in Equations (40), (41), (42), and (43), and that by Table 2, $\rho = \frac{P\,w_s}{\theta}$ and $G = \left(\frac{P}{\mu}\sqrt{\frac{\theta}{w_s}}\right)$, one may substitute in, say, Equation (41), for k, ρ, and G, so as to reduce that equation to an identity, that is, to $L = L$. A similar process reduces all the other equations, in this group, to identities, thereby showing the equivalence of the algebraic forms in Equations (41) to (43), and (11), (57) and (58); or in Equations (40) to (43) and Table 2.

In the case of Equations (11), (57), and (58), or Table 2, the fluid is assumed to be elastic and the solids, incompressible. In the case of Equations (40) to (43), the solids are elastic and the fluids incompressible. Of course, any, or all, the materials may have the property of elasticity or any other properties, if, as explained in Example 2, these properties are suitably "adjusted."

DISCUSSION

H. BATEMAN,[28] ESQ. (by letter).—A numerical coefficient in a mathematical expression for a property of a complete physical system, S, can depend only on numbers which measure the system relative to itself. These numbers will be called the proportions of the system. In some cases they may be regarded as obtained by means of some measuring apparatus included in the system, but in most cases they are supposed to be known from some former measurements to which the system was subjected and from recognized laws relating to their constancy or mode of variation since these measurements were made.

In an ultimate physical analysis a proportion will be either the ratio of the measures of two entities of the same physical type (for example, two lengths or two velocities), or a definite function of such ratios (a product, for instance). A compound expression such as a Reynolds' number is in this sense a proportion of a system. By using the kinetic theory of gases, Dr. Th. von Kármán has shown that the Reynolds' number can be regarded as the ratio of two lengths multiplied by the ratio of two velocities. One of the lengths may be taken to be the mean free path of a molecule and one of the velocities the velocity of sound in the fluid.[29]

When a theoretical expression for a numerical coefficient is lacking one cannot strictly speak of a theory of similarity except in particularly simple cases. Generally, one must be content to discuss the validity of the working hypothesis that the coefficient depends essentially upon a certain finite set of proportions which may be called the dominant proportions of the system, S.

A theory of model testing tacitly assumes the existence of motions and configurations which are strictly similar in the geometrical and dynamical senses although sometimes the situation is simplified by the assumption of steady motion and then it may happen that a proportion involving gravity or an acceleration ceases to be dominant. Much depends, however, upon circumstances.

When a proportion is dominant it is customary to speak of a corresponding effect, such as scale effect, compressibility effect, etc. In this sense one can speak of a gravity or acceleration effect.

The writer agrees with Mr. Groat in his main contentions, but is inclined to say that, although Galileo[30] and Newton recognized the existence of the gravity effect, the credit belongs to W. Froude for the discovery that the associated proportion is often dominant when the physical system involves a solid body and two fluids which are separated by gravity. This discovery was essentially of an experimental nature because generally certain inequalities must be satisfied by the proportions, in order that one may be dominant, or that two may be dominant relative to the others. A valuable discussion of the theoretical basis of model strength tests for aeroplane structures has been given by Messrs. W. L. Cowley and H. Levy.[31] In laying down conditions for the similarity of structures these writers recognize that in many cases there is some latitude in the scope of selection of material for the model.

[30] "Growth and Form," by D'Arcy Wentworth Thompson, Cambridge Univ. Press, 1917.

Physical considerations relating to the structure of matter and the texture of surfaces make it seem improbable that strict similarity can ever be attained in model testing.

When a model has a simple form the number of geometrical proportions needed for its description is small, but in order to specify accurately the shape of an airfoil a large number of proportions are needed. If these proportions are chosen at random without any guiding theory or experience, it is impossible to say which of them will be dominant. A model made with the aid of a template may seem to be of the right shape with a fair degree of accuracy, yet the errors in some proportions, needed for the accurate description of the shape, may be large while those in others may be small. If it happens that the great accuracy is attained in the case of unimportant proportions and the low accuracy in the case of proportions which are really dominant, tests with the model will give misleading results.

In hydraulics, model testing is often uncertain on account of the irregular form of the bed of a river and the substance of which it is composed.[32] Some interesting tests of the validity of the theory of similitude in hydraulics have been made by C. Camichel and his co-workers.[33]

W. P. Roop,[34] M. Am. Soc. C. E. (by letter).—Mr. Groat's effort to make the experimental method based on the theory of similitude more accessible to members of the Society must command the liveliest sympathy from a member of the staff at the United States Experimental Model Basin where the theory of similitude constitutes the "breath of life."

There are, however, certain statements in his treatment of the subject which receive a degree of emphasis not altogether appropriate to a dispassionate consideration of the subject. For one, the writer must demur to the author's remark that nothing ever has been added to any of Newton's theories.

In Proposition III Newton[35] establishes the idea of terminal speed of a body falling through a resisting medium, but the writer does not find that he anywhere traces this effect to frictional, as opposed to dynamic, causes. It is not surprising, therefore, that he should believe that the "resistance of globes in infinite mediums is in * * * the duplicate ratio of the velocity * * * "; or that, "a cylinder, a sphere, and a spheroid of equal breadths equally hinder the passage of the water * * *", and that "the forementioned bodies are equally acted on by the water * * *". On the contrary he seems to suggest in the second paragraph of Proposition XL that it is the inertia of the fluid rather than its friction that is primarily concerned.

Detailed discussion of Newton's ideas is perhaps not in order here, but one or two further allusions are necessary. Proposition XL has as its purpose "to find by phenomena the resistance of a globe moving through a perfectly fluid compressed medium". Whether by this he meant an inviscid fluid is not clear. In the discussion of Experiment 12 he uses these words:

---

[34] Lieut. (C. C.), U. S. N., New York Shipbuilding Co., Camden, N. J.

[35] "Principia," Book II.

> "The more swiftly the globes move, the less are they pressed by the fluid at their hinder parts; and if the velocity be perpetually increased, they will at last leave an empty space behind them, unless the compression of the fluid be increased at the same time."

One might suppose from this that Newton was aware of all the intricate processes of eddy formation and cavitation that cause such inconvenient complexity in fluid dynamics.

However, this would be reading into his words, meaning which is certainly not contained in them in an unambiguous way. He did not know that a sphere moving at uniform speed would meet no resistance at all in an infinite frictionless fluid; that its actual resistance, including that due to eddies, owes its origin to the fact that fluids are not frictionless.

Apparently, Mr. Groat still is under the impression that frictional drag on a solid surface due to tangential motion of a fluid across it is ordinarily proportional to the square of the speed. At the Experimental Model Basin such a statement is considered completely erroneous, and if such a law of friction were used, it would lead to gross errors in power estimates.

Possibly some details as to this point may be of interest because they will illustrate the fact that the successful application of the model method depends on development of a suitable experimental technique as surely as upon sound theoretical analysis.

Even Froude,[36] sixty years ago, was aware that the friction on a plank towed edgewise was not proportional to the square of the speed of the plank through the water. He thought that it varied according to a speed exponent which departed from 2.00 by a fixed amount, and by the use of this assumption obtained for the first time, in a field where many others had failed, a practicable model method for estimating power requirements for ships.

More recently Gebers,[37] at Vienna, Austria, made careful friction tests and arrived at a result differing somewhat from that of Froude. A large number of friction tests have also been made at the U. S. Experimental Model Basin in the thirty years of its existence.

Data from these three sources have been summarized in a paper recently published,[38] which shows that their precision is not sufficient to permit investigators to distinguish between two types of friction formula, in one of which the exponent may be $\frac{5}{3}$, or even less.

Nevertheless, in spite of arbitrary model scales, which Mr. Groat states are permissible only if the exponent is 2.00, and in spite of variability of actual frictional resistances—in short, in spite of the impossibility of application of the model method for absolute power calculations—it is true that the model method excels all others so long as its function is restricted essentially to that of providing comparisons between existing and proposed full scale projects, not differing too much in type.

Mr. Groat's insistence that dynamic similitude is the one and only kind seems to be somewhat academic. In his "Conclusions" he states: "When that [Newton's] theorem is fully satisfied, Reynolds' number will be satisfied". As Newton says nothing of viscosity, the writer assumes that Mr. Groat must have it in mind that viscous action is itself ultimately a dynamic phenomenon, in which, however, the bodies are of molecular dimensions; but the scale on which molecules are built cannot be controlled. In order that two similar dynamic systems should have at the same time equal speed-length ratios and equal values of Reynolds' number it would be necessary to adjust the kinematic viscosity of the fluid separately for each speed. This is obviously impracticable, and as a matter of fact it is unnecessary. In practical work on ship resistance no attempt is made to satisfy rigorously the conditions of full similitude. It is true that a large part of the uncertainties would be eliminated if rigorous similitude could be achieved; but this cannot be done and engineers are dependent on a friction formula showing variation of friction when equality of Reynolds' numbers is not obtainable.

The really important point is that success in ship-model work is achieved, not by insistence on theoretical rigor, but by acceptance of a procedure that is only partly based on similitude, justified by the fact that it produces the desired results. In all discussions of similitude the fact should not be lost from sight that the power required to drive a ship actually can be predicted with rather high precision by means of model tests. The methods used in accomplishing this are the products of long evolution. It may not be generally known that model tests on ship resistance were made by Benjamin Franklin as early as 1768.

From the point of view of ship-power estimates the writer would say that the conditions for successful model work include long continuance of model tests under uniform circumstances as to technique, with frequent full-scale comparisons.

A person who expects to be able to draw valid conclusions from one or two or a dozen model tests in a new field in which the possibilities of unforeseen scale effects have not been explored fully had better prepare his mind for disappointment. It is unfortunate that such disappointments in the past have led some engineers to overlook the fact that, under the right conditions, the model method may be made to yield results otherwise unobtainable. Extension of its use on a long-term basis might well lead, as Mr. Groat suggests in his concluding remarks, to the creation of "a new department of engineering design". He is quite right also in referring to the necessity for development of a "corps of specialists". Some progress in this direction is being made at the U. S. Experimental Model Basin and as appreciation of the importance of the subject becomes more general, progress may be expected to become more rapid.

A. V. Karpov,[39] M. Am. Soc. C. E. (by letter).—The use of models in connection with engineering studies is not a recent development; it has become extensive only in the past few years. The advent of aeronautics and the successful use of models in the investigations of the complicated problems of this new branch of engineering have brought out the importance of model studies, not only in aeronautics but in many other fields of engineering endeavor, and started the general trend of the extensive use of models in involved engineering studies and investigations which is evident to-day.

The excellent presentation of the underlying theoretical principles of model studies by the author will probably do much toward the removal of the misconceptions that are so common in the model work of the past. Mr. Groat discusses the models involving dynamic problems, which are naturally the more complicated.

In connection with the arch dam investigation that is being conducted by the Company with which the writer is connected, it was necessary to determine the conditions that will govern the building of a model of an arch dam, in order to study the structural and design problems arising in this investigation.

This work stresses not only the theoretical aspects of the problem, but the practical ones as well, and is included in this discussion in its entirety.

Similarity Conditions Between an Arch Dam Model and Its Prototype.—Past experience in solving complicated engineering problems by model studies not only justifies the use of models, but shows that in many cases the only way in which reliable results can be obtained is by making proper model studies.

The first step in making such study is to determine what, in the engineering sense, is a model. A very common conception, even in engineering circles, is that any representation of the prototype in an arbitrary scale is already a model; but from the engineering point of view, a scalar representation of the prototype can be called a model only when, from a study of its behavior, conclusions can be derived that will disclose the behavior of the prototype. This means that a certain relationship is to exist between the behavior of the model and prototype, which necessarily must be of a rather simple nature and which is brought about by the fulfillment of the similarity conditions.

These similarity conditions are governed by the purpose for which the model study is to be made and may cover a wide range of different requirements. In a number of simpler problems the only similarity condition to be met is the proper scalar representation of the prototype; in more complicated problems additional requirements will be included and there are still other problems in which the similarity conditions will require that the model is not a true scalar representation of the prototype. In many cases the relationship between the properties of the material or materials that are used in the prototype and in the model is covered by similarity requirements that may be of no less importance than requirements covering the geometrical relationship between the shapes of the prototype and the model.

The scope of the similarity conditions depends not only on the problem itself, but often, to a larger extent, on the kind of information that is to be obtained from the model study. The similarity conditions may be simple if the study is restricted to the influence of some main factors. With the increase of the number of factors that are to be included in a study the similarity conditions increase very rapidly in number and in scope.

---

[39] Designing Engr., Hydr. Dept., Aluminum Co. of America, Pittsburgh, Pa.

In studies of the more complicated structural problems practically every model represents a certain compromise between the rigid theoretical requirements and some practical considerations.

The cost of the model study measured in terms of time and money is the most important of all the practical considerations; if it could be neglected, the best possible model on which to make the studies would be the prototype itself.

The following analysis of the similarity conditions of a model of a simply supported concrete beam will serve as an illustration:

A.—If the purpose of the study is to determine the deflections and stresses of a prototype beam under uniform or concentrated loads of such character and magnitude that the deflections due to shear and the dead weight of the beam can be neglected, then the similarity conditions can be formulated very simply:

> (*a*) The model is to be a true scalar representation of the prototype.
>
> (*b*) The material of the model is to be such that, in the range of stresses of the model, the variations of the modulus of elasticity are similar to the variations of the modulus of elasticity of the material of the prototype in its corresponding range of stresses.
>
> (*c*) The loadings of the model are to be proportional to the loadings of the prototype, but no limitations apply to the value of the model loadings.

B.—If the same study is to be made under such conditions that the dead weight of the beam cannot be neglected, then the similarity requirements introduce the following additional conditions:

> (*d*) The specific gravity of the material of the prototype and of the beam should be equal.
>
> (*e*) The loadings of the model are to be not only proportional to the loadings of the prototype, but the ratio of the loadings of the prototype and model is to be equal to the square of the linear scale of the model.

C.—If the study is to be extended so that it includes the deflections due to shear, then the additional similarity condition will be:

> (*f*) The ratio of the modulus of elasticity in shear and of the modulus of elasticity in flexure of the model material within the range of the stresses of the model is to be the same as that of the material of the prototype within its range of stresses. In other words, the Poisson's ratios of the model and prototype materials are to be equal at corresponding stresses.

D.—If the same study is to be made on a reinforced concrete beam, then the representation of the reinforcement in the model can be so inconvenient that the practical compromise would be to make a model that is a scalar representation of the prototype in its length only. Such a model would have cross-sections which would not be scalar representations of the prototype. It would represent the reinforcement by a proper increase of the size of the part of the beam section that includes the steel.

E.—The practical compromise that probably will be necessary to make Model Studies A to D possible would be to simplify the similarity conditions by assuming that the modulus of elasticity and Poisson's ratio of the material of the prototype are constant, and to choose a material for the model that is fairly uniform, the modulus of elasticity and Poisson's ratio of which can be assumed as constant.

F.—No restrictions apply to the linear scale of the model and to the value of the modulus of elasticity of model material, but for models that satisfy the similarity conditions in Model Study B, the following conclusions can be derived:

> (*g*) The deflections of the model are proportional to the square of the linear scale multiplied by the ratio of the moduli of elasticity of the prototype and model materials.
>
> (*h*) The stresses of the model are proportional to its linear scale.

G.—If it is desirable that the geometrical resemblance of the model and prototype is strictly retained after the application of the load, an additional condition will be imposed:

> (*i*) The ratio of the moduli of elasticity of the materials of the prototype and model is to be equal to the linear scale of the model.

H.—If the model is to be tested to destruction then, again, an additional condition will be:

> (*j*) The ratio of the moduli of rupture of the materials of the prototype and model is to be equal to the linear scale of the model.

An arch dam represents a more complicated problem than a simply supported beam and, keeping in mind the purpose for which the model study is to be made, the problem can be stated in a general form, as follows:

Determine the similarity conditions of an arch dam model in which the deflections and stresses are to have some simple relationship with the deflections and stresses of the prototype under conditions that are well below the destruction point of the prototype.

A certain amount of judgment must be exercised to classify and give the proper weight to the different similarity requirements and the most practical way would be to formulate the theoretical similarity conditions and, later, to bring them into agreement with the practical requirements. No single method is known that would determine all the similarity conditions and the entire problem is to be considered from different points of view. The first and most formal will be the conclusions that can be derived from the application of the dimensional theory, but this theory alone by no means covers all similarity conditions; some additional conditions that are not based on this theory, must be derived.

Similarity Conditions Derived by Application of Dimensional Theory.— The dimensional theory can be applied to the studies of an arch dam model, as follows: The deflection can be expressed as,

$$\delta_p = \psi' \left(\rho_p, \gamma_p, E_p, S_p, g, l_p\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (63)$$

and the stresses,

$$f_p = \psi \left(\rho_p, \gamma_p, E_p, S_p, g, l_p\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (64)$$

in which,

ψ' and ψ = some unknown functions;
ρ_p = mass per unit of volume of the material of the dam;
γ_p = mass per unit of volume of the loading liquid of the dam (water);
E_p = modulus of elasticity in flexure of the material of the dam;
g = acceleration due to gravity;
l_p = length scale; and
S_p = modulus of elasticity in shear of the material of the dam.

If μ_p is Poisson's ratio of the material of the dam, then:

$$S_p = \frac{E_p}{2\,(1 + \mu_p)} \tag{65}$$

and since μ_p is not a dimensional quantity, the dimensional Equations (63) and (64) can be written;

$$\delta_p = \psi'\,(\rho_p, \gamma_p, E_p, g, l_p) \tag{66}$$

and,

$$f_p = \psi\,(\rho_p, \gamma_p, E_p, g, l_p) \tag{67}$$

Expressing all the quantities of Equations (66) and (67) in terms of mass, M, length, L, and time, T, then:

$$\rho_p = \gamma_p = M\,L^{-3} \tag{68}$$

$$E_p = M\,L^{-1}\,T^{-2} \tag{69}$$

$$g = L\;T^{-2} \tag{70}$$

$$l_p = L \tag{71}$$

The deflections have the dimensions, L, and from Equation (66) the dimensional equation will be,

$$\delta_p = \rho_p^{\,x}\,\gamma_p^{\,y}\,E_p^{\,z}\,g^u\,l_p^{\,v} \tag{72}$$

making the necessary substitutions:

$$L = L^{(-3x-3y-z+u+v)}\;M^{(x+y+z)}\;T^{(-2z-2u)} \tag{73}$$

The following equations can be written by equalizing the powers of L, M, and T:

$$1 = -3x - 3y - z + u + v \tag{74}$$

$$0 = x + y + z \tag{75}$$

and,

$$0 = -2z - 2u \tag{76}$$

Solving these equations:

$$z = -u \tag{77}$$

$$v = 1 + u \tag{78}$$

and,

$$x + y = u \tag{79}$$

Substituting in Equation (72),

$$\delta_p = l_p \left(\frac{\gamma_p \, g \, l_p}{E_p}\right)^u \left(\frac{\rho_p}{\gamma_p}\right)^x \dots\dots\dots\dots (80)$$

Assuming that the material follows Hooke's law and that no buckling or other disturbances which would distort the deflections occur, then δ_p will be proportional to $\frac{1}{E}$ and, consequently, from Equation (80), $u = 1$, and,

$$\delta_p = \frac{\gamma_p \, g}{E_p} \, l_p^2 \, \phi'_p \left(\frac{\rho_p}{\gamma_p}\right) \dots\dots\dots\dots (81)$$

in which, ϕ'_p is an unknown function.

Using the subscript, m, the deflections of the model can be written similarly to Equation (81),

$$\delta_m = \frac{\gamma_m \, g}{E_m} \, l^2_m \, \phi'_m \left(\frac{\rho_m}{\gamma_m}\right) \dots\dots\dots\dots (82)$$

From Equations (81) and (82),

$$\frac{\delta_m}{\delta_p} = \left(\frac{l_m}{l_p}\right)^2 \frac{\gamma_m}{\gamma_p} \, \frac{E_p}{E_m} \, \frac{\phi'_m \left(\frac{\rho_m}{\gamma_m}\right)}{\phi'_p \left(\frac{\rho_p}{\gamma_p}\right)} \dots\dots\dots\dots (83)$$

By making the ratio, $\frac{\rho_m}{\gamma_m}$, in the model the same as the corresponding ratio in the dam (that is, the ratio of the specific gravities of the material of the structure to the loading fluid), it will become a model constant, and,

$$\frac{\delta_m}{\delta_p} = \left(\frac{l_m}{l_p}\right)^2 \frac{\gamma_m}{\gamma_p} \, \frac{E_p}{E_m} \dots\dots\dots\dots (84)$$

because,

$$\frac{\rho_m}{\gamma_m} = \frac{\rho_p}{\gamma_p} \dots\dots\dots\dots (85)$$

In the same way from Equation (67),

$$f_p = \rho_p^x \, \gamma_p^y \, E_p^z \, g^u \, l_p^v \dots\dots\dots\dots (86)$$

and since the dimension of f_p is $M \, L^{-1} \, T^{-2}$,

$$f_p = E_p \left(\frac{\gamma_p \, g \, l_p}{E_p}\right)^u \phi_{fp} \left(\frac{\rho_p}{\gamma_p}\right) \dots\dots\dots\dots (87)$$

in which, ϕ_{fp} is an unknown function.

The stresses do not depend on E_p. Consequently, $u = 1$, and,

$$f_p = \gamma_p \, g \, l_p \, \phi_{fp} \left(\frac{\rho_p}{\gamma_p}\right) \dots\dots\dots\dots (88)$$

For the model, similarly,

$$f_m = \gamma_m \, g \, l_m \, \phi_{fm} \left(\frac{\rho_m}{\gamma_m}\right) \dots\dots\dots\dots (89)$$

and,

$$\frac{f_m}{f_p} = \frac{\gamma_m}{\gamma_p}\frac{l_m}{l_p}\frac{\phi_{fm}\left(\frac{\rho_m}{\gamma_m}\right)}{\phi_{fp}\left(\frac{\rho_p}{\gamma_p}\right)} \quad \text{(90)}$$

Considering, again, $\frac{\phi_{fm}\left(\frac{\rho_m}{\gamma_m}\right)}{\phi_{fp}\left(\frac{\rho_p}{\gamma_p}\right)}$ as a model constant,

$$\frac{f_m}{f_p} = \frac{l_m}{l_p}\frac{\gamma_m}{\gamma_p} \quad \text{(91)}$$

Equations (84) and (91) give the similarity conditions of the model that can be derived from the dimensional theory.

Introducing the linear scale,

$$R = \frac{l_m}{l_p} \quad \text{(92)}$$

These equations can be written:

$$\delta_m = R^2 \frac{\gamma_m}{\gamma_p}\frac{E_p}{E_m}\delta_p \quad \text{(93)}$$

and,

$$f_m = R\frac{\gamma_m}{\gamma_p} f_p \quad \text{(94)}$$

In order to arrive at these equations the two following assumptions were made, without which the similarity conditions would be so complicated that the model would be impractical:

> (1) The materials of the prototype and model shall follow Hooke's law, which means that the modulus of elasticity, E, is constant in the prototype and in the model.
>
> (2) The ratio of the specific gravities of the material of the prototype and its loading fluid, $\frac{\rho_p}{\gamma_p}$, is equal to the same ratio of the model, $\frac{\rho_m}{\gamma_m}$.

Similarity Conditions Covering Non-Dimensional Factors.—In applying the dimensional theory the factors that have no dimension cannot be covered, and the similarity conditions for such factors have to be investigated separately.

Poisson's ratio is a non-dimensional factor and is to be investigated by a different method. This ratio influences the conditions of the dam in two ways: First, directly, by the introduction of stresses at right angles to the stress developed by the applied force; and, second, due to the dependence of the modulus of elasticity in shear on Poisson's ratio and the consequent dependence of the shear deflections on this ratio. These factors will be considered separately.

The direct influence of Poisson's ratio can be handled in the following way. Due to Poisson's ratio, μ_p, of the dam material, a stress, f_p, will produce in a restrained unit cube of the dam a stress, f'_p, at right angles to it,

$$f'_p = \mu_p f_p \qquad \text{(95)}$$

and similarly for the model,

$$f'_m = \mu_m f_m \qquad \text{(96)}$$

To retain the similarity conditions between the dam and model it is necessary that,

$$\frac{f'_p}{f'_m} = \frac{f_p}{f_m} \qquad \text{(97)}$$

and, consequently,

$$\mu_p = \mu_m \qquad \text{(98)}$$

The indirect influence of Poisson's ratio can be treated in a similar manner:

The deflection of any part of the prototype due to shear will be,

$$\delta_{sp} = \frac{1}{S_p} \int s_p \, dl_p \qquad \text{(99)}$$

in which, s_p is unit shear; and dl_p, differential distance.

Similarly, for the model,

$$\delta_{sm} = \frac{1}{S_m} \int s_m \, dl_m \qquad \text{(100)}$$

From Equations (92) and (94),

$$dl_m = R \, dl_p$$

$$s_m = R \frac{\gamma_m}{\gamma_p} s_p$$

Substituting these values in Equation (100),

$$\delta_{sm} = \frac{1}{S_m} (R)^2 \frac{\gamma_m}{\gamma_p} \int s_p \, dl_p$$

and,

$$\frac{\delta_{sm}}{\delta_{sp}} = \frac{S_p}{S_m} (R)^2 \frac{\gamma_m}{\gamma_p}$$

To retain the similarity between the model and prototype, $\frac{\delta_{sm}}{\delta_{sp}} = \frac{\delta_m}{\delta_p}$, and, from Equations (93) and (65),

$$\frac{E_p}{E_m} = \frac{S_p}{S_m} = \frac{2\,(1 + \mu_m)\, E_p}{2\,(1 + \mu_p)\, E_m}$$

and, $\mu_p = \mu_m$. This will add the condition:

(3) Poisson's ratios of the prototype and model materials are to be equal at corresponding stresses.

Similarity Conditions Derived from Geometrical Similarity.—In order to have the prototype and model similar in their geometrical shape before and after the loadings are applied, the linear deflections of the model are to be in the same linear scale as the model itself. Therefore, $\delta_m = R\,\delta_p$. Introducing this relation in Equation (93),

$$R\,\frac{\gamma_m}{\gamma_p}\,\frac{E_p}{E_m} = 1 \quad \text{.........................(101)}$$

or,

$$\frac{E_m}{E_p} = R\,\frac{\gamma_m}{\gamma_p} \quad \text{.........................(102)}$$

which introduces the additional condition:

> (4) The ratio of the moduli of elasticity of the model and prototype is to be equal to the scale of the model multiplied by the ratio of the specific gravities of the loading liquids of the model and prototype.

Similarity Conditions Covering Discontinuities.—An actual arch dam cannot be built as a continuous structure; depending on the methods by which it is built, it has a number of construction joints which may become planes of discontinuity.

The construction joints of the dam are to be represented in the model so as to maintain the similarity between the model and dam.

The dam has horizontal and vertical construction joints. The horizontal construction joints are kept uneven and rough across the block in order to insure a better bond between the successive layers of concrete and as long as the dam is not loaded no separation or opening of these joints can take place. The vertical construction joints divide the dam into separate blocks and although bonding boxes are provided, these joints are much more definite than the horizontal joints, and when the dam is not loaded they may open due to the contraction of the concrete. The horizontal construction joints can carry a limited tension that is much less than the tension that can be carried in a concrete block between the joints, but the vertical joints cannot carry any tension. In conformity with these conditions the horizontal and vertical joints of the model are to be treated differently.

The horizontal joints are construction joints only, and it can be assumed that after the dam is constructed no measurable horizontal joints are left. Even if the dam is loaded far below its destruction point, the tension stresses in some of the joints can be higher than the ultimate tension that can be carried over the joint. In this case, a rupture of such joints will take place starting at the surface and extending to some point at which the tension stress is low enough to be carried by the joint.

In indicating the ultimate unit tensile stresses that can be carried over the joints of the prototype and model by f_{jp} and f_{jm}, respectively, the requirement would be that,

$$\frac{f_{jm}}{f_{jp}} = \frac{f_m}{f_p} \quad \text{.........................(103)}$$

and from Equation (94),

$$\frac{f_{jm}}{f_{jp}} = R\,\frac{\gamma_m}{\gamma_p} \quad \text{.........................(104)}$$

which adds the additional condition:

> (5) The ratio between the ultimate unit tensile stresses that can be carried by the horizontal joints of the model and prototype is to be equal to the linear scale of the model multiplied by the ratio of the specific gravities of the loading liquids of the model and prototype.

The vertical joints of a dam can have a physical dimension and, in such case, have to be represented in the model as joints of a certain size.

Considering the vertical joints of an actual dam, the action of these joints can be represented by two steps: First, Poisson's ratio of the dam material causes a part, b'_p, of the width of joint, b_p, to be closed; and, second, the remaining part of the joint, b''_p, will increase the deflection of the arch.

Considering a block of the length, s_p,

$$b'_p = \mu_p \frac{1}{E_p} f_p \, s_p \tag{105}$$

and, similarly, for the model,

$$b'_m = \mu_m \frac{1}{E_m} f_m \, s_m \tag{106}$$

and,

$$b'_m = \frac{\mu_m}{\mu_p} \frac{E_p}{E_m} \frac{f_m}{f_p} R \, b'_p \tag{107}$$

Substituting Equation (94),

$$b'_m = R^2 \frac{E_p}{E_m} \frac{\gamma_m}{\gamma_p} \frac{\mu_m}{\mu_p} b'_p \tag{108}$$

If the action of the remaining part of the joint is to be represented in the model so as to result in deflections of the model that are of the same scale as the deflections due to elastic deformations, then, from Equation (93),

$$b''_m = R^2 \frac{E_p}{E_m} \frac{\gamma_m}{\gamma_p} b''_p \tag{109}$$

and, since $b'_m + b''_m = b_m$,

$$b_m = R^2 \frac{E_p}{E_m} \frac{\gamma_m}{\gamma_p} \left[b''_p + \frac{\mu_m}{\mu_p} b'_p \right] \tag{110}$$

Remembering Equation (98),

$$\frac{b_m}{b_p} = R^2 \frac{E_p}{E_m} \frac{\gamma_m}{\gamma_p} \tag{111}$$

which adds the additional condition:

> (6) The ratio of the width of the vertical construction joints in the model and prototype is to be equal to the square of the scale of the model multiplied by the ratio of the specific gravities of the loading liquids and by the inverse ratio of the moduli of elasticity of the model and prototype.

Similarity Conditions Covering Foundations and Abutments.—The elastic deformations of an arch dam are by no means limited to the dam itself, but are carried through the foundations and abutments. The previously developed formulas and statements concerning the dimensional theory, non-dimensional factors, and geometrical shape can also be applied to the foundation and abutments. It is obvious, however, that the size of the elastic foundations that are practically infinitely large as compared with the size of the dam cannot be represented in a practical model, and some compromise must be made in the very beginning if the model is to be feasible.

The theoretical investigation of foundation deflections made by Fredrik Vogt, Assoc. M. Am. Soc. C. E., entitled "Ueber die Berechnung der Fundamentdeformation", disclosed the fact that the action of the infinitely large elastic rock foundation can be closely represented by an imaginary block of definite dimensions, made of elastic material and rested on a fixed non-elastic and non-yielding base.

The dimensions of such a foundation block and its elastic properties depend on the elastic properties of the foundation rock. The investigations available in this respect are very meager as far as the elastic properties of the ground rock and the relationship between these properties and the sizes and elastic properties of the imaginary foundation block are concerned. It can be stated in general terms that the following condition should be added:

> (7) The action of the infinitely large foundation rock may be represented by a block of elastic material of some definite dimensions, which has a fairly low modulus of elasticity so that by supporting it on a base of a material of a high modulus of elasticity, the conditions of an elastic foundation block supported on an unyielding non-elastic base can be represented.

Similarity Conditions Covering Influence of Temperature Changes.—In the study of the stresses and deflections of the model due to different temperatures the following simple relationships are obvious:

$$c_p \, T_p = c_m \, T_m \qquad (112)$$

and,

$$T_m = \frac{c_p}{c_m} \, T_p \qquad (113)$$

in which, c_p and c_m are the coefficients of thermal expansion of the prototype and model; T_p is the difference in temperature of the material of the dam between the time the dam was built and the time under consideration; and T_m, the corresponding temperature difference of the model.

The only theoretical complication that would enter is, that consideration should be given not only to the coefficients of thermal expansion of the materials of the prototype and models, but also to the materials of the actual foundation and the imaginary foundation block; but that is a practical impossibility, and being of no importance, is to be neglected. The additional condition to be included can be formulated, as follows:

> (8) The ratio of the temperature differences of the model material, between the time of testing and building of the model, and of the temperature difference of the material of the prototype, between the time for which the investigations are made and the time of the building of the prototype, should be equal to the ratio of the coefficients of thermal

expansion of the materials of the model and the prototype, provided that these coefficients are sufficiently uniform to be assumed as constant.

Type of Model.—These similarity conditions are general, and any model of an arch dam that is to be used to study the stresses and deflections should satisfy them.

An attempt to build a model covered by this set of similarity conditions will meet with many obstacles, and in order to build one with a reasonable expenditure of time and money a number of additional compromises are necessary. These must be determined, analyzing separately each of the similarity conditions as applied to a particular problem to be investigated.

The dam described in this discussion is the Calderwood Arch Dam on the Little Tennessee River, which is about 200 ft. high and about 800 ft. long at the crest. Two different kinds of models were considered: First, one in which, at a number of points, the deflections of the down-stream surface and the strains at the down-stream and up-stream surfaces of the model could be measured directly; and, second, a model in which some information could be obtained about the distribution of stresses through the thickness of the model.

The first type would represent a model along the more conventional lines; the second could be obtained by the use of a modification of the photo-elastic method of stress determination. The second model would look very attractive if practical results could be obtained, having the following advantages:

(*a*) Determinations of stress through the thickness of the model as against the determination at the up-stream and down-stream surfaces of the model only.

(*b*) The possibility of the use of a smaller model and, consequently, a possible saving in cost.

The disadvantages of such a model can be summarized as follows:

(*c*) This method has not been used on three-dimensional models. The possibilities are that it would require considerable time to make the improvements or modifications that would be necessary in order to adapt the method to the conditions of an arch dam model.

(*d*) The usual transparent materials used in this method have a high modulus of elasticity and the proper reproduction in small scale of the details of the prototype would be difficult.

(*e*) Considerable time would be necessary to determine by test and trial the material that would be suitable for such a model.

Considering the uncertain features of the photo-elastic method, it was decided to build a model of the Calderwood Dam according to the first method, and the following discussion is based on this decision.

Loading Liquid.—One of the most important points, which governs all other conditions, to a considerable degree, is the choice of the loading liquid.

Condition (2) requires that the ratio of the specific gravities of the loading fluids of the model and prototype shall be equal to that of the materials of the model and prototype. This requirement is fundamental, because if it is neglected, the relationship between the arch and gravity action of the model will be distorted and the study of the behavior of the dam will be made difficult and uncertain due to the necessity of correcting the results to take care of a number of secondary influences that will be introduced. From the practical point of view, the choice of the loading liquid of the model is rather limited. Either the same liquid must be used as in the prototype (which is water, the specific gravity of which is equal to 1), or the next reasonable possibility would be the use of mercury which has the specific gravity of 13.6.

Using water, the specific gravity of the material of the model should be about 2.4, the same as for concrete, the material of which the dam is constructed. Using mercury, the specific gravity of the material of the model will be 2.4 × 13.6 = 32.84. That would practically exclude the use of mercury, because no known material has such a high specific gravity, and the only way to approximate these conditions would be by the use of some artificial method of loading the model with additional loads or springs.

The choosing of water as the loading liquid will determine the specific gravity of the material of the model equal to about 2.4 and will simplify the similarity conditions considerably since $\frac{\gamma_m}{\gamma_p} = 1$, and Equations (93), (94), (102), (104), and (111) can be written:

$$\delta_m = R^2 \frac{E_p}{E_m} \delta_p \qquad (114)$$

$$f_m = R f_p \qquad (115)$$

$$E_m = R E_p \qquad (116)$$

$$f_{jm} = R f_{jp} \qquad (117)$$

and,

$$b_m = R^2 \frac{E_p}{E_m} b_p \qquad (118)$$

Scale of Model.—The choice of the scale of the model is entirely arbitrary from the theoretical point of view; but of course it is very much limited by practical considerations. The amount of material in the model, and probably the cost of it, is proportional to the cube of the scale and the area that is covered by the model. Probably also the time necessary to make the tests is proportional to the square of the scale. That would mean that the scale of the model must be chosen as small as possible in order to reduce the cost and time and increase the convenience of the use of the model.

On the other hand, the stresses are proportional to the scale and the deflections to the square of the scale so that the larger models will give better results as far as observations are concerned. Furthermore, if the model is to be a true representation of the prototype the horizontal, and particularly the vertical, construction joints must be represented and that can be done satisfactorily only if the scale of the model is large enough. For the model of the Calderwood Dam it was decided that the smallest scale that could be used was 1:50, and the following considerations are based on a model of such scale.

Modulus of Elasticity of Model Material.—Assuming the modulus of elasticity of the concrete used in the prototype as 3 800 000 lb. per sq. in., from Equation (116), $E_m = \frac{3\,800\,000}{50} = 76\,000$ lb. per sq. in.

Assuming that the maximum deflection of the prototype under consideration will be about 0.5 in., the maximum deflection of the model from Equation (114) will be $\delta_m = \frac{0.5}{50} = 0.01$ in.

The proper observation of the behavior of the model under load will include not only the measurements of the maximum deflections, but the series of measurements at a considerable number of points ranging from $\delta_m = 0$ to $\delta_m = 0.01$ in.

From a practical point of view the deflections that are to be measured at the many points must be kept reasonably large so that the measurements can be made with simple instruments and without the use of complicated and involved measuring devices.

Besides the possibility of measuring the deflections with a sufficient degree of accuracy, the following important point should be stressed: If the model is made of an elastic material and the deflections are relatively large, the secondary influences, such as uncontrollable changes of temperature, inaccuracies in the size of construction joints, displacements of the abutments, etc., have only a small influence on the total deflection, and can be partly accounted for and partly neglected. For stiffer models these secondary influences become more important, and the value of deflection measurements decreases rapidly due to secondary influences as well as to the decreasing degree of accuracy of the measurements.

The requirements of retaining the similarity of the geometrical shape of the dam and model before and after the load is applied, are theoretically correct, but, practically, a considerable increase in the deflections can take place before it could influence the results to a noticeable extent. From these considerations it was deemed advisable to use a material for the model with a much lower modulus of elasticity than that which is required theoretically.

Poisson's Ratio of Model Material.—Poisson's ratio for the concrete used in the prototype is about 0.20 and that for the material of the model should be the same.

If the material of the model has a different Poisson's ratio, then the results of the tests will be influenced in two ways: First, the direct influence that results in redistribution of stresses; and, second, the indirect influence that will manifest itself in a different value of the modulus of elasticity in shear and, consequently, disturb the behavior of the model as far as the shearing deformations and the part of the stresses due to such deformations are concerned.

The direct influence of Poisson's ratio can be taken care of in the model by a proper variation of the size of the vertical construction joints.

An arch dam as well as the model is restrained in the horizontal direction along the axes of the arches, is only partly restrained in the vertical direction due to the weight of the structure that rests on it, and has practically no restraint in the horizontal directions at the up-stream and down-stream faces of the dam. Consequently, Poisson's ratio can influence the stresses and deflections in the horizontal direction along the axes of the horizontal arches, but it is of no concern in the horizontal direction between the faces and in the vertical direction.

In the horizontal direction the influence of Poisson's ratio will be felt, due to the loads that are applied in the vertical direction and the direct water pressure at the up-stream face of the dam.

Selection of Model Material.—The known arch dam models of the past were built as follows: (*a*) Concrete loaded with mercury; (*b*) celluloid loaded with mercury; and (*c*) rubber loaded with water. None of these meets the similarity conditions with any degree of satisfaction.

The most important discrepancies are the improper ratio of the specific gravities of the loading liquid to the model material and the fact that all these models were built as continuous structures, which could carry considerable tension in all directions.

In selecting the material the first consideration is naturally given to the possibility of making the model out of concrete, the same as the prototype.

Concrete models loaded with water, however, will show very small and uncertain deflections. In order to increase the deflections in the models built in the past, mercury was substituted for water as the loading liquid. This increased the deflections manifold, but at the same time violated an important similarity condition concerning the ratio of the specific gravities of the loading liquid and the material of the model.

The celluloid models loaded with mercury and the rubber models loaded with water have the same drawback. The relationship between the arch and gravity action of the dam is greatly distorted and, consequently, from studies made on such models no proper conclusions can be derived as to the behavior and shape of the dam.

These considerations eliminated the use of concrete, celluloid, or plain rubber as a model material, and a search for a more suitable material was necessary.

For the chosen scale of the model (1:50), and by assuming the maximum range of possible stresses in the prototype to be from 300 lb. per sq. in. tension to 1 000 lb. per sq. in. compression, the corresponding range of stresses in the model material is from 6 lb. per sq. in. tension to 20 lb. per sq. in. compression. In general, this represents a very narrow range of stresses for most of the materials that could be considered.

Besides the requirements that are directly covered by the similarity conditions the material to be selected must satisfy a number of requirements that follow from the similarity conditions indirectly, and that have to be met within the range of stresses in the model.

These are the requirements that characterize the elastic and plastic properties of the model material. The condition of a constant modulus of elasticity must be extended to cover a uniform modulus of elasticity in all directions, which would preclude the use of materials with pronounced directional properties.

On the other hand, the constant modulus of elasticity will preclude materials with pronounced plastic properties that are characterized by a slow recovery or a high permanent set, and materials that have any considerable skin or internal stresses.

The necessary practical consideration will be to have the material such that it could be brought to the many required irregular shapes without prohibitive expenditure of time and money.

The specifications for the required material based on all previous considerations and in the stress range of the model are summarized in the order of their importance, as follows:

(1) Specific gravity of 2.4.
(2) Uniform elastic properties without any pronounced directional qualities.
(3) Absence of skin or internal stresses.
(4) Low modulus of elasticity.
(5) Reasonably uniform values of the modulus of elasticity at various unit stresses.
(6) Low permanent set.
(7) Low plastic properties.
(8) Properties that will permit the material to be easily furnished in the required irregular shapes.
(9) Poisson's ratio close to 0.20.
(10) Uniform coefficient of thermal expansion.

No material is commercially available or even known that would meet this list of specifications in its entirety, so that the problem resolved itself into the development of a material of the desired qualities. Although the work done to date (1930) in developing such material seems to be rather promising, it showed clearly that considerable additional time must be spent before the ideal material can be found, particularly if the low value of Poisson's ratio is to be maintained.

The practical compromise that was decided on was to drop this requirement and to develop a material that meets the more important demands reasonably close, leaving to the future the development of a material that meets all the specifications. This decision will probably make necessary some corrections in the results of the model test.

A preliminary search disclosed the fact that the combination of the two requirements—specific gravity of 2.4 and low modulus of elasticity—precludes a range of well-known and commercially used materials, most of which have low specific gravities at low moduli of elasticity.

The search made of different, less known materials having cellulose, cellulose acetate, etc., bases, showed that they all have a specific gravity much lower than 2.4 and that the new materials that could be obtained by loading the known materials to the desired specific gravities were unacceptable on account of the high modulus of elasticity and uncertain elastic properties.

Rubber compounds showed the best promise and an extensive co-operative research was made in this field. The main difficulty in this research was that all the customary rubber tests are made at high tensile stresses which approach the ultimate, and very little is known about the general behavior of rubber compositions at low stresses.

Practically nothing is known about the behavior of highly loaded rubber compounds of high specific gravity at low compressive stresses. This research can be summed up briefly as follows:

(*a*) A large number of rubber compounds of the desired specific gravity of 2.4 can be made by using the commercially available fillers.

(*b*) As a general rule, these heavily loaded rubber compounds are unstable and show uncertain elastic and highly developed directional properties at low compressive stresses.

(*c*) The values of Poisson's ratios of different compounds can be varied in rather wide limits; but the tests made, thus far, developed unsteady compounds with directional properties for low values of Poisson's ratio. The customary manufacturing processes seemingly do not give the refinement in control that is necessary in order to obtain material of the same quality by repeated fabrication of compounds of the same composition and manufacturing procedure.

(*d*) From the different compounds it was possible to pick some that, as long as the high values of Poisson's ratio were accepted, have steady and fairly uniform non-directional elastic properties and a low modulus of elasticity, which properties could be satisfactorily repeated.

(*e*) The attempt to find a material that would meet these requirements, having at the same time a low Poisson's ratio led to the conclusion that such material is possible and feasible, but that a considerable amount of research would be required, that would include not only the composition but the manufacturing procedure as well.

Adopting the research made as a basis, it was decided to use for the model a litharge rubber compound of the required specific gravity of 2.4, with a low modulus of elasticity of about 500 lb. per sq. in., and with a high Poisson's ratio approaching 0.5. This compound has uniform and stable elastic properties, and it is only slightly influenced by aging or repeated loading, showing very small differences at a time interval of about six months and at repeated loadings that ran as high as 5 000 lb. per sq. in. hydraulic pressure.

The fabrication of this material can be repeated infinitely, insuring the possibility of manufacturing any desired quantities similar to the original samples; it can be cemented together easily, or cut on a band-saw, insuring the possibility of making blocks of any desired shape and size.

Tension in Horizontal Joints.—In accordance with Equation (116) the ratio of the ultimate unit tension that can be carried over the horizontal joints of the model and prototype must be equal to the scale of the model. A number of difficulties will be encountered in an attempt to fulfill this condition: First, the value of the ultimate unit tension that can be carried over the horizontal joint of the dam is uncertain; and, second, it is rather difficult to provide a joint in the model that would be ruptured at a low tensile stress with any degree of accuracy. The compromise that was reached was to decrease the number of horizontal joints, placing them on the model corresponding to larger lifts than those that were actually used in the prototype.

Foundations of Model.—The proper representation of the foundation conditions of a model is uncertain, due to the fact that practically no information concerning this subject is available.

The practical compromise that was decided upon, was to make the foundations of the model of the same material as the model of the dam, in blocks of arbitrarily chosen sizes, but with provisions that will make it possible to change them, substituting blocks of different size. At the same time the foundation blocks were partly restrained in the horizontal direction by means of rubber struts, which could again be made of different size and located at different heights. The lower part of Fig. 1 shows this arrangement.

The expectations are that the proper conclusions can be obtained by repeating the tests with foundations of different sizes and with different amounts of restraint. Furthermore, a study of the influence of the elastic deformations of the rock on the behavior of the dam will be made possible.

General Arrangement and Plan of Model.—The model is to be an exact representation of the actual dam constructed to a scale of 1:50, of rubber compound, inside a concrete tank as shown on Fig. 1.

FIG. 1.

Not only will the arch proper find its representation in the model, but the same rubber compound will be used to represent a reasonable part of the abutments and foundations of the actual dam.

The model will be built of separate blocks that are the exact replicas of the concrete blocks of the dam between its vertical joints, but of greater heights than the lifts or distances between the horizontal joints of the actual dam. The necessary modifications in the size of the vertical joints are to be made.

Water is to be used as the loading liquid and deflection and strain measurements are to be made at different points of the dam and are to be repeated for different conditions of foundation deflections.

As far as similarity is concerned, the study of this model can be made by considering the following conditions (see Conditions (1) to (8), previously defined):

(*a*) Condition (1) is assumed to be satisfied.
(*b*) Conditions (2), (7), and (8) are actually satisfied.
(*c*) Conditions (5) and (6) are partly satisfied; and
(*d*) Conditions (3) and (4) are not satisfied.

Conditions Assumed to Be Satisfied.—Condition (1), concerns the assumed constancy of the moduli of elasticity of the dam and model materials.

Conditions Actually Satisfied.—Condition (2) concerning the ratio of the specific gravities of the loading liquids and the material of the dam and model, is in this class.

Two other factors in this class are: Condition (7) concerning the representation of the foundations; and Condition (8) concerning the ratio of temperature differences, in model and prototype, between the time of building and the time of observation.

Conditions Partly Satisfied.—Condition (5) concerning the ratio of the ultimate unit tensions in the horizontal joints of the dam and model is partly taken care of by increasing the size of the horizontal lifts in the model, as compared with the prototype. The expectation is that no corrections will be necessary in the results of the tests on account of this discrepancy.

Condition (6) concerns the size of the vertical construction joints. Some corrections may be required in the results of the tests to take care of the discrepancy, due to the difference in Poisson's ratios.

Conditions Not Satisfied.—Condition (3) concerns the equal values of Poisson's ratio for the materials of the model and dam. Some corrections may be necessary in the results of the tests, and an attempt will be made to take care of part of the discrepancy by a proper dimensioning of the vertical construction joints.

Condition (4) concerning the ratio of the moduli of elasticity of the material of the model and prototype, is necessary to retain the geometrical similarity of the shape of the models and the prototype before and after the load is applied. The expectations are that the difference in observations due to this discrepancy will be so small that it can be neglected.

Acknowledgments.—This work is a part of the arch dam investigation that is being conducted by the Aluminum Company of America at the request of Edwin S. Fickes, M. Am. Soc. C. E., under the direction of James W. Rickey, M. Am. Soc. C. E., and Mr. J. P. Growdon. The research work in rubber compounds in the Research Laboratory of the Goodyear Tire and Rubber Company was made under the direction of Dr. L. B. Sebrell by Messrs. R. D. Evans and M. J. DeFrance. The Aluminum Research Laboratories of the Aluminum Company of America are assisting in the investigation and, under the direction of R. L. Templin, M. Am. Soc. C. E., R. G. Sturm, Assoc. M. Am. Soc. C. E., and Mr. R. L. Moore, tested the physical properties of the rubber compounds. Messrs. J. P. Den Hartog and J. G. Baker, of the Research Laboratory of the Westinghouse Electric and Manufacturing Company, assisted in formulating the similarity conditions based on the application of the dimensional theory.

JASPER O. DRAFFIN,[40] M. AM. SOC. C. E. (by letter).—Although the writer cannot add anything to the content of this paper, he wishes to express a feeling of satisfaction that this type of study is receiving attention. To examine the validity of assumptions concerning the principles underlying the use of models is very valuable, because so much hydraulic practice is based upon information obtained from models. More work of this character is needed and the author is to be congratulated for what he has done.

It is impossible to read the accounts[41] of the work done in European laboratories without being impressed by the large amount of space devoted to discussions of models. It is also of interest to note the increasing importance attached to the theory of models.

Undoubtedly, the study of river flow and control in the United States has lagged behind that of Europe, but this condition is changing. The 1927 floods in New England and in the Mississippi River Valley, added to the Ohio floods of two decades ago, have emphasized the growing importance of flood-control works and have resulted in a public demand for relief from such disasters. This demand has brought responsible opinion to the point of studying flood flow and control by means of models, as evidenced by the establishment of the National Hydraulic Laboratory for the study of these problems.

There are still, however, many people who doubt the possibility of predicting the action of a great river in flood flow by experiments on a small model of that river. If the confidence of the people in the ability of the engineer to solve such gigantic problems is to be retained, all the available theory must be brought to bear upon the design of the models which determine how such great works are to be constructed.

It may not be amiss to call attention to the fact that the early experiments with models were made in a somewhat crude fashion and that the methods have gradually improved. From the early work of Dubuat to that of Reynolds, of Vernon-Harcourt, and, more recently, the work of Mr. Groat, is a long step, and great progress has been made in the use of the model as well as a clearer understanding of the significance of the various elements involved in its design and use. Considering the great variety of engineering structures which are built after or tested by models, such as bridges, dams, machinery, ships, and airplanes, as well as structures involving the flow of water, it is desirable that there should be considerable diffusion of knowledge about the necessity of careful design of models and the methods by which it may be achieved. Some experimenters seem unaware of the limitations of their experiments. It is well that the elements of viscosity, temperature, and surface tension should be given prominence by the author since, as Mr. A. C. Chick points out,[42] these factors may be important under small heads or with small openings.

ED S. SMITH, JR.,[43] ESQ. (by letter).—The author's paper attacks the present usage of models and unjustifiably urges that the broad generalization of Newton be used for all cases of fluid flow. This viewpoint seems to be a mistaken one since the correct and adequate basis for flow similarity in pipes is the Reynolds number and not that of Newton. The writer's experience with quantity-rate fluid meters shows Mr. Groat's theory to lead to an incorrect basis for flow similarity for pipes and confirms the present usage, based on the Reynolds number, which permits accuracies of within one-fourth of 1% to be realized with Venturi meters when metering one fluid-using datum obtained with another fluid, for example.

Excellent use has been made by Mr. Groat of Newton's basis for flow similarity in its proper field—open channel flow and the fluid transportation of sand and gravel (non-fixed shape and non-homogeneous fluid)—but the writer maintains that Newton's basis (with g as the acceleration of gravity, as used by Mr. Groat) simply does not apply to the ordinary case of the steady flow of homogeneous fluids in closed conduits of fixed shape, and that consequently Newton's basis is absolutely not generally applicable; it must be used only in its proper field. For the case mentioned it can only enter in so far as it may be considered in the internal acceleration of the fluid which is taken care of fully in the derivation of the Reynolds number from the balance of inertia and viscous forces within the fluid. Thus, the Reynolds number is the basis upon which data are correlated for this case in which whatever accelerations are involved are certainly not due to gravitation.

Newton's law of similarity (Equation (1)) applies primarily to liquids with free surfaces, as Froude brought out for the wave-making resistance of ships, or the flow of liquids in open channels where the effect of the surface enters—including the case of weirs and Venturi flumes.

For steady flow in a closed conduit of fixed shape, including Venturi tubes and orifices, the Reynolds number is the adequate and correct basis for flow similarity and the correlation of data, as established beyond question by innumerable experiments. This criterion also holds for airplanes, dirigibles, submarines, and for air and water propellers, with an additional term to take care of the various slip ratios.

Fortunately, it is possible to subject fluid flow phenomena to an independent analysis which definitely establishes the variables and operators involved so that one may test the fitness of a generality, such as Newton's expression, to the case of fluid flow through a closed conduit of fixed shape. For this case the Reynolds number is found to be pertinent. In Fig. 2, the flow, Q, through a closed conduit is divided into two streams. One stream flows through a long capillary tube, M, in which the resistance to flow is due to viscous forces, and the other flows through a nozzle, N, or orifice, in which the resistance to flow is due to the inertia of the fluid.

In another paper[44] the writer has demonstrated that, from the known laws of flow, the ratio of flows (that is, "flow similarity") and the coefficient for the example given, depend only on the Reynolds number and not upon Froude's ratio (Newton's law involving the acceleration of gravity), as specified by Mr. Groat. Consequently, for closed conduits, gravity is shown to have no effect on the flow distribution. A familiar proof of this is that the direction of the axis of flow in a nozzle with respect to the vertical has no effect upon the performance of the nozzle. The Reynolds number is adequate and proper for use in the example cited herein and does not require the assistance of Newton's ratio for correlating data. The writer would appreciate Mr. Groat's confirmation, as an authority, that this is correct or, if he should fail to agree, then to demonstrate a solution of this problem in his closing discussion.

[44] "Quantity-Rate Fluid Meters," by Ed. S. Smith, Jr., *Transactions*, Am. Soc. Mech. Engrs., Paper HYD-52-7*b* (Fig. 6).

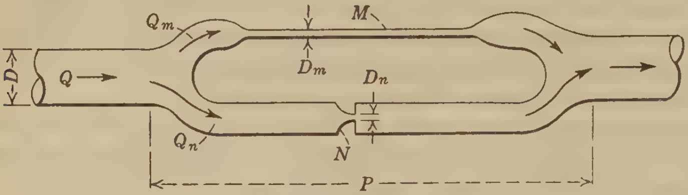

FIG. 2.

The method of similarity is a most valuable one in the field of fluid flow, but it must not be used blindly. In every case, the engineer must consider carefully which of the various physical quantities and phenomena is involved, and then select the proper dimensionless ratio as the basis for similarity. In the case of fluid flow in closed conduits this is the Reynolds number; for open channels subject to wave action it is Froude's ratio (Newton's ratio, using g as the acceleration of gravity); while, for expansible fluids, it is the acoustic velocity ratio. For example, in the case of airplane propellers (of which Mr. Groat treats in Appendix I) the tips frequently approach the velocity of sound and a correction for the compressibility of air is certainly required. The writer has proposed the use of the acoustic ratio, $\frac{x}{k}$, in which, x is the ratio of differential to absolute pressure and k is the ratio of specific heats, for fluid flow through quantity-rate meters. This acoustic ratio, $\frac{x}{k}$, may readily be modified so as to be applicable to the air-propeller problem when testing with another gas than air; this may prove to be more convenient in actual use than the acoustic velocity ratio.[45]

Mr. Groat's treatment of the case of air propellers (which does not involve Newton's, or Froude's, ratio) is inadequate and incorrect. It emphasizes the point that the various engineering fields require engineers actively engaged therein to be familiar with the use of the method of similarity so that they can make effective use of it. This is preferable to having "similarity engineers" attempting to use the method in fields with which they are unfamiliar.

---

[45] See "Similarity and Model Experiments," by A. H. Gibson, *Engineering*, March 21, 1924, p. 358, for correct "air screw" theory.

While the method of similarity has been highly useful in the field of fluid flow, this has been so largely because the pertinent variables have been sufficiently simple (density and viscosity) to be easily susceptible to attack by the method of dimensional analysis.

However, for structural similarity, the dimensional method may easily require considerable assistance before the results will be most useful, since hardness, toughness, resistance to shear, tearing, and plastic deformation seem scarcely to have been defined adequately in a dimensionally sound way. Furthermore, these bring in the factor of direction so that the problem introduces vector quantities which may or may not be covered by dimensional analysis in determining the proper basis for similarity—along this line is the familiar fact that work and torque have the same dimensional units: $F \times L$.

Complete use also must be made of established methods of detailed analysis wherever possible for checking the application of this general method of similarity to structures, or any new field. Otherwise, it will suffer temporary loss of confidence and, therefore, usefulness, due to improper use without adequate physical understanding. Wonderfully useful as this method is, it does not enable one to obtain something for nothing, being in fact a convenient basis on which to correlate data for most effective use.

The conclusions from the foregoing comments are:

1.—The present usage of models for flow in pipes, based on the Reynolds number without the encumbrance of Newton's ratio (actually Froude's), is entirely consistent with sound theory, being unquestionably established by a great mass of accurate data.

2.—For this case of flow in pipes, it is not necessary to synthesize fluids (to meet the joint requirements of the Reynolds number and Newton's ratio, since the latter does not apply).

3.—It is necessary to follow the specific dimensionless ratio which is pertinent to any given case, rather than to attempt to use a too broad (and, hence, generally incorrect) generalization, such as Newton's ratio, for all cases. It is a step backward to apply a universal cure-all to cases in which it obviously does not work.

These conclusions are completely in opposition to those of Mr. Groat.

Dr. Ing. F. J. Eisner[46] (by letter).—The writer agrees with the author in attributing to Newton the enunciation of the fundamental relation for comparability of forces, but it is not correct[47] to read into Newton's conception the so-called "law of corresponding velocities," as it is understood to-day, resulting from the special action of gravity on the surface of the earth. This law of corresponding velocities is a special form of Newton's fundamental relation and should be ascribed justly to Reech, Froude, and Helmholtz.

According to Newton's general statement, the basic relation between corresponding forces in similar systems holds rigidly for all kinds of forces;

---

[46] Head, Dept. of Applied Mathematics, Prussian Experiment Inst. for Hydr. Eng. and Shipbuilding, Berlin, Germany.

[47] See W. Herrmann, *Zeitschrift* d. Vereines Deutscher Ingenieure, 1931, pp. 611-616.

but, except for certain cases to be mentioned subsequently, this general statement does not in itself constitute a "law of transference" applicable to models of a definite linear scale-ratio to the prototype. A true "law of transference" stipulates that by choosing only this linear scale-ratio and the model media all transference rules are definitely and strictly determined solely by this single ratio, as are likewise all particular conditions for fulfilling the requirement of force-similarity under the free action of the forces actually produced by the physical properties of the chosen media and by the imposed movements.

These physical properties other than density are not taken into account in Newton's general statement. That statement is one of the most ingenious in mechanical science, but with present-day requirements for real and practical similarity, it is too general; since, in the most universal manner possible, it states only the fact that forces acting upon masses produce accelerations. Hence, the only physical property it involves is density, or mass distribution, $\rho = \frac{w}{g}$, which is always constant and independent of location in space since the specific weight, w, varies directly as the acceleration, g. To eliminate all ambiguity the author's notation for acceleration should be supplemented by differentiating between accelerations in general due to forces of any kind acting on masses and the acceleration due to gravity on the earth's surface. For the purposes of this discussion, the former will be designated by b and the latter by the particular value, g. Then Equation (1), which expresses Newton's general relation for comparability should read:

$$b = \frac{V^2}{D} \quad \text{(119)}$$

This modification must be applied to all the author's deductions and discussions which deal with Newton's relation as distinguished from the Froude-Helmholtz law.

Newton's statement considers all forces without regard to their physical origin, and takes into consideration only the density or mass distribution, ρ. If only pure mass forces, or those of the type, $F \propto \rho L^2 V^2$, are acting. Newton's requirement suffices for the establishment of a similarity law. In all other cases, true laws of similarity are deducible only when the special types of forces (other than density) produced by the special physical properties of the media are also taken into account. Then each particular property creates a new law of transference from model to prototype.

A true law of similarity expresses a definite relation between the three basic unit ratios, L, F, and T. If one of these is arbitrarily chosen (usually the length, or the linear-scale ratio, L), the other two are then fixed by the selected ratio (usually the scale ratio), together with the governing force-producing physical property (other than density) of the media in the model and prototype. In the particular case under consideration this property governs the phenomena and, therefore, pertains to this special similarity law. If, as in the case of Newton's general statement, the influence of the physical properties (other than density) is not considered, then, mathematically, F, L, and T may each be selected arbitrarily. In that event there is no true "law of similarity" and no certain practical possibility of producing model phenomena in reliable agreement with the prototype phenomena because every force (other than mass forces) which the experimenter brings into action on the model, must be caused by some physical property of the model media. This is the real reason why the author's Equations (11), (12), and (20), which when modified by the writer's notation become,

$$L = R \quad \ldots\ldots (11)$$

$$\frac{V^2}{L} = \frac{L}{T^2} = \frac{B}{b} \quad \ldots\ldots (120)$$

$$f_1(L, F, T) = \theta'(P') = \theta'(\rho) \quad \ldots\ldots (121)$$

and,

$$\frac{F\,T^2}{L^4} = \rho \quad \ldots\ldots (61)$$

are insufficient to establish a true model law. This is the fundamental reason also, why Newton's requirement should be regarded solely as a general statement and not as a law of similarity in any special sense (excepting, always, cases in which mass forces or those proportional to $\rho\, L^2\, V^2$ act alone). This word "solely" is to be regarded as a limitation only as applied to practical model construction and interpretation of model results. Of course, the most important and the most brilliant accomplishment was the original conception of the general law (which includes all subsequent particularizations); but the immediate practical application of such a law is often impossible or unknown until particularization has been made. The great difficulty of performing such particularization and the fact that each particular law was developed by a different investigator so many generations after Newton first enunicated the general statement are shown clearly by the history of the science of similarity.

Equation (11) denotes geometric similarity; Equations (120) and (121) together denote general dynamic and kinematic similarity. Full mechanical similarity is ensured only if in a geometrically similar model similar paths are described in corresponding times (requirement for kinematic similarity) through the free action of the natural forces produced by the physical properties (special dynamic similarity). One or the other of Equations (120) and (121) may be replaced by an equation denoting similarity of "corresponding" times. In any event there are three independent equations in L, F, and T, the solutions of which give values of the three basic unit ratios, which are not expressible in terms of any single one of them as is necessary for the expression of a true law of similarity.

Such a law cannot be obtained until a fourth relation, Equation (21), involving some physical property other than density, is introduced. Each physical property, such as viscosity, elasticity, kinematic specific weight (that is, the effect of the earth's attraction), capillarity, etc., requires a particular form of Equation (21) resulting in a particular solution; that is, expressing a particular relation between L, F, and T, making possible the expression of any two of these unit ratios in terms of the third.

In order to obtain the clearest and most precise statements possible of the conditions for a mechanical law of similarity the physical properties (other than density) should be introduced solely in their kinematic form thus: $\nu = \frac{\mu}{\rho}$, kinematic viscosity; $g = \frac{w}{\rho}$, kinematic specific weight or earth gravitation; $\varepsilon = {}^{E}$, kinematic modulus of elasticity, etc. The introduction of density according to Newton's general statement assumes in advance the requirement of general dynamic similarity. This is a new and a very important point of view.

The fact that each physical property results in a different relation between *L, F,* and *T* has an important consequence. If, as is usual, two or more physical properties other than density enter simultaneously into a problem, either the results obtained are entirely irreconcilable throughout (that is, the only possible model is the prototype itself), because the choice of model media is so limited in most cases that it is practically impossible to obtain a reasonable model-scale ratio, or the establishment of perfect similarity is not possible. This vital condition limiting the possibility of similarity has been designated by the writer in his lectures at the Technical University of Berlin as "Zusammenwirkungsgrenze" (literally: "together-working limit").

In the entire field of practical model science there are many other limitations. In the special field of laboratory practice for the solution of practical hydraulic engineering problems seven limits are recognized by the writer. The characteristics of these seven limits; the means of overcoming them whenever it may be possible; the cases of "incomplete" and "empiric" similarity; the cases of a predominating physical property; the very important question of obtainable accuracy and its influence on the scale ratio; and other aspects of the problem are all discussed in the writer's contribution to the "Handbuch der Experimentalphysik." [48] An abstract and some new viewpoints are to be found in the "Handbuch der Physikalischen und Technischen Mechanik".[49] There is also a brief sketch in the "Physikalisches Handwörterbuch".[50]

As emphasized in the foregoing remarks, Newton's general requirement embraces similarity in general without specific reference to particular physical properties, except density. The elaboration and extension of the general statement to specific physical properties and the resultant possibility of model construction (that is, of bringing into action on a model the actual forces due to the properties of the model media) must be credited to later investigators. An excellent summary of all these laws covering not only mechanics, but the entire field of physical science, is given by Weber[51] in two well-known papers read before the Schiffbautechnische Gesellschaft in 1919 and 1929, the first of which is referred to by the author. The second paper is more comprehensive in every respect. The present discussion covers very briefly only the following four laws of similarity, with which the practical hydraulic engineer is chiefly concerned. (1) Law of Gravitational Similarity; (2) Law of Viscous Similarity; (3) Law of Elastic Similarity; and (4) Law of Capillary Similarity.

(1).—Law of Gravitational Similarity.—This law, or to use its less exact name, the law of "corresponding velocities," was first enunciated by Reech in 1852, and independently by Froude in 1869, in the course of his famous ship-model experiments. It was also independently discoverd during the theoretical and practical investigations of Helmholtz in 1873 on the formation of waves at the surface of contact between two fluids of different densities (particularly for cloud formation in meteorology).

(2).—Law of Viscous Similarity.—The author ascribes this law to Stokes. It is true that Stokes considered forces caused by the action of fluid viscosity, but the mathematical enunciation of this action had already been accomplished by Newton. It is also true that Stokes worked with problems of similarity, involving the action of viscosity, but he did not carry his analysis through to the enunciation of a special law of viscous similarity. If the development of a correct expression for viscous tension were the determining factor, the author might with more justification ascribe the viscous law to Newton rather than to Stokes. As a matter of fact, neither Newton nor Stokes succeeded in establishing such a law. That accomplishment should be credited—as is commonly done—to O. Reynolds (1883). It is only by ascribing a misconception to Stokes' work that the author is able to give Stokes the credit, but Stokes has indeed never been guilty of such inaccuracy. The history of the development of the law of viscous similarity shows the great difficulties of particularizing Newton's general statement into a true practical and usable specific law of similarity.

(3).—Law of Elastic Similarity.—According to Weber[51] this law is to be attributed to Cauchy (1829).

(4).—Law of Capillary Similarity.—The writer (since 1920) has attributed this fourth law to Weber himself (1919). The designation of the special law of capillary similarity as "Weber's Law" has been fully accepted by European scientists and likewise has been adopted[52] by John R. Freeman, Past-President and Hon. M., Am. Soc. C. E.

Each special similarity law involves its own dimensionless number or characteristic expression based upon and containing the governing physical property. This number, as is known, must be of the same numerical value in the model as in the prototype, in order to produce similarity. In the European notation, the Froude-Helmholtz Number is designated by F; the Reynolds' Number by R; the Cauchy Number by C; and the Weber Number by W.

The author's Equations (16) and (17) involve the simultaneous action of gravity and viscosity. In this case, the possible values of the ratios,

---

[52] "Hydraulic Laboratory Practice," pub. in 1929 by the Am. Soc. Mech. Engrs.

L and T, lie within very narrow limits, because the variation of gravity obtainable by natural means on the earth is exceedingly small and the range of viscosity of the commonly available fluids is restricted by practical considerations, such as lack of transparency, evaporation, diffusion, etc. Thus, either the practical operation of these natural limitations dictates a model of a scale scarcely differing from that of the prototype or the "together-working-limit" it encountered and no model is possible except the prototype itself.

Exactly the same reasoning holds for the author's Example 1 which involves the simultaneous action of elasticity and gravity. His Equations (29), (30), and (31) are identical with Cauchy's law of elastic similarity. Equations (37) and (38) indicate the resulting "together-working-limit." Again, the only model possible is the prototype itself.

The author's Example 2 involves the simultaneous action of gravity, elasticity, and viscosity. Hence, the three dimensionless numbers of Froude, Cauchy, and Reynolds must each have the same magnitude for the model as for the prototype. The author's Equation (40) is a characteristic form that may be written as $\frac{\mathsf{R}^4\,\mathsf{C}^3}{\mathsf{F}^4}$. The numerical equality of this characteristic in prototype and model is not, as indicated by the author, in itself sufficient to satisfy the condition for mechanical similarity—namely, the equality of each of the three individual factors, F, C, and R, in model and prototype. The author's development of Example 2 is nevertheless instructive and very valuable in showing the tremendous difficulties of arriving at a practical solution of problems involving the "Zusammenwirkungsgrenze."

The writer does not share the author's optimism as to the possibility of finding suitable media or even of creating artificial media adaptable for model work. Exceptions may occur, but, in general, the physical properties of available materials are so well known and their possible range of application to model work are so limited, that there is little justification for the hope of establishing a new branch of engineering. The author's illustration of a ship model in mercury is not well chosen because, despite several theoretical advantages, the use of mercury has many practical disadvantages. The different nature of the adhesion phenomena between hull and water in the prototype and hull and mercury in the model tank would produce different wave and wave-resistance effects. The opaqueness of the mercury would prevent visual and photographic observation of important subsurface flow phenomena and, furthermore, the prohibitive cost of installing and operating a mercury-filled towing tank of adequate size is in itself enough to eliminate the practical use of mercury.

The author has included an historical treatment of the subject, and he deserves great credit for bringing the important and timely subject of model science to the attention of American engineers. In Europe, and particularly in Germany, several similar studies have been made, which are most ably presented in the two important papers by Weber previously mentioned. These articles summarize the knowledge of the theory of similarity and model science as well as its history, but they do not treat of the limitations in practical application. These practical limitations for the particular field of hydraulic engineering have been fully discussed by the writer.[48]

The writer wishes to express his thanks to H. Kramer, Lieut., Corps of Engrs., U. S. A., Assoc. M. Am. Soc. C. E., and Lt. H. W. Ehrgott, Corps of Engrs., U. S. A., for their willing co-operation and critical assistance in preparing the translation of this discussion.

BENJAMIN F. GROAT,[53] M. AM. SOC. C. E. (by letter).—Engineers and designers are losing the advantages of Newtonian model engineering by neglecting those necessary features which convert models from indirect uncertain indicators to direct primary tools for accurate design.

This does not mean that one may not prefer and use the analytical method, when it is available. It does mean that there is a promising field for those who would cultivate and add to their professional equipment a valuable branch of research; a branch which enables one to make a theoretically correct solution of any dynamical or statical problem of design, even though no analytical theory may exist for such solution.

It also means that there is a great opportunity for engineering research of the most intelligent kind since it is necessary to formulate suitable technique in the various fields, to secure suitable materials and conditions for models, and especially to establish ways and means for synthesizing materials, or adjusting their properties, or both, so as to render them fit for useful service as constituent parts of models.

The research engineer who advances the part of the technique just mentioned will find plenty of glory in his successful achievements. The real prime foundation stone of any branch of engineering is an independent body of free-thinking capable engineers, who have no restrictions placed upon their activities, inventions, and writings, and who, therefore, may proceed to make of themselves real promoters of the advancement of engineering science.

No capable engineer should dismiss the idea of espousing Newtonian model engineering as an accurate technical system for design and research. Correct model engineering can supplant the most accurate analytical method. This new branch of engineering is constructed of the same elements of exactness as the analytical method, and it may be applied when the analytical method is deficient, impossible of application, or wholly wanting, all of which conditions actually exist. The only errors are those of observation and experiment, errors that are equally potent in all theoretically exact methods which involve physical relations. Thus it is, that Newtonian model engineering stands upon the same footing that supports the analytical method, namely, exact dynamical theory.

It should be most carefully observed that the writer does not criticize the great engineers of the past who have used models—he has only the most enthusiastic admiration for their famous achievements—but the successes of these engineers cannot in the least be ascribed to any inherent virtues of the models which they used. It would be far more nearly correct to state that the type of model engineering they used was rescued from total failure by the outstanding ability displayed by the engineers, two of the greatest of whom were W. Froude and R. E. Froude.

---

[53] Cons. Engr., Brookline, Mass.

The most careful scrutiny reveals that the advantages of true dynamic models have rarely, if ever, been secured. In every case it will be found that much redundant experimentation, unnecessary work, or pure speculation, was made to arrive at questionable relationships between a proposed structure and its model. This has been carried to such an extent that there was, in the end, no unique use for the model, the performance of the prototype having been independently determined by more or less reliable methods with which the engineer was familiar. Even the definition of the word "similarity" has been involved in obscurity. In all writings on that subject it will be found that, although the word has been used repeatedly, no adequate definition has been given with the exception of that in the writer's paper (see "Historic Background").

As some of the discussers fail entirely to grasp the ideas advanced by the writer, it will be justifiable to mention some of the original features of his paper, at the same time admitting that the foundation stone upon which he builds, was firmly laid by Newton in the theorem previously quoted. The whole point is that this theorem has never been understood except in a limited sense. This non-understanding is undoubtedly due to its extreme breadth and sweeping scope.

The three principal original features of the paper are:

(1) Association and solution of Equations (11), (12), (20), and (21), to develop the general specifications for any true dynamic model (see "Summary of Equations of Similitude").

(2) First discovery and publication[54] of the fact that true dynamical similarity depends only on the respective dynamical properties of the materials for the model and prototype, and on the general conditions under which they must work, but not at all upon the form or action of either of these devices. It is this fact which places true dynamic model engineering upon a theoretically exact foundation of its own.

(3) Explanation of the general nature of the technique to form materials and produce conditions by means of which Newtonian model engineering may be made effective.

The method is proposed to the designer as a direct, theoretically exact, systematic means for arriving at the proper construction and operation of all types of true models to serve as accurate primary tools for the design of engineering works generally, including, for example, steam turbines, hydraulic turbines, ships, airplanes, submarines, buildings, extensive water-power projects, etc. There is no limitation to the applicability of Newtonian models for such purposes, whatever may be the conditions and properties of materials and fluids to be suitably represented in the models by different materials and fluids, either real or virtual.

Such properties and conditions may include: Sliding friction, rolling friction, elasticity, fluid flow and viscosity, electricity and magnetism, cohesion, capillarity and surface tension, mass attraction, gravity at the earth's surface, acceleration generally, and any other dynamical characteristics, perhaps even including the dynamical features of chemical affinity and the modern atomistic theory, if one should be so enthusiastic as to delve into such interesting questions.[55]

---

[54] "Ice Diversion, Hydraulic Models, and Hydraulic Similarity." *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1138.

While such studies are delightful and highly instructive, it is clear that the world awaits a master generalization, before the nature and constitution of matter can be understood. The impression made upon the writer is that many authors seem anxious to assert the "limitations of classical mechanics," or, even its "failure" before they really have an explanation of their own difficulties and while they still seem compelled to use Newton's laws in the usual way for most of their work. Nothing illustrates better the force of fashion, even in science, than the present outcry against Newton's laws by those who continue to use them. The truth is that those who fall into the fashion, really do not understand the true situation, thereby making exaggerated and untrue statements.

(*1*) *Equations of Similitude.*—When the model has been constructed according to the principles explained in the paper, and is then properly set in operation, it will, in all essentials, be a theoretically exact reproduction of the proposed structure, or works, of which it is a true model. The systematic conditions may be made clear by reference to Table 3, which furnishes a general basis, or program, for the branch of design which the writer describes as "Newtonian model engineering," or the technical methods of constructing any model which is to perform with theoretically exact Newtonian similarity.

TABLE 3.—CHARACTER OF EQUATIONS OF SIMILITUDE.

Equation No.	Type of similarity.	Nature of the condition imposed by the equation.
(11)	Geometrical	Form and position only.
(12)	Kinematical	Similar motions in similar times.
(20)	Dynamical	Similar forces upon similar masses.
(21)	Physical	Dynamical properties imitated in suitable manner.

It is to be noted that Equation (11) is not independent, thus, the other three equations determine L, F, and T. Equation (21) may represent two or more equations involving as many physical constants, in which case the additional constants are to be made consistent by "adjusting" their values by the artifices of model engineering as illustrated in the paper, and as may be devised by the model engineer at different times to suit the occasion.

In Equation (21) (Table 3) the imitation need not be visual, or sensible, but merely virtual. Effective dynamical similarity is the essential requirement. It is well known, for example, that certain forms of rigid bodies are exactly equivalent in the dynamical sense without being geometrically similar.[56]

---

[55] See "Atomic Structure and Spectral Lines," by Arnold Sommerfeld, translated from the German by Henry L. Brose, about 1923; also, "Atoms, Molecules and Quanta," by Ruark and Urey, 1930.

[56] Routh's "Elementary Rigid Dynamics," Sixth Edition, Section 115.

Geometrically dissimilar rigid bodies which are dynamically equivalent in a vacuum may not, however, be dynamically equivalent when immersed in a fluid. One must be very careful about departing from geometrical similarity. The writer does not advise it except with the greatest caution.

(2) *Statistical Method.*—There is another feature of dynamic models which should be thoroughly understood. This applies especially to models of fluid flow. When the engineer uses the analytical method in arriving at a design, he usually deals with hypothetically stable conditions which have no existence in fact. Lines of flow are assumed to be fixed and the flow along them is assumed to be steady. In the case of a dynamic model, as a tool of design, the engineer is applying a "statistical" method; that is, the actual motion is, in one respect, like that postulated in the kinetic theory of gases, in which the actual configuration of the system is never twice the same at any two distinct instants, but in which the average condition, as deduced by Maxwell's law (application of the theory of probability), is perfectly stable, although any actual condition may never be the one indicated by the average—the system may never actually be in its average state. Theoretically, similarity can be made more exact for an irregular river bed than cut and fill can be determined for rough ground by well-planned engineering.

Hence, one concludes that if he can confine his model observations to measures which give the proper statistical averages, as to the pressure on the side of a containing reservoir, he need not invoke the kinetic theory, or the theory of probability, if the result is simply to be another average deducible by known means from such observations upon the model. It will be proper to explain that, in the paragraphs preceding Table 1, the writer did not mean that it would be of service to use the kinetic theory of liquids in the study of turbulence, but, rather, to study the rate of formation, and the distributions of sizes and rotations of eddies. Of course, this would not be as satisfactory as an exact determination of the mechanism of turbulence.

In what follows, some questions raised by the discussion will be treated in a more or less connected discourse based upon the writer's studies and experience, the intent being to illuminate the situation for the benefit of those who are interested in accurate dynamic models, especially as related to the science of hydrodynamics, which science has been involved with so much complexity, that one is very apt not to realize the true simplicity of its nature. An effort will be made to indicate the true status of these sciences of fluid dynamics so that one may have a grasp of their nature without having to unravel mathematical complexities.

The success of model engineering, like that of all other branches of engineering, depends upon the knowledge and judgment of the engineer in charge. He must be careful to see that all actions likely to have an appreciable influence have received his attention. In the gas problem (Appendix I, Table 2), it was as necessary to have regard to the elasticity (compressibility) of the fluid, as to the viscosity. In a problem of a different type, this may not be at all necessary, as, for example, when one experiments with a model conduit for the sole purpose of ascertaining the coefficient of fluid friction of the flow of a liquid which is practically incompressible. However, let the engineer in all such cases observe both the temperature and viscosity, for it is upon these that all hydraulic friction depends, as pointed out in the paragraphs in the paper preceding "Conclusions." Example 2 is a case in which the compressibility of a gas has been neglected for reasons explained in that example.

Whether or not it is necessary to take account of the elastic properties of a gas depends upon the extent to which such properties will be exercised in the model. Generalized, this is true of all properties of materials. The question of fluid elasticity (compressibility) has been stated clearly in Example 2, but it may be repeated that the elasticity of a gas may be provided for by proper control of the pressure, as was the case in Appendix I. The reason for this is that the pressure has the same dimensions as any elastic moduli. Furthermore, it is important to notice that the acceleration ratio (in a closed pipe system, for example) can be controlled by the pressure ratio, as it was in the first part of Example 3, where it was shown that the acceleration ratio, for closed pipes, could be made 125 by suitable pressure adjustments. This will be a most valuable fact to remember, when the question of the flow of a fluid in a closed pipe is involved. The principle will be very useful at times.

It may be further suggested that one need not be too punctilious about small unexplained variations in any of the coefficients and properties, because knowledge of them is limited. Moreover, as time passes, formulas will be subject to any changes which may show themselves necessary to ascending degrees of accuracy, but that has only favorable bearing on the principles of true model engineering.

(3) *Bertrand's Models.*—In 1848, M. J. Bertrand discussed Newton's theorem in a paper entitled: "Note sur la Similitude en Mécanique."[57] Of this, Routh states that the demonstration was "much improved."[58] The writer thinks the proof of the theorem was a secondary matter, and that the title of the paper shows clearly a fact of much greater importance, namely, that Bertrand had probably been the first really to read from Newton's theorem of similitude the possibility of actually constructing a dynamic model in certain cases, illustrating his ideas by proposing models of several machines, including a hydraulic turbine and a locomotive. Bertrand even mentions a substance which might create a proper coefficient of rolling friction for the wheels. Evidently, however, he did not seriously have the idea of using different materials, conditions, and artifices in the model, which would create exact similarity by suitably altering its physical properties and mechanism, because he clearly states that rolling friction requires a condition not at all realizable, that is, a coefficient reduced to one-fourth the value of the homologue. Bertrand anticipated Reech, Froude, and Helmholtz in stating Froude's law.

Bertrand's discussion of similitude, showing that dynamical equations of similar systems must be identically equivalent, seems to anticipate Stokes' discussion to the same effect in the paper on pendulums previously discussed

---

[57] *Journal de l'Ecole Polytechnique,* Tome XIX Cahier XXXII, p. 189.

[58] "Elementary Rigid Dynamics," Sixth Edition, p. 292.

(see "Analysis of Stokes' Remarks upon Similarity"), but Bertrand did not use any property equations, such as the writer's group represented by Equation (21), which are to be combined with Equations (11), (12), and (20). The writer has demonstrated by Equations (11), (12), (20), and (21) that similar systems can be constructed and set in similar motions by Newtonian model engineering, whatever may be the form and conditions of the prototype.

(4) Fundamental Corollary.[59]—The possibility of constructing a dynamically accurate model is proved by the solution of Equations (11), (12), (20), and (21) in view of the fact that Equation (21) represents as many equations as there are extra properties requiring the attention of the engineer. An important corollary may be read from the relations as follows:

> The advantages of constructing a Newtonian model to the specifications given by Equations (11), (12), (20), and (21), lie in the fact (proved by their solution) that the method depends only upon the given materials of which the structure (prototype) is composed and upon the given physical conditions (pressures, accelerations, etc.), under which the structure (prototype) operates, but not at all upon the particular type, form, or motion of the structure (prototype), or of any of its parts—the method makes the ratios of homologues independent of every physical constant and coefficient which can be associated dynamically with the structure, with its model, or with both.

This corollary is a generalization which includes, as special cases, the conditions described in the paragraphs following Equation (45) relative to the expressions "eliminating gravity" and "non-accelerated motion." In fact, the paragraphs referred to might be taken as including a statement of the corollary.

Therefore, the designer needs no correction factors for his experiments upon the model, other than the "conversion ratios," all of which may be derived immediately from the ratios L, F, and T, as found by Equations (22), (23), and (24), and as mentioned in the paragraph preceding Equation (2). Even these will be unnecessary if he uses model "weights, measures, and watches," in making his observations, as described in Example 2, and in the reference there given.[14] His model is a theoretically perfect representative of the prototype and needs no correction.

The problem thus reduces itself to the selection, or making, of suitable corresponding materials for the model, or of devising representative artifices, and to the arranging of suitable conditions under which the model must operate. These will be the principal matters requiring the intelligent attention of the engineer. The action of the proposed structure will then be determined directly by tests of the Newtonian model, instead of by unnecessary and doubtful corrections to be applied to the tests of a model of other type. For two fluids separated by gravity the corollary shows that this has no effect on similarity in a true dynamic model constructed to the specifications of the equations of similitude.

(5) Classification of Coefficients.—Coefficients cannot be understood until they are classified. For this purpose two important distinctions must be made by the model engineer:

---

[59] Also a corollary of theorem and discussion stated in *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), pp. 1187–1188.

First.—The distinction between (Class *a*), dimensioned coefficients, and (Class *b*), dimensionless, or self-cancelling, coefficients.

Second.—The distinction between (Class 1), "property coefficients," or "physical constants," or "general co-ordinates," or parameters, of a system, and (Class 2), "type coefficients," or "non-property" coefficients. (Limit coefficients are treated in Article (9).)

The importance of the first distinction lies in the fact expressed generally by the fundamental corollary previously stated, that when a coefficient is purely dimensionless (Class *b*), its values in similar systems will be identical. Hence, in similar systems (model and prototype), dimensionless coefficients are self-cancelling from all ratios of homologues which contain them. The model engineer, therefore, may disregard them, as having any material bearing on the construction and testing of the model. There is just one caution—care must be taken by the engineer to see that any particular coefficient in question really is effectively dimensionless.

As an example, the coefficient of sliding friction is usually considered to be dimensionless; that is, as the ratio of two forces, or as the tangent of the "angle of friction," but it is a dimensionless "property coefficient" (Class b_1). If the kind or character of either, or both, the mutually sliding materials is changed, the value of the coefficient will change correspondingly. Thus, the ratio between the "friction" and the "pressure" is determined by the value of the coefficient, which latter, however, is a joint property of the sliding materials, and, therefore, cannot be regarded as being dependent upon the ratio of friction to pressure. Hence, a theorem is established:

Theorem I.—As related to a dimensionless property coefficient (Class b_1), a material acts as a "dimension" and cannot be changed in a model without requiring a compensatory adjustment of some kind, in accord with the principles of Newtonian model engineering.

It is the duty of the engineer to see that dimensionless property coefficients have appropriate values in model and prototype.

Theorem I raises, therefore, the second broad distinction between coefficients. The important characteristic of the "type" or "non-property," coefficient, as distinguished from all others, is that its value depends only upon the type, form, and action of the particular system (either the model, or the prototype, for example) with which it is associated. It depends only upon the ratios of like kinds of numbers, including not only the ratios of like geometrical magnitudes, but also the ratios of like property magnitudes. For example, a type, or non-property, coefficient, might depend upon the ratio of two physical constants, or properties, of like kind associated with different parts of the same system (specifically, for example, the ratio of a modulus of elasticity of the steel reinforcement of a concrete beam, to the same kind of modulus of elasticity of the concrete). Hence, a type coefficient is the antithesis of the dimensionless property coefficient, in that the value of the type coefficient (necessarily dimensionless) depends upon the distribution of certain like features in a given system; whereas, the dimensionless property coefficient determines the distribution of certain like features in a given system. It appears that all type coefficients (Class 2) are dimensionless

(Class b), but that some dimensionless coefficients may be identified with property coefficients and physical constants (Class 1).

It will be very much worth while to study further the nature of type coefficients, that is, purely dimensionless coefficients (Class b_2). By the foregoing, such coefficient must be the ratio of an action (or characteristic feature) at one part of a system, to the same kind of action (or characteristic feature) at another part of the system. For example, the thermal efficiency of a steam engine is a coefficient of Class b_2, since it is the ratio of the energy delivered by the engine to the energy supplied in the fuel. In this relation, it is important to observe that this coefficient is calculable, because the dynamical and thermodynamical equations of steam engineering are very accurately known. If these equations were not known, or even only partly known, the efficiency of the engine would become a purely empirical coefficient, which could be found only by experiment, either upon a Newtonian model or upon the engine itself, or its equivalent, another engine of the same size and type operated under the same general conditions, as by use of the same kind and grade of fuel, etc.

It is important to fix clearly in the mind just why a purely dimensionless coefficient is calculable when the theory involved is complete. The reason is that the complete theory represents by equations all things of the same type, so that all the parts, motions, and performance of an engine, for example, can be determined by the equations of the associated science; that is, the output and the input, and, therefore, the ratio, are calculable. If any part, or action, of the mechanism of a given system is not correctly and completely represented by the equations of the science involved, then the theory is incomplete and the equations must fail to give a solution; in which case, some, or all, of the dimensionless coefficients of the system cannot be calculated.

Let it now be observed that when the theory of a particular system is complete and correct, all the type coefficients of the system become wholly unnecessary to the solution of any problem of the system. In other words, it is a theorem that:

Theorem II.—The necessary use of a purely dimensionless coefficient is an infallible mathematical criterion that the complete mechanism of the dynamical system is not represented by the dynamical equations in which that dimensionless coefficient must be introduced in order to effect an empirical solution.

The failure to obtain a rational mathematical solution is not due to the nature of the problem, but to the nature of the equations—they do not represent the system. The cause of every empiricism in engineering is lack of the knowledge of the corresponding dynamical mechanism necessary to furnish a sufficient number of satisfactory equations.

It will be understood, of course, that the writer does not refer to mathematical difficulties of reduction. A problem is here considered solved if the conditions of the problem can be introduced into dynamical equations (including experimentally constructed curves, or tables), which, when solved by any process (say, by trial and error) must necessarily give a theoretically exact result.

(6) *Class 1.—Property Coefficients, or Physical Constants.*—Examples of the "constants" are, the "constant of mass attraction" and the acceleration of gravity at a fixed position on the earth's surface. Examples of variables are, specific gravity, specific weight, and density—the density of a gas depends upon temperature and pressure. Among the property constants as ordinarily assumed are: (*a*) The "bi-constant" systems of isotropic elastic coefficients now in general use;[60] (*b*) the elastic moduli, pliabilities, and strains, which are functions of Coefficients (*a*); (*c*) the coefficient of viscosity; (*d*) dynamical electric and magnetic constants; and (*e*) any other fixed properties of materials, or conditions under which similar structures must work. Capillarity and surface tension belong together. Observe that Poisson's ratio, which is a dimensionless number, classed as b_1, may be derived from any two independent elastic constants, or moduli of elasticity.

Coefficients of Class 1 measure the dynamic physical properties with which the model engineer is principally concerned. An improper value of any coefficient of this class in a model of a proposed, or existing, structure would destroy the similarity in a measure dependent upon the discrepancy. It is by proportioning correctly each of the coefficients (Class 1) in the model, that the engineer imposes the conditions of true similarity. In this sense, the scale-ratio may be treated either as a physical constant to be suitably "adjusted," or as an arbitrary constant against which all other affected property constants must be matched in proper relation. By allowing the scale-ratio to be somewhat dependent, it may render the use of certain materials, or other conditions, permissible, when that is desirable. All such adjustments and requirements are properly indicated by Equations (11), (12), (20), and (21). Any dynamical science depends upon properly determined (hypothesized, or experimentally established) Class 1 coefficients which are entirely independent of size, form, and action, of the particular apparatus involved. They are postulates of the science, as, for example, the coefficient unity in Newton's formula, "force equals mass times acceleration" (that is, $F = kma;$ $k = 1$); or the coefficient of viscosity as hypothesized by Newton, which solves all problems in pure viscous flow, but fails completely in problems of turbulence, for want of knowledge of its complete functionality.

(7) *Class 2.—Type Coefficients, or Non-Property Coefficients.*—All these coefficients are dimensionless, and may be better illustrated under Class *b*. (See remarks under "Classification of Coefficients.") Confusing the idea of the two different values of the same type coefficient which generally result from two different adjustments of general conditions of operation of the same mechanism, with the idea of two values of the same type coefficient for two distinct but similar mechanisms under similar general conditions of operation, has been the most fruitful source of misconceptions of true Newtonian models. In the former case, the two values are generally different. In

---

[60] One can find no better assemblage and elucidation of the principles of elasticity than that given by Professor Bateman under the title, "Elasticity," in the Fourteenth Edition of the Encyclopaedia Britannica; another source of first importance, is Pearson's edit of Todhunter's "History of Elasticity;" Appendix *b*, on notation, gives a foundation.

the latter case, they are necessarily the same. These two conditions occur simultaneously in Newtonian similarity.

Hence, in considering the theory of models, no attention need be given to the variations of type coefficients in one and the same system, since no conclusion as to the accuracy of models can be reached thereby. This results most clearly from the equations of similitude and their fundamental corollary, as previously stated. Every model engineer must understand this matter most fully, or he is certain to waste an immense amount of time in redundant labor and effort. For example, it avails naught to think of the size, form, or service, of a reinforced concrete beam as having any bearing on the specifications for the construction of a true dynamic model because a Newtonian model depends only upon materials, physical constants, and the general conditions for the service.

(*8*) *Class b.—Dimensionless, or Self-Cancelling, Coefficients.*—The case of a dimensionless property coefficient has been illustrated under Article (5), "Classification of Coefficients," which includes a cautionary remark calling attention to the importance of knowing that such coefficients had been made effectively dimensionless. As typical of purely dimensionless coefficients, Poisson's ratio in elasticity, and the coefficient of hydraulic "skin friction" in the presence of turbulent flow, may be mentioned. Poisson's ratio is classed here because it is a type coefficient of a material, thus becoming a type coefficient of any system containing the material.

The fact that Poisson's ratio is calculable by the elastic formulas, whereas, the coefficient of skin friction for turbulent flow cannot be calculated by the formulas of hydrodynamics and aerodynamics, is a positive mathematical criterion that the mechanism of elasticity is well represented by the elastic equations, but that the mechanism of turbulent flow of fluids is not represented by the present equations of fluid dynamics. When the mechanism of turbulence and eddying motion is properly introduced into hydrodynamical and aerodynamical equations, the dimensionless coefficients of hydraulic skin friction will become calculable in either science, just as Poisson's ratio is now calculable in elastic problems when the values of the two necessary independent elastic property coefficients are given.

Let it be observed that no dimensionless coefficient of hydraulic skin friction is necessary in the case of pure viscous flow, regardless of the nature of the conduit. This is the rigorous mathematical criterion showing that the mechanism of pure viscous flow is well represented by the fluid dynamics arising from Newton's definition of the coefficient of viscosity.[61] That one definition expanded the theory of hydrodynamics (aerodynamics included) so as to cover completely the field of pure viscous flow. Any difficulty of solving a problem in pure viscous flow is solely one of mathematical reduction, and not one of incomplete dynamical equations. Thus, the question suggests itself, may not some simple definition, or hypothesis, now carry the theories of fluid dynamics throughout the domain of turbulent flow? (See Article 14.)

Poisson's ratio and the coefficient of hydraulic skin friction are both dimensionless, and, therefore, both are self-eliminating from problems of true model construction. The model engineer need have no regard for them at all when he designs his model according to the requirements of Equations (11), (12), (20), and (21). When the property coefficients of the materials and conditions of the model are properly adjusted, by means of these equations, all purely dimensionless coefficients become at once automatically adjusted in their proper ratios, expressing what Professor Bateman would undoubtedly term "proportions of the system," calculable from simpler component proportions. As these dimensionless coefficients depend only upon the types of their respective systems, and as these systems have been made dynamically similar in the Newtonian sense by the model engineer, the values of any two corresponding, or homologous, dimensionless coefficients must be identical. Thus, the model engineer makes no tacit assumption of similarity. He simply creates similarity by the engineering control of all acting dynamical conditions. These dynamical conditions are very much limited in number in fluid dynamics, just as the generalized co-ordinates of problems in rigid dynamics are very much limited in number by the Lagrangian method. Even if R (scale) is counted as a property, or condition, the greatest number of such constants which the writer has encountered in the problems given, is only six. Finally, therefore, these dimensionless coefficients cancel from all ratios of homologues which contain them. They disappear from all relations between the model and its prototype. Hence, all efforts to treat such coefficients individually are wholly redundant in Newtonian model engineering.

---

[61] "Principia" (1687), Hypothesis, Lib. II, Sec. 9.

One more suggestion may be appropriate. Some physical coefficients have not been properly determined. It may have been imagined necessary to place them in a term the dimensions of which were such that the whole term gave the measure of the effect which it was desired to represent. The failure of the experimenter to do this with effect may mean that he is doing it with a single coefficient when more than one is needed.

(9) Limit Coefficients, Arbitrary, or Natural.—This type, as an arbitrary limit coefficient, is well represented by an arbitrary limiting safe stress in a material, while the natural limit coefficient would be represented by a modulus of rupture. If a model, for example, is to have a correct modulus of rupture, the material of the model must have the property of rupturing under the proper "model stress." In the usual method of the past this condition has frequently been produced by an artificial loading, with use of the same materials in the model and structure; but the writer believes this results merely by following precedents, and that true models will be found much more satisfactory for many purposes.

After all, Newtonian model engineering differs in no essential respect from any other branch of engineering—it advances along its own special path. In many cases, of course, the character of the research will not be concerned with limit coefficients, except to see that stresses are confined to proper values.

(10) Newtonian Cancellation of All Coefficients.—In the broadest view, the type coefficients, or "proportions," of a system must include every kind of measurable quantity which can be associated with different parts of the same system. Any dimensionless term, or factor, containing a dimensioned coefficient is nothing but the ratio of the coefficient to its own dimensions,

and, therefore, may be looked upon as a type coefficient, or proportion, of the system.

If the dimensioned coefficient is not divided by its own dimensions, it may be both multiplied and divided by them so as to produce a term or factor containing it. Reynolds' number is a good example. It represents the ratio of length and velocity to kinematic viscosity. Thus, the engineer, in framing his particular Reynolds' number, selects the product of a certain length and velocity to compare with the virtual product of length and velocity, as expressed by the kinematic coefficient. This is truly a type factor of the system, corresponding exactly to the purely dimensionless self-cancelling Type *b* coefficients previously described. Thus, these corresponding type factors, or proportions, of the respective similar systems (just typified by Reynolds' number) must have identical values in systems which have been made dynamically similar by the model engineer. Hence, they must cancel, and with them the dimensioned coefficients which they contain, when comparing a model with its prototype. Therefore, since it has already been shown that all dimensionless coefficients cancel, in Newtonian dynamic model engineering, it follows that:

Theorem III.—All coefficients of every type vanish from the ratios necessary to connect experiments upon the model with corresponding experiments upon the prototype. And, a curve giving the value of an experimental dimensionless coefficient for the model plotted against the value of a corresponding dimensionless number appurtenant to the model, will coincide with the corresponding curve plotted against the same dimensionless number for the prototype.

This, of course, is just what is proved generally by Equations (11), (12), (20), and (21).

An excellent illustration of the foreging proposition is the following reasoning taken partly from letters of instruction written by the writer in July, 1928: In the case of turbulent flow in a pipe or open channel, the friction gradient may be written:[62]

$$\frac{H}{l} = \left(f' \frac{4\nu}{rv} + f \right) \frac{v^2}{2rg} = \psi \ldots\ldots\ldots\ldots\ldots (122)$$

in which,

r = hydraulic mean depth;
l = length of, or reach of, the pipe or channel;
v = actual mean velocity in the cross-section;
f = dimensionless coefficient of loss due to turbulence;
f' = dimensionless friction factor due to viscous resistance;
ν = kinematic coefficient of viscosity; and,
H = friction head lost in the length, l.

Equation (122) exposes the fundamental nature of the whole theory of similitude, when Newton's theory of similarity for systems of particles in space which re-act upon one another only during the moments of collision, is extended so as to include the possibility of viscous reactions during a finite time interval of contact.

---

[62] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 840, Equation (10).

Let it be required to examine Equation (122) to see what conditions are necessary to secure both geometric and dynamic similarity of model to prototype: First, by definition, geometric similarity requires that the longitudinal slope, $\frac{H}{l}$, in prototype, and $\frac{H_m}{l_m}$, in model, at homologous points, shall be the same. In fact, it is a condition imposed in the problem, that all pairs of homologous linear dimensions, whether they are longitudinal or otherwise, shall be in one fixed ratio, namely, the scale ratio of the homology; and, second, dynamical similarity requires that all pairs of homologous forces shall be in a fixed ratio, be similarly situated, and be similarly directed. This is the force ratio of the homology which was first described by Newton; for example, any pair of homologous centripetal forces acting upon a pair of homologous masses so as to cause them to move in geometrically similar curves. Since the intensities of these forces are measured by the respective centripetal accelerations produced by them, and since the accelerations are, respectively, $\frac{v^2}{r}$ and $\frac{v^2_m}{r_m}$, it must follow that the forces are as $\frac{mv^2}{r}$ to $\frac{m_m v^2_m}{r_m}$, in which, m and m_m are the homologous masses involved. Hence, if $\frac{F}{F_m}$ is the force ratio:

$$\frac{F}{F_m} = \frac{m\frac{v^2}{r}}{m_m\frac{v^2_m}{r_m}} = \frac{mg}{m_m g_m}$$

In the particular case when $g = g_m$, as when both model and prototype, or homologous parts of them, are exposed to accelerations due directly to the earth's gravity (the pipe is not full of water under pressure, or is there a water-fall in the river), it is at once apparent from the foregoing equations, that $\frac{v^2}{r} = \frac{v^2_m}{r_m}$, or that all homologous accelerations must be equal. However, this is only a special case of acceleration. In the general case, as in similar pipes running full of water under pressure, there is still required an acceleration ratio, in order that dynamical similarity may exist, as in the first part of Example 3, where it is shown that the acceleration ratio must be 125 to create similarity in the horizontal discharge; and as it was shown in Appendix I that just such an acceleration must exist under pressure when it is required to make the same fluid represent itself as a model of itself.

It is thus clear that a necessary condition for similitude is that ψ shall have the same value at any pair of homologous points, the respective dimensions introduced being also correspondingly homologous. Of course, ψ will not necessarily have the same value at all points in a natural stream, nor in a model of a stream. It is also very clear that this condition can be secured by imposing in ψ the conditions that, $\frac{rv}{\nu} = \frac{r_m v_m}{\nu_m}$ and $\frac{rg}{v^2} = \frac{r_m g_m}{v^2_m}$.

Hence there are two equations for the two quantities, $\frac{r}{r_m}$ and $\frac{\nu}{\nu_m}$, from which Equations (16) and (17), may easily be derived expressing the necessary relation between L, G, and ν to be satisfied for conditions of similarity. In this reduction the hydraulic radius, r, evidently has the dimension of length, so that $\frac{r}{r_m}$ is the linear scale ratio.

It is interesting to notice that the condition expresses the equality of homologous values of both Reynolds' (Stokes') number, and Froude's (Newton's) number, in that most interesting relation which the writer has pointed out as expressing the necessary condition that the flow in a viscous fluid may not be such as to destroy Newtonian similarity. In other words, to make the illustration complete, equal homologous values of ψ express Equation (11) and equal homologous Froude's (Newton's) numbers express Equation (12). Equation (20) has been obscured by making the problem kinematical, as remarked under the heading, "Properties of Materials," in the paper, the implication being that $\frac{F}{\rho} = \nu^2$, since, in this case, all forces are to be measured per unit density; equal Reynolds' (Stokes') numbers express Equation (21), or the condition that the dynamical physical property, viscosity, has been properly imitated in the model. This may be verified by confirming references to Equations (11), (12), (20), and (21), under, "Summary of Equations of Similitude," Table 3, as to the character of the equations, and Table 1, after dividing the line containing F throughout by ρ.

(11) Type Factors and Form Factors.—When like magnitudes are merely geometrical, as lines, areas, and volumes, pure dimensionless coefficients (Type *b*), are commonly known as "form factors" ("shape factor" of a helical inductance coil); but when such proportions of the system include, as in the writer's paper, the ratios of all kinds of denominate numbers, velocities, masses, forces, physical constants, etc., the name, "type factor," may be sufficiently broad to describe the ratio; for a ratio such factor must be, since it is the product of two or more other ratios, or merely itself a ratio of simple dimensions.

A most important example of a type factor is the recognized permanency, as to time and place, of the ratio of a "statistical," or average velocity, at a point in any stream, conduit, or pipe, as compared to the mean velocity as to time and position in any given cross-section of the flow, which permanency occurs under permanent fixed conditions which govern the flow, even though the resulting flow may be turbulent and, therefore, unsteady at every point of the channel. Under these conditions, the time-average mean-velocity throughout any given cross-section becomes a kind of "generalized coordinate" (Lagrangian method) of the flow in the channel, thus reducing enormously the number of variables involved. The permanence of values of the "statistical" type-factors of a given system, or mechanism, under fixed general conditions, may be referred to as the "principle of fixed average type-factors." The values of homologues are the same in two similar systems.

That these variations of mass-motion can be treated by the laws of probability, much as Maxwell applied his law to the distribution of molecular velocities in the kinetic theory of gases, would appear to be a certainty. The average mass-motion at a point, as thus defined by implication, might be compared with what Jeans calls "mass-motion,"[63] as distinguished from molecular motion, while the variable component of the mass-motion (as here defined) would find its analogue in Jeans' molecular motions. The difference between the mechanism of a continuous fluid and that of an aggregation of individual particles must not be disregarded, however, although the mechanism of the kinetic theory is, as Sir James states (page 10), so "extremely fine-grained" that it is practically indistinguishable from that of a continuous medium.

(12) No Tacit Assumptions in Newtonian Model Engineering.—In extending the ideas from a simple form-factor to a type-factor, as just defined, it must be carefully observed that the values of any two homologous type-factors, as between two geometrically similar systems, will not be identical unless the systems are similar in the Newtonian dynamical sense. Newton's theorem postulates initial similarity; therefore, it is as much the engineer's duty to see that similarity exists initially as it is to construct a model which is potentially similar to its prototype in the dynamical sense. When this requirement is satisfied, the systems will be similar and will move with similar motions, if the model engineer has properly applied Equations (11), (12), (20), and (21), to determine the essential characteristics of the model.

The establishment of initial similarity by the model engineer is by far the least of his difficulties. When he is designing a structure of any kind, the motions and actions of the structure are completely in his control. He can make them whatever he chooses, just as the entire architectural design of a structure is at his disposal. He simply constructs and tests his ideas in miniature, by means of his model, perhaps re-designing his model until it and its operation are satisfactory. The re-design would not necessarily be difficult, since, by the fundamental corollary, one determination of materials, properties, and conditions for the model is sufficient for all forms of the same general type. Thus, the materials for a former model will serve in the next of the same type. The problem then reduces itself to building the structure, and starting it under conditions of similarity. By the equations of similitude (Equations (11), (12), (20), and (21)), or their corollary, the resulting motions, however complex, must be similar to homologues in the model. This has been most clearly illustrated in Example 2, as in the explanation of the method of starting similar weights suspended by similar springs. If one desires an experimental demonstration, no better one can be found than Stanton and Pannell's experiments, previously referred to so many times.[64] In such experiments, Newtonian similarity surely establishes itself when conditions are properly adjusted by the engineer.

There are also to be found, among about one thousand papers on viscosity and related action, which have appeared during the fifteen years (1916–1931), a number of other verifications, precisely to the same effect. Among all these, however, Stanton and Pannell's paper still stands as the outstanding example.

---

[63] "Dynamical Theory of Gases," Chapter VII, by Sir James Hopwood Jeans.

[64] Collected Researches, National Physical Laboratory (British).

In this connection there is one caution to be heeded. Changing the shape, including roughness, of the boundary will change coefficients, notwithstanding the fact that the coefficients of similar systems must be equal; that is, must change equally, when changes occur. It is exactly here that so many have failed to make the distinction between the change in value of a coefficient in a particular system, and the continued equality of two homologously changing coefficients in different, but similar, systems.

It is scarcely necessary to give an example relative to the establishment of initial similarity between rigid systems, since the proof for fluid systems must apply with greater force.

(13) Generality of the Newtonian Method.—It appears clearly that the model of the tank discharging mercury (Example 3) differs in no essential manner from the model of a ship, since, by the fundamental corollary, the form of the model does not affect the specifications for the materials of the model, nor the general nature of the conditions for testing the model. Of course, it will be understood that different materials may be equivalent, as model materials. Hence, there is considerable latitude for the use of judgment and expediency, even after the general conditions for the model have been fixed upon. This is an aid rather than a hindrance.

For another instructive illustration, one might imagine the model tank with mercury, and its prototype tank with water, to be converted into corresponding ships (tugboat and its model, say) by actual wrecking and reconstruction in a series of "similar" operations. No change at all would be required in materials, fluids, and general controlling conditions. The only necessary and sufficient condition is that the model retain its Newtonian character of dynamic similarity, which it must do, since the engineer has provided the proper materials and conditions of operation.

(14) The Nature of Turbulent Flow.—The writer desires again to refer to his discussion[65] of the paper by Messrs. Nagler and Davis, which is to be considered as part of this closure. In this discussion the general nature of pure viscous flow, and also of turbulent flow, is explained.

The prime cause of every eddy is viscosity, because, if the fluid were not viscous, it would be frictionless, and no eddy could be formed. The prime cause of the ultimate stilling of every eddy is viscosity, because if the fluid were not viscous it would be frictionless, and by Newton's first law of motion, there would be nothing to stop the rotation. There can be no other kind of loss of energy, since it was clearly pointed out that there can be no such thing as loss due to impact, either of fluid upon fluid, or of fluid upon a solid, or the reverse.

It does not seem that these facts have been consistently digested, even by the foremost scientists, because the conclusion is irresistible that all hydraulic friction of every possible type depends primarily and ultimately upon viscosity, whereas it has been asserted by the most profound authorities that turbulent friction is independent of viscosity (see paragraphs and footnotes immediately preceding "Conclusions").

---

[65] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 842.

If all frictional loss is due to viscosity, then there must be an actual mechanism involving viscosity, which, when revealed, will furnish a perfectly rational system of dynamical equations sufficient to solve any problem of actual fluid flow without the necessary use of empirical type coefficients, as discussed under "Dimensionless Coefficients (Type *b*)."

While the writer has not yet attempted to set up this rational system of equations, he does believe he can state the general nature of the postulates which must be made to furnish the footing of the complete science of dynamical viscosity.

When one is concerned with the physical properties and constitution of matter, and when it is desired to set up their characteristics upon an ultimate rational basis, the question of the divisibility of matter is among the very first to arise. Perhaps the next question is as to the divisibility of energy. Chemists, physicists, and mathematical savants have long since satisfied the scientific world that matter is discontinuous, and that its ultimate form is divided progressively into molecules, atoms, and electrons; although it must be admitted that there is yet much obscurity surrounding the ultimate nature of matter, and energy too, as will be apparent after consulting the references previously made. Let it be observed that, as a consequence, the postulation of the divisibility of matter into equal elements must carry with it the elementary subdivisions of energy; for energy must exist only as associated with the ultimate elements of matter in their mechanical relations.

The question of procedure arises. Shall it be by the dynamics of continuous, or discontinuous, matter? Moreover, is there any particular mathematical form which will have an advantage over all others? What place has the kinetic theory of gases? In particular, shall Newtonian dynamics, which has furnished, and still furnishes, the foundation for all studies in mass-motion (even for studies by those who seem to think Newton's laws no longer have any applicability) be discarded?

The writer answers these questions by saying that he thinks there is no reason at all why the engineer should discard Newtonian dynamics, nor any reason why the kinetic theory of gases should enter into dynamical problems of engineering, unless the constitution of matter should enter into the problem in some vitally important manner. The reason for this conclusion is that both the constitution of matter and the kinetic theory of gases are, as pointed out for the kinetic theory by Jeans (see Article (11), "Type Factors and Form Factors"), so very "fine-grained" that, for practically all engineering problems, matter may be treated as being absolutely continuous, but, of course, this must be carefully borne in mind as a fundamental hypothesis of modern engineering. It is too frequently the case that a fundamental hypothesis fails to be understood, because the familiar use of it without thought is so frequent that one might even find difficulty in explaining his equations fully, if asked to do so. The nature of the kinetic theory of gases in relation to viscosity will be discussed subsequently. Until then, the discourse will proceed on the Newtonian basis, and upon the hypothesis of continuous matter and continuous energy. Even then, it will be shown that Newtonian dynamics is pre-eminently the base of the kinetic theory of viscosity.

Transposing l, Equation (122) is the writer's general formula for the flow of any viscous fluid in any type of channel, or pipe, open or closed.

The factors, f', f, and the entire quantity in the parenthesis are each dimensionless, Type b, coefficients of friction. The acceleration, g, need not necessarily be that due to gravity, but may be the actual effective acceleration controlling the flow, as in the case of a fluid in a closed pipe running full under pressure. One must regard the fact that an acceleration must control every case of fluid motion. When that acceleration was not gravity, and when the flow was supposed to be uniform, it has been a frequent mistake to lose sight of the necessary acceleration to introduce the flow, maintain it, and especially to generate and maintain turbulent conditions. Equation (122) is perfectly general. It covers every case of fluid flow. It represents the resistance on the side of a ship, or on the sides of one of Froude's boards.

It is true that a coefficient had been proposed by D'Aubisson in the form, $a + \frac{b}{v}$, but in that coefficient no regard was had for viscosity, nor were the component coefficients introduced in the same manner used, and for the same reasons given, by the writer when forming the coefficient for Equation (122).

To get a little nearer to a practical understanding of the writer's coefficient (F, say) within the parenthesis of Equation (122), and to make those who deal with pipes more at home, let R_1 be the resistance per unit area of wet pipe skin, and d, the diameter of the pipe, so that $d = 4r$. Then, the following reduction is easily traced:

$$R_1 = \frac{\rho g H (\pi \frac{1}{4} d^2)}{\pi d l} = \rho g \frac{1}{4} \frac{d}{l} \left(F \frac{l}{\frac{1}{4} d} \frac{v^2}{2g} \right) = \frac{1}{2} F \rho v^2$$

or,

$$\frac{R_1}{\rho v^2} = \frac{1}{2} F = \frac{1}{2} \left(f' \frac{16\nu}{dv} + f \right) = \frac{1}{2} \left(f' \frac{4\nu}{rv} + f \right)$$

which shows that the familiar dimensionless coefficient of hydraulic skin friction, represented by F, is precisely double the usual coefficient of skin friction in the familiar formula, $R' = f_2 \rho A_p v^2$, in which, A_p is the area of the skin, and f_2, the coefficient. It is also important to notice that $\frac{1}{2} F \ (= f_2)$ is the ordinate used by Stanton and Pannell in the plottings of their experiments previously, and hereafter, mentioned.

It is most important to notice carefully that Equation (122) is a perfectly rational formula, complete in every respect but one; and that the final perfection and corresponding alteration of its form would in no sense invalidate it as an exact theoretical representative of the flow in the pipe, or other channel. The only difference would consist in the substitution for f' and f of terms containing what the writer will call, and what Lagrange perhaps would have called, "generalized co-ordinates of turbulence." These co-ordinates would include all those dimensionless type-factors of the system which in any way affect the delivery of the kinetic energy of the mass-motion to the "energy-sinks" of viscosity as it operates in turbulent motion.

The words, "source" and "sink," have usually been employed in hydrodynamics to indicate points, lines, areas, and volumes, which may be considered as productive or destructive of the fluid, to suit the assumptions of the problem. The words are used herein to indicate the transformation of energy from one form to another. In particular, it should be stated that a "viscous-sink" would refer to the loss of energy by reason of the conversion of kinetic energy of flow into heat by viscous friction. Treatises on fluid dynamics give formulas for the dissipation of energy by viscous flow. In reality, all the energy is conserved by being converted from kinetic energy of flow to kinetic energy of molecular motions; but, as a factor in the dynamics of flow, such viscous friction must be regarded as an "energy-sink." Any treatment of viscosity by the kinetic theory of gases which does not consider the increase in molecular motion due to the transformation of mass-motion into molecular motion must be decidedly incomplete.

The reasons why Equation (122) is perfectly rational in form have been fairly well explained elsewhere,[66] but it is very difficult to explain a generalization which involves a wide variety of conditions. Perhaps it will be possible to illuminate the subject somewhat more by explaining the nature of the principal experimental facts which can be cited in support of the formula. The first of these has already been explained as a "most important example" in Article (11), "Type Factors and Form Factors." This is nothing but an application of the well-established fact that the average velocity of a fluid at any point in the cross-section of a steadily flowing turbulent stream, bears a fixed ratio to the mean velocity in the cross-section, when the times of observing velocities have been of sufficient duration to furnish reliable averages.

This same permanency of ratio must hold for the time-average velocity at any point of an average eddy which exists at any point in the cross-section of the stream. The eddies move with translation, of course, but there is a "statistical" eddy at any given point. The detailed dynamics includes the translatory motion of the eddy, but it is not necessary to consider this here, if one considers average conditions rather than details.

Perhaps the most important experimental facts to consider, relative to the generation of an eddy, are: Viscous friction depends upon the rate of shear, or the transverse velocity gradient; this rate may be increased up to a certain critical limit (determined by Reynolds' critical velocity, and the distribution of the previously existing pure viscous flow); beyond this limit the flow breaks into turbulent, or eddying, motion.

In view of these established facts, one might think that some kind of bond, or elastic stress, is suddenly broken when the rate of shear (strain) exceeds the critical limit; but it is well known in hydrodynamics that pure viscous, or laminar, motion can be resolved into three components:[67] Translation, rate of shearing distortion, and rotation; as long as these three components exist unchanged, laminar motion results. Furthermore, in laminar flow, as a simple example, the distortion means a rate of stretch along an axis, and a rate of contraction along another axis perpendicular to the first, these axes being at an angle of 45° with the direction of laminar motion. Therefore, calling to mind Maxwell's definition of the "rate of relaxation" of elastic stress,[68] the writer concludes that, instead of the breaking of an elastic bond by exceeding the critical rate of strain, the contrary is the fact, and that it is the excess of the rate of strain over the rate of relaxation that causes the elastic bonds to hold, and, hence, to suppress, or reduce, the rate of deformation, thereby permitting the component of rotation to prevail in producing a rotation of the element as a whole. Poisson, it appears, also had similar ideas, deducing equations of viscous flow from equations of elasticity by assuming strains to relax as fast as they were generated.[69] The same equations were also deduced by Navier in 1822.[70]

---

[66] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), pp. 834-841.

[67] "Hydrodynamics," by Lamb, Article 30.

In illustration of this action of a viscous fluid, one may experiment upon a very soft piece of candy (say, 3 or 4 lb.) on a marble slab. If the candy is picked up by the hand very slowly, the relaxation of the candy will cause it to stretch and pull apart. If it is picked up with sufficient celerity, the candy will hold together as a more or less rigid solid, and it may be transferred to a plate with very little distortion.

Thus, it is seen that the component rotation of the viscous fluid is left to produce rotation when the rate of shearing strain exceeds the rate of relaxation, and that these persisting elemental rotations will combine to form eddies and turbulence in place of the previously existing laminar flow. Of course, the principle is precisely the same, whatever the nature of the initial purely viscous flow, whether laminar, or even existing initially in a previously formed eddy. Eddies and vortices are usually screw motions.

Whether the motion is laminar, or rotary, viscous friction can occur only through the mechanism of shearing distortion, and in no other way, excepting some other possible action of cohesion, but the writer is inclined to believe that this will not be found to be effective.

The entire question of hydraulic friction thus reduces to the study of pure viscous friction, as it operates in directly resisting the flow; as it operates in the formation of eddies; and as it exists in the eddies, after they are formed. There can be no doubt that the whole eddy system in any turbulent flow is produced primarily by viscous action.

Of course, the pipe, or other envelope, will have a great bearing upon the distributions of viscous action. The shape of the envelope, for example, will have a great influence upon the form of the flow, and, therefore, upon the relative motion which must occur between neighboring filaments of the fluid. In other words, the coefficient of viscosity will be combined in some determinate manner with all the type-factors of the channel (including all dynamic type-factors), to form the two dimensionless coefficients, f' and f.

---

[68] "Collected Papers," Maxwell, Vol. II, pp. 31, 39, *et seq;* also *Philosophical Transactions,* Vol. CLVII, 1866.

[69] L'Ecole Polytech. (1829), tome XIII, p. 139.

[70] *Memoires* de l'Acad. des Sciences, tome VI, p. 389.

This will be entirely independent of that factor in F which contains the kinematic coefficient of viscosity in the numerator. There will be independent necessity for f' and f, since one relates to pure viscous action directed against the flow, as in the boundary film, while the other relates to pure viscous friction (the only kind there can be) within the eddies.

The pure viscous action directed against the flow must vary as the rate of distortion. Hence, because of the fixed relations of all average velocities at given points to the mean velocity in the cross-section, previously mentioned, the resulting resistance from this cause will be in proportion to the mean velocity in the cross-section directly.

The rate of eddy generation is produced and maintained by the action of the combined mechanism in converting mass-motion into turbulence. As in the preceding case, the rate of conversion must be proportional to the velocity at the point of conversion, and, therefore, to the mean velocity in the cross-section; but, in this case, the entire velocity changed to eddy motion must finally be dissipated by the viscous action in the eddy, so that the resulting loss of energy is proportional to the square of the velocity at the point of diversion, and also, therefore, to the square of the mean velocity in the cross-section.

Hence, there is but one natural mechanism for the conversion of fluid motion into heat; but this mechanism operates under two regimens, one of which is pure viscous resistance in "pure viscous" flow, and the other is pure viscous resistance within an eddy. Consequently, turbulent motion is only an intermediate stage of motion occurring temporarily in fluid flow, as between effective mass-motion and the ultimate molecular heat motions of the fluid. It is the result of one of those "irreversible" processes of Nature. It is merely one progressive stage in the universal degradation of energy enunciated by Carnot in the second law of thermodynamics, which was first understood and built into the foundation of the science of energetics by Lord Kelvin. Had it not been for the combined greatness of intellect and magnanimity of the greatest of philosophers it is a question whether Carnot's theory would be known to-day by his name.

Because there are only two regimens of viscous friction, there can be but two terms in Equation (122), one of which must clearly be proportional to the first power of the mean velocity when there is no turbulence ($f = 0$), and the type-factor, f', is constant (unity) by reason of the permanence of relative conditions in pure viscous flow (that is, the theory of pure viscous flow is perfect, and complete); the other of which must as clearly be jointly proportional to the square of the mean velocity and the whole type-factor, F. As between similar systems, F is constant. For changing conditions in a given system, F is variable. If the conditions in two systems are changed, but in such manner that the two systems remain similar, then the two coefficients, F, change equally and remain equal. Wave-making is distinct.

It must not be forgotten, however, that Equation (122) cannot be considered a complete formula of hydrodynamics, or of aerodynamics, until the type-factors, f' and f, have been replaced by effective generalized co-ordinates. Hence, in closing this section, it cannot be emphasized too strongly, that engineers who would make discoveries by means of Newtonian models, should begin the experimental study of turbulent flow at the very earliest opportunity. Success in this respect will enable the engineer to fill the great lacuna of fluid dynamics, which is treated in the following section.

(*15*) *The Great Lacuna of Hydrodynamics and Aerodynamics.*—When the general nature of the particular mechanism involved in a particular apparatus (mechanism covering a particular class of machines and motions of parts and fluids) is correctly postulated, the general dynamical equations may be made to represent the mechanism by introducing the terms, or equations containing the new property coefficients (Class 1) which have been defined by the postulates. This creates a new science, or branch of engineering analysis, which thenceforth becomes capable of solving all problems that involve nothing beyond the general nature of the mechanism defined.

Hence, the equations established by the postulations of the science will suffice to determine all the dimensionless type-coefficients of any particular apparatus of the class defined, thus rendering the use of purely dimensionless coefficients, as in empirical formulas, wholly redundant, since the solutions may proceed without explicit evaluation of the unnecessary coefficients.

This was illustrated by previous reference to Newton's creation of the dynamical science of pure viscous flow, solely by the definition of the coefficient of viscosity (Class 1), and by nothing else except his own laws of motion (see Class *b*, Coefficients).

It is now to be shown that no such science of turbulent fluid motion has yet been created, and that, in this respect, all the present sciences of fluid dynamics are wholly barren. To this end it will be highly instructive to make an exploration into these barren domains of dynamics to gain an exact view of the nature and extent of this great lacuna, at least as it relates to turbulent fluid motion:

First.—Solve a problem in "pure viscous flow;" say, that of Article 318, Article 319, or Article 320, Third Edition of Lamb's "Hydrodynamics" (the writer's solution of the pipe problem, Lamb's Article 319, is given in very simple terms elsewhere.[71] The other two problems may be solved with corresponding informality). Theoretically correct results are immediately and very easily deduced in each case in terms of a few working conditions (time included), boundary conditions, limits of integrations, and property coefficients (viscosity, density, etc.), results which are consequently independent of any system of co-ordinate axes. These given data become ultimate true "generalized co-ordinates" of the motions of the millions of particles involved, provided that care has been taken to see that these "co-ordinates" are independent of each other. Each such "co-ordinate" represents a "degree of freedom," which is nothing more than a degree of ability to change the form, or type, of the system and its motions. By means of them (or an equivalent system), a calculation may be made which will determine the instantaneous position of any given particle, or its path.

Observe that among these "co-ordinates" may be found the property-coefficient of viscosity, μ; another is the physical-constant, ρ, or density.

---

[71] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 835.

No non-property coefficients (dimensionless type-coefficients) are explicitly involved, as necessary to the solutions. If they were, the successes of the solutions could not possibly be ascribed to the accuracy of the science of hydrodynamics, for the solutions would have been wholly empirical as a consequence, to the extent that the hydrodynamic formulas would have been of no theoretical service.

Second.— Let one then attempt to solve a simple problem involving turbulent flow; say, the problem of turbulent flow in a pipe as discussed by Lamb.[72] A result is even more immediate than before, but only by use of a purely non-property, dimensionless, type-coefficient of "skin friction" (the usual empirical coefficient), of which the value cannot be found by any known hydrodynamic method, or formula.

It is this last fact which suddenly discloses the nature and extent of the great lacuna of hydrodynamics and aerodynamics, as a gaping void which the writer believes has not been fully appreciated hitherto, especially by hydraulic engineers. This great lacuna can now be bridged with theoretical accuracy only by Newtonian model engineering, or by constructing the full-sized structure, and then testing it in place. Under "Turbulent Motion," [73] Lamb states:

> "It remains to call attention to the chief outstanding difficulty of our subject. * * * It must unfortunately be confessed that the theoretical explanation of the instability of linear flow under the conditions stated, and of the manner in which eddies are maintained against viscosity, is still somewhat obscure. * * *"

These words are too mild. There is a complete failure of hydrodynamics and aerodynamics, for want of a correct theory of the mechanism and functions of viscosity, and perhaps, also, of another property, say, cohesion, in producing turbulent motion. It may be remarked, that determination of the rate of eddy generation will be sufficient to determine all the loss due to pure turbulence, since the kinetic energy of the eddies is all rapidly dissipated in the form of heat motions. By the "principle of fixed average type-factors" (see Article (11), "Type Factors and Form Factors"), the loss of head due to pure turbulence will appear in a term by itself which is proportional to the exact square of the mean velocity in the cross-section, or its equivalent. Any direct loss due to viscous action, as in the boundary film, will be directly proportional to the mean velocity, and must also appear in a term by itself, when the dynamical equations are finally perfected.

In Article (14), "The Nature of Turbulent Flow," the writer has endeavored to give his views as to the nature of the mechanism which must be expressed mathematically, in order to establish rational turbulent fluid dynamics. It should be mentioned that correct fluid dynamics cannot be created by use of the present hydrodynamical and aerodynamical equations. They will be barren for this purpose, until emended on the basis of enabling postulates, perhaps creative of new property coefficients.

(16) Confusing Laws.—It seems that the first positive step toward founding Newtonian model engineering was taken by M. J. Bertrand in his paper

---

[72] "Hydrodynamics," Article 344, p. 591.

[73] *Loc. cit.*, Articles 344 and 345

previously quoted and cited. After mention of Newton's similitude Bertrand refers to one of Galileo's dialogues in which the latter called attention (probably for the first time) to the fact that a large machine is not relatively so capable of resisting destructive loads as a small one.[74] (Stress is proportional jointly to linear scales and specific weights. This covers such quantities as moduli of elasticity, etc.). This very true remark has been repeated by numerous writers without reference to Galileo.

The criticism however, is based wholly upon the assumption that strengths of materials and the stresses to which materials are subjected must act without any application of the arts of the engineer to improve or preserve the proper relative strength in the model. If correct model engineering is to be applied, the argument would have no theoretical force; there would simply be a practical difficulty to be overcome by the engineer. To imagine that the criticism blocked the use of true dynamic models would be confusing the dynamical properties of materials with the laws of similarity.

The following discussion not only shows that confusion of ideas persists, but it will illustrate the truth of the fundamental corollary; show the characters of the two classes of coefficients, a and b; and give further suggestions as to the construction of dynamic models.

Bertrand states, and Routh repeats, that the ratios of homologous sliding frictions are correct since the friction is proportional to the pressure, but rolling frictions are not in correct ratios, since they are inversely proportional to the diameters of the homologous wheels. If resistances of air are proportional to areas and squares of speeds, the air resistance to the model will be correct. (The writer's paper[75] on "Ice Diversion," etc., gave this also).

It would be unfair to say of these authors that they really had the thought that similarity would be impossible in the case of rolling friction, and in the case of air resistances which do not vary as the square of the velocity; but they neither say, nor show, that it is possible, thus leading a hasty reader to assume that it is impossible. Other writers have made similar statements.[76] A caution against making an error of this kind is clearly stated under "Historic Background" in the writer's paper. It must be remembered that similitude is distinct from every other physical law. The only point of contact is when one of these physical laws happens, in its limited sense, to express the same relations stated or implied in Newton's Theorem of Similitude, thus causing the concomitant property-coefficients to appear in dimensionless type-factors, and, therefore, to be self-eliminating from relations between similar systems, as explained under Article (10), "Newtonian Cancellation of All Coefficients" (see Article (26), Conclusion No. 10).

Notice this feature in the following treatment of sliding and rolling friction. Consider a problem referred to by Routh:[77]

---

[74] *Transactions,* Am. Soc. C. E., Vol. LXXXII (1918), p. 1188; also, p. 288, Equation (26) of the present paper.

[75] *Transactions,* Am. Soc. C. E., Vol. LXXXII (1918), p. 1138.

[76] Units, Dimensions of, Eleventh Edition, Encyclopaedia Britannica, v. 27, p. 738, by J. Larmor.

[77] "Elementary Rigid Dynamics," Article 165, p. 138.

"A carriage (R. R., or horse) on n pairs of wheels is dragged on a level horizontal plane by a horizontal force, $2P$, with uniform speed. Find the magnitude of P."

By the fundamental corollary, no regard at all need be given to the fact that the machine is an old-fashioned carriage. The problem would be precisely the same for an automobile, or a locomotive. Of course, the actual design and construction of a model might be far more difficult in one case than in another. In the case of the carriage it may not be necessary to have regard to many properties, whereas, in the case of the locomotive, the model engineer would find plenty of use for his ability. Overcoming difficulties is one of the chief delights of a good engineer; to run in a rut is by no means so glorious.

To spot the physical properties requiring attention, one may glance at Equations (11), (12), (20), and (21), treating the first three as was done in the writer's paper. Equation (21) becomes simply, $L = R = f$, if f is the coefficient of rolling friction, of which the dimensions are merely length. The symbols refer to ratios of homologues. Since the coefficient of sliding friction is dimensionless, it is self-eliminating from ratios of homologues, so long as the rubbing surfaces are of the same materials, in which case it requires no further attention. There may be several different coefficients. Ratio G need not refer to gravitations. Suppose, for example, that (neglecting effects of gravity on parts like connecting rods) gravity is "eliminated" in the sense mentioned immediately following Equation (45), as by running the carriage on a level plane, not necessarily in a straight line. Then a proper ratio, G, must be preserved in Equation (12), or one could not start or stop the model consistently or operate it on curves.

Proper treatment of the equations of similitude gives for Equations (22), (23), and (24): $L = R = f$; $F = \rho f^3 G$; and $T = \sqrt{\frac{f}{G}}$.

Characteristics are, $\mu = 1$; $\frac{\text{weight}}{\rho f^3 G} = 1$, the symbols, of course, relating to ratios of homologues. The values, L, F, and T, thus found, in terms of known property ratios, give all other ratios of homologues, by use of properly dimensioned forms. Air resistance has been neglected, but may easily be included by the methods presented, if necessary.

If the same materials compose the rubbing surfaces in model and prototype, the density ratio of these will be inconsistent if the density ratio is not to be unity. Whether this is serious is a matter for engineering judgment. The difficulty may be avoided by: (*a*) Using the same or equivalent materials when $\rho = 1$; (*b*) using different combinations of materials giving equal coefficients, μ, when $\rho \neq 1$; and (*c*) by any artifice which gives proper values, as by change of lubrication, or even by use of a special bearing in the model, etc.

Thus, the solution is effected without knowing the exact nature of the prototype. Let the definite problem proposed by Routh now be solved. Suppose the carriage to be pulled along an asphalt pavement, for which, $f = 0.012$.[78]

---

[78] Kent's Handbook (1923), p. 1705.

Then, since $R = f$, a much better roadway must be selected for the model if it is to be small. The coefficient for a steel roadway may be $f = 0.001$, thus giving $R = 12$, the scale ratio. If the model is to be tested on a hill, gravity must act, thus making $G = 1$. As there seems here to be no important reason for change of materials in making the model, the density ratio may be unity. Therefore, $L = R = f = 12$; $F = 1\,728$; and $T = \sqrt{12} = 3.46$; from which, for example, the velocity ratio and power ratio are, respectively, $V = \frac{L}{T} = \frac{12}{3.46} = 3.46$; and $P = FV = 6\,010$, so that the power requirement for the model is very small. (Note that P varies as the density ratio.)

Turning to Routh's solution, it is now easy to show that the pull on the model is in the proper relation to the pull on the carriage, and that it is because the coefficients, μ and f, have been allowed to have, or made to have, proper values in the model by application of proper technique.

It is highly instructive to notice how the coefficients eliminate themselves, when taking the ratio of homologous members of similar equations, using any of Routh's three forms for P. This illustrates perfectly the theorem of the equality of homologous type-factors (Articles 4, 10, and 11). In this respect, the theories of fluids and rigid bodies are identical.

Nothing has been said of the properties of the roadways, beyond the values of f, since there would seem to be no great importance in this, unless elasticity and variations of f with velocity are to be considered. If necessary, elasticity may be treated as in the paper. If such matters are to be considered, it may be recalled that rolling friction offers a great field for the research engineer, since this form of friction is not thoroughly understood, while use of 20 000 000 automobiles in the United States indicates that much use could be made of a correct theory.

(17) *D'Alembert's Paradox.*—Professor Bateman has described this "paradox" in a most excellent article on "Hydromechanics and Hydrodynamics" in the Fourteenth Edition of the Encyclopædia Britannica. The writer thinks it is really not a paradox, because such phenomena as a stationary float, "dead water," log in a pool below a dam, and even a float moving up stream, are matters of common experience. The stationary sphere in D'Alembert's paradox (or stationary cylinder, in two dimensions) is secured by creating a system of forces symmetrically placed, proportioned, and directed, about the center of symmetry. This dynamical system, therefore, must hold the sphere in equilibrium when it rests at the center of symmetry.

Any one of the stream-line surfaces surrounding the sphere in infinite liquid may be chosen as the shape of a pipe, or conduit, which envelope, as a study of the figures presented by Lamb[79] shows, must swell out about the sphere, or cylinder, according with the shape of the body at the center of symmetry. The body will remain at rest in frictionless fluid only when at rest at the center of symmetry of this envelope. If the body (sphere or cylinder) is now displaced up stream somewhat, while the flow of liquid is throttled properly at some down-stream point to maintain down-stream pressure, the body will continue to move up stream with further closing of the throttle, until the flow is completely shut off or materially reduced by the body of the sphere (or cylinder) obstructing the inlet end. On the other hand, if the body is displaced down stream it will continue to move down stream until it cuts off the flow by choking the outlet end, or is itself ejected. Dynamically, there is no difference between the actions in the up-stream and down-stream ends, so long as the fluid remains frictionless.

---

[79] "Hydrodynamics," pp. 74 and 232.

It makes no material difference in the experiment if the fluid is viscous, say, water. The body will remain at rest if it is located at a proper point up stream from the original center of symmetry of the envelope, while the flow is properly throttled at the valve down stream. This results from the fact that the pressure is greater on the down-stream face of the body than on the up-stream face, by an amount just equal to, or greater than, the friction, or viscous drag, on the sides of the body. The experiment is most simply made by letting water enter horizontally through the depressed lip of a small bowl or hemi-spherical vessel. A bowl, or cup, of somewhat smaller size, partly filled with water to give it depth, when floated near the entering stream, will move toward and against the entering stream until it is stopped by the side of the vessel, supposing that the crest of the opposite side of the vessel is at an elevation slightly higher than the crest of the lip, but low enough to permit the water to spill over the side at that point. If the entering water has a downward component entering at the lip the effect is increased. Of course, a better apparatus can be specially constructed for laboratory purposes, but it will not be more instructive. The principle was used by the writer in planning ice diversion works at Massena, N. Y., to cause ice to tend to drift up stream from the divergent channel and then on down the main stream. The combined effect of this and the ridges accomplishes the object, and the ice drift is actually up stream when the draft of water is not in excess of the constructed capacity; even in the case of over-loading the intake, there is no consequential amount of ice entering the intake, because the power-house now operates all year, whereas, before, it was compelled to shut down in winter.[80] (See Footnote 5, p. 276.)

Returning to the case of a frictionless fluid flowing past a sphere, or a sphere moving in such fluid, Newton was quite correct in stating that a cavity would form if the pressure were too small for the velocity, or the velocity too great for the pressure, a fact seldom mentioned by writers, but which is noted by Lamb.[81] It is perfectly clear that, whether fluid is frictionless or viscous, the inertia of the fluid will cause a cavity if the velocity and curvature of the stream lines are great enough; and this is why there must be different accelerations in model and prototype under different pressures. (For effective areas of impact, see Article (18), "Momentum.")

(*18*) *Momentum.*—The coefficient of viscosity and the kinetic theory of gases have been brought into the discussion by several references. Neither of these subjects can be understood without a correct conception of the nature of momentum, the actual misuse of which concept is an error of no infrequent occurrence, especially in hydraulics. Routh's "Elementary Rigid Dynamics" contains two excellent chapters on momentum and *vis viva.*

---

[80] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1138.

[81] "Hydrodynamics," p. 98, under "Discontinuous Motion."

No formula for friction loss in fluid flow can be safely based upon a momentum change as an action isolated from the circumstances and details of that change. Without refined definitions and explanations the important relation for present purposes is:

Theorem IV.—A definite system of forces acting upon a definite mass (particle) free to move, produces a definite change in the momentum of the particle; but the converse is not true—a definite change of the momentum of the particle does not require any definite system of forces, for there are an infinite number of force-time relations which will produce the same change of momentum during the time of the action.

It is a most important consequence, that the time rate of change of momentum is not necessarily, and not usually, any definite general function of the forces existing at the beginning and end of the change. On the other hand, it must be understood that, although a definite change of momentum does not demand any definite system of forces, yet all systems of forces which produce that definite change must be equivalent to each other in the sense that the effective "whole force" is the same in all. In substance, Routh states that the resolved component in the direction, z, of the "whole force" expended in the time, $t_1 - t_0$, is defined by $\int_{t_0}^{t_1} m\,Z\,dt$, Z being the instantaneous component of the accelerating force acting upon the mass particle, m, in the direction, z.

Consider the case of a vessel discharging water at a velocity, v, through a horizontal pipe under the head, h. It is well known that the effective whole force causing that discharge through an orifice in place of the horizontal pipe, would be equal to a reaction on the apparatus due to twice the head, h, acting on the effective area of the orifice. This reaction must remain precisely the same for the case of the horizontal discharge, but the actual head on the discharge may be any whatever, depending upon the length and friction of the pipe. Hence, it is clear that there is no fixed relation between observed head (pressure) and change of the water's momentum. One must have positive knowledge of the circumstances of the change of momentum to be in a position to connect that change with pressures and potentials.

It is clearly incorrect to state (as usual) that the reaction of the discharge is "due to twice the acting head," for there is no possibility of a double head. The error lies in the customary statement which, properly, should read to the effect that it is the area upon which the head acts that must be doubled. This will be clear when one observes that in a reservoir the water must be accelerated from rest to a velocity of discharge, v; that is, the mechanism of the usual reservoir can provide an acceleration averaging only half ($\frac{1}{2}v$) sufficient. Therefore, the area of approach must be double the effective orifice (*vena contracta*) area to supply water enough. That area is provided by automatic reduction of the pressure on the side of the vessel in the vicinity of the orifice—thus admitting flow to the orifice from all directions—and it is here very interesting to observe that the convex area of a hemisphere is exactly twice the area of its base. If double pressure could be made effective in the reservoir, without alteration of the head, no drop in pressure around the orifice would occur; but that is clearly impossible in the absence of extra mechanism. Statistical analysis would develop an infinite number of equivalent methods of approach to the orifice, all giving the same reaction.

Another illustration of loose uses of the principles of momentum is furnished by the formula, $\frac{(v-v')^2}{2g}$, for the friction loss due to abrupt change of pipe section. This formula appears in many of the older textbooks. That it still persists is shown by the fact that Professor Gibson[82] uses it, and without explanation, leaving the reader to assume that wherever there is abrupt increase in section the entire change of momentum is lost, instead of being conserved to a greater or less extent, depending upon the circumstances of the change. William C. Unwin, Hon. M. Am. Soc. C. E., was careful, in giving the original deduction of the formula[83] to explain that it was based upon an assumption as to the pressure at the beginning and end of the action, and that it was equivalent to saying that the change of momentum is wholly lost. Necessity for this assumption and its explanation, so carefully made by Professor Unwin, is the criterion of Theorem II which shows that the problem of loss due to sudden expansion, and its formula, $\frac{(v-v')^2}{2g}$, fall within the great lacuna of fluid dynamics previously disclosed. This problem cannot be solved solely by the principles of momentum (insufficient dynamics) until the physical mechanism of turbulence has been properly introduced into dynamics. Meanwhile, tabulations of values for the empirical coefficients to be applied directly to the velocity head are to be preferred.

It may be emphasized again in other words, that no problem in correct dynamical physics can be solved without use of the dynamical physical constants defined by the theory of the particular branch of science to which the particular problem belongs. To this extent Newton's laws of motion are insufficient, *per se,* to the solution of any problem. On the other hand, they are necessary to such solution. The postulates of a science defining physical constants merely describe the mechanism which governs the application of Newton's laws by showing how they are to be applied. It is in this way that Newton's laws form the footings for all branches of mathematical dynamics. Stokes' failure to notice this in the case of viscosity was discussed in connection with Equation (10) of the writer's paper. This insufficient but necessary application of Newton's laws may be the cause of so much misunderstanding as to the status of pure dynamics.

That the formula, $\frac{(v-v')^2}{2g}$, really has no place in fluid dynamics is shown by the well-known fact that an "open," or "free," jet of water entering a large reservoir by abrupt expansion of section at entrance is capable of supporting a very material head of water in the reservoir. This head, therefore, must be conserved from the kinetic head existing prior to the change of momentum; thus, a corresponding part of the momentum is also conserved.

---

[82] "Hydraulics," Encyclopaedia Britannica, Fourteenth Edition, Vol. 11, p. 972.

[83] Encyclopaedia Britannica, Eleventh Edition, Vol. 14, "Hydromechanics," pp. 45-46.

A clearer understanding of fluid dynamics will be cultivated, if the criticized type of analysis is abandoned; especially if, at the same time, the terms, "shock" and "impact," are changed to "rate of delivery of energy to the sinks of viscosity." This latter term, or a descriptive abbreviation, will be a constant reminder of the true nature of all energy losses in hydraulics, and will point to the right path for the research engineer to follow, in formulating the dynamical science of eddying motion. The latter is all that is needed to complete dynamical science as to viscosity. When that is accomplished, there will be no further need for empirical coefficients of hydraulic friction, since the perfected science will determine all friction losses, just as the present science of pure viscous flow now solves all its problems without necessary recourse to special coefficients for special problems.

(*19*) *Momentum Transfer.*—The foregoing remarks on momentum will be a great help relative to the questions of momentum transfer, as raised in the discussion. The misuse of this concept has resulted in a most serious fundamental error in the deduction of the formula connecting the molecular free paths with the coefficient of viscosity of a gas. Before disclosing and correcting this error, however, it will be necessary to explain the nature of momentum transfer by several homely but perfect illustrations.

Suppose two railroad trains traveling at different speeds in the same direction along two parallel tracks, as a passenger train moving at 60 ft. per sec. on one track, and passing a freight train moving at 40 ft. per sec. on the other track. If a ball is thrown laterally (perpendicularly, horizontally) from the freight train so as to impinge on the smooth flat front of a passenger coach, the ball will "transfer" 40 ft. per sec. of "freight" momentum, which will be increased by $60 - 40 = 20$ ft. per sec. by the impact (necessarily supposed inelastic), which is exactly sufficient to increase "freight" momentum to "passenger" momentum, by the mutual impulse between the ball and passenger train. Observe most carefully that there is no mutual impulse, or action, in the direction of train motion, between the ball and freight train, because the ball is thrown "laterally;" it is the passenger train which meets the resisting impulse. The lateral component motion of the ball will not be altered, as there is supposed to be no friction between ball and front of cars, except that of inelastic impact in the direction of train motion. It must also be carefully noticed that the "lateral" impulse of throwing the ball has no effect at all upon the freight train in the direction of train motion. It is most important of all, in the question about to be considered, to remember that the mutual impulse of two bodies necessary to bring them to the same motion in any given direction must necessarily be wholly inelastic in that direction. It is about to be shown how a virtually inelastic impulse can be generated by collisions of perfectly elastic bodies.

If, now, the ball is thrown laterally from the passenger train to the freight train, so as to impinge on the smooth flat rear of a freight car, the ball will transfer 60 ft. per sec. of "passenger" momentum, which will be decreased 20 ft. per sec. by the inelastic impact necessary to decrease passenger momentum to freight momentum. There is no mutual impulse, or action, in the direction of train motion, between the ball and passenger train, because the ball is thrown "laterally;" it is the freight train which feels the accelerating impulse.

If the trains were moving at the same speed in the same direction, the lateral transfer of a ball carrying the momentum of either train to the other would have no impulsive effect on either train in the direction of train motion. The two trains may be of equal weight. The freight train may consist of an engine drawing a "string of flats," one flat for each passenger coach engine and tender. Each flat may be equipped with a powerful crane. If then, the cranes should load the passenger train on to the "flats," the total momentum of the freight train will be doubled, but no impulse will occur in the direction of train motion, because of the equal speeds of the two trains during the loading. Another illustration is provided by imagining each molecule arriving in any stream of molecules to be piloted by one of Maxwell's "demons" in such a way that it does not collide with any molecules of the stream. No resisting impulse to the flow of the stream can occur.

The conclusion is that mere transfer of momentum from one position to another, as by motion of a particle carrying momentum from one system to another, has no impulsive effect, by itself, and that it is only when the particle arriving in a system has its velocity changed thereby, that any impulse can occur by reason of the transfer:

Theorem V.—The mere removal of a mass from, or its addition to, a system of particles moving with a common velocity, cannot have any impulsive effect upon the system when that mass has initially the common velocity of the system, or when it does not collide with any molecule of the system.

It is failure to recognize this fundamental truth which has caused the serious error in the kinetic theory of gases as mentioned in the foregoing remarks.

(*20*) *Kinetic Theory of Gases.*—Before explaining the nature of the error in the kinetic theory, it will be well to review a few of the principles of that science, especially in its relation to hydrodynamics and aerodynamics; for engineers will wish to be familiar with every science which is alleged to be useful in model theory, whether the allegations can be supported or otherwise. If the allegations are true, it will be all the more important to learn that the kinetic theory cannot be applied with accuracy in any way until the existing errors are corrected, not only in formulas, but also in the numerous constants which have been computed by them. Moreover, there is still another error which affects the kinetic theory in its relation to hydrodynamics, and this, too, will be made clear by reference to the writer's remarks under Article (15), "The Great Lacuna."

In adding this necessary corrective contribution to kinetic theory the writer asks merely that engineers base conclusions upon analysis of what is said, rather than rely upon supposed authority. The lack of such careful constructive analysis and consideration is clearly evident in some statements made in the discussion. The writer attributes this to no prejudice, but, rather, to insufficient attention to his presentation, and to the consequent failure to confine those statements of discussion to actual facts. By ascribing false ideas and remarks to the writer, one is certain to arrive at false conclusions, however apparently correct the logic may seem.

The great lacuna of hydrodynamics was disclosed under its appropriate heading. It follows at once, that any theory which connects relations between existing hydrodynamics and the kinetic theory of fluids must be either wholly invalid, or at least open to the gravest suspicion, as to every relation which involves turbulent motion of the fluid. This conclusion is of particular force relative to the calculation of the coefficient of viscosity from assumed conditions which involve nothing more than a state of pure viscous motion, when the coefficient is intended for use under conditions of turbulence. In other words, the great lacuna spreads itself over into the domain of the kinetic theory, which, consequently, must be quite as barren in the region of turbulence as hydrodynamics itself. Therefore, both these sciences are unfit, in their present state, to solve the simplest problem in their respective fields, when turbulence and eddy motion are involved. Neither science has yet been equipped with the complete mechanism of viscosity, the prime cause of all fluid friction, as previously shown for hydrodynamics, and, hence, for all its relations to other sciences.[84]

Space here cannot be devoted to any study of kinetic theory, beyond that necessary to answer questions arising from the discussion. Should the engineer be interested in deeper studies, reference should be made to the best works upon the subject, of which there are surprisingly few in the English language. A treatise by Sir James Hopwood Jeans includes the statistical theory and quantum dynamics.[85] From the chemical point of view, the work of Oskar Emil Meyer describes the kinetic theory at the time of its most rapid primary development.[86] It was first published in German in 1877 and was later translated into English by Robert E. Baynes. The only recent publication in the United States is the work of Leonard B. Loeb,[87] which describes the most recent experiments. All other treatises on this subject are referred to in these books with one exception which, unfortunately, has received little or no notice. That is the work of Severinus J. Corrigan,[88] which the writer believes is really based on the first idea of the nature of the "electron" and "quantum."

While some preliminary "excavation" had been made, the first three "foundation stones" of the theory were: (1) Experimental discovery by the botanist, R. Brown (1827)[89] of the microscopic "Brownian Movement" among small particles of matter suspended in a liquid, motions now known to result from "bombardment" by molecular motions of the liquid. Not until 1911 was there any extension of experimental knowledge of such motions among gas molecules. At this time, the experiments of Professor R. A. Millikan,[90] of the University of Chicago, showed that minute oil drops floating in air were certainly subjected to visible bombardment by gas molecules, movements which could be measured and plotted into a diagram for statistical analysis; (2) Joule's[91] experimental determination of the mechanical equivalent of heat, and his application (1848) of the kinetic theory showing that the temperature, internal energy, and pressure of the gas, were associated with the kinetic energy of molecular motion. The mechanical equivalent connected external work and internal energy with the specific heats. He also showed that the total molecular kinetic energy in a gas volume must be distributed equally among any three rectangular directions chosen at will; thus, one-third the molecules in the volume may be considered to move parallel to each of any three rectangular co-ordinate axes, which gave at once an approximation to the mean molecular velocity (square root of mean square); and (3) in 1859, Maxwell[92] published his first paper on the "Dynamical Theory of Gases," in which he promulgated the idea of applying the formal theory of probabilities as treated in the method of least squares, to the random velocities of the molecules, which he assumed had equal possibilities in all directions, the magnitudes of the velocities being distributed among the molecules according to the law of error, which, as applied in the kinetic theory, is called "Maxwell's Law." Many other great names are associated with the kinetic theory. They must be sought in the references to gain a correct notion of the labors of these men. The quantum theory of Planck will also be found. The work of the first three mentioned is that most closely associated with the questions now to be discussed.

[86] "The Kinetic Theory of Gases," by Oskar Emil Meyer.

[87] "Kinetic Theory of Gases," by Leonard B. Loeb, 1927.

[88] "The Constitution and Functions of Gases, the Nature of Radiance, and the Law of Radiation," by Severinus J. Corrigan, Pioneer Press Co., St. Paul, Minn. (1895).

To gain some idea of the absolute magnitudes of the kinetic theory, one may consult Jeans' treatise (page 8), or Loeb's (Appendices I and III), both of which have been previously mentioned. Some of these magnitudes are:

Number of molecules per cubic centimeter, Avogadro's number	2.7×10^{19}
Number of molecules per gramme molecule, Loschmidt's number..	6.06×10^{23}
Electronic charge in electromagnetic units...........	1.59×10^{-20}
Molecular diameter of hydrogen, in centimeters........	2.32×10^{-8}
Velocity of hydrogen molecule, in centimeter seconds....	18.39×10^{4}
Hydrogen mean free path, in centimeters..............	1.83×10^{-5}

This exhibit certainly warrants Jeans' conclusion, or statement,[93] that the kinetic theory is so "fine-grained" that "the phenomena exhibited by a gas constituted in the way described will be indistinguishable, so far as experiment and observation go, from those of a continuous medium."

(*21*) *Kinetic Theory Unnecessary in Model Engineering.*—This follows from what has just been said, but the writer has shown the same thing in quite another way, by means of Equations (10), (11), (20), and (21) and their fundamental corollary, previously stated. The necessary and sufficient conditions for similarity are expressed by only the first three equations. If any two systems whatever, satisfy these three equations, the two systems will be similar, regardless of their nature and form. If it is then required to introduce into the systems some new dynamic physical action, it can be done by adjusting the appropriate physical constants by means of Equation (21), which equation may call upon the engineer in charge for certain assisting technique. It follows that, if the technique is required only to adjust the physical constants of continuous matter, or of discontinuous matter found by experiment to satisfy the assumption that it is continuous, there will be no necessary use for any theory of discontinuous matter, such as the kinetic theory; and, as experiments without number have shown gases to act as continuous substances for the ordinary problems of engineering, there should be no urgent need for the use of the kinetic theory in model engineering.

On the other hand, the writer sees no reason at all why the kinetic theory could not be applied, had there been defined and determined the proper physical constants necessary to set up a model gas, or even a model atomistic atmosphere, for example. When the atomistic theory is completed, and experiment has been applied to the corresponding mechanisms, it will almost surely be found that Nature has already provided many atomistically similar systems. In another generation as remarkable as the past, as it was with radio, engineering science may enable every school boy to construct atomistic models by means of "stock parts" on sale at the nearest variety store.

The conclusion is that gases, as well as liquids, may still be treated as continuous, and that the kinetic theory has found no place in model engineering, especially since it was shown in Article (15) that the great lacuna of fluid dynamics also extends to the kinetic theory, as it relates to problems in turbulent flow.

(*22*) *Limitations of a Science not Necessarily Limitations on Newtonian Model Engineering.*—This question is involved in Professor Bateman's reference to Professor Dr. Th. v. Kármán's work. The very next, and more extensive, article in the same journal, which is also by Kármán, is even more interesting than the former.

Nothing illustrates the truth of the proposition better than the facts disclosed in the writer's paper, and this closure, that, although hydrodynamics is a barren science in the domain of turbulent motion, a true model of a hydraulic system may be constructed so as to perform with theoretical exactness, because the only physical constant upon which turbulence depends is known with practical accuracy—the coefficient of viscosity.

All that is needed to complete the theory of hydrodynamics is to know the complete functionality of the coefficient of viscosity, that is, the complete method of its operation. By the fundamental theorem of similarity the construction of a true dynamic model is entirely independent of any method of operation or mechanism. It depends only upon Newton's law of similarity, and the engineer's ability to match physical properties, materials, and general conditions against that law, as indicated by Equations (10), (11), (20), and (21). In other words, the great lacuna of hydrodynamics does not extend into the domains of Newtonian model engineering.

Properties, materials, and general conditions being made by the engineer to satisfy the requirements of Newton's law of similarity, the model will be similar to the prototype regardless of the functions of the physical constants. This is the great advantage of a Newtonian model, which becomes a veritable calculating machine for the solution of the most difficult problems of mechanics.

It is concluded, that a model in the region of the Brownian motion (a model particle suspended in water, say), as suggested in Professor Kármán's papers, does not depend for its accuracy upon the motion, but only upon the compatibility of the physical constants which govern the Brownian motion, properties of molecules, etc. A Newtonian model constructed on these lines must be exact, even in the Brownian region. In the same way, in passing to the region of the velocity of sound, the engineer is not at all concerned with that fact, but only with the physical constants which control that velocity; that is, with the modulus of elasticity and viscosity of the gas. If these have been properly treated, the model will perform with accuracy with respect to the propagation of sound. No attention need be given to the detailed mechanics of the propagation. This is another question answered in its relation to Professor Kármán's papers, as referred to by Professor Bateman.

The velocity of a projectile is another such case. Although the laws of resistance are not at all known theoretically, yet, if the physical constants (viscosity and elasticity, certainly) are known, there is nothing to obstruct a Newtonian model, other than the difficulties of engineering technique. The celebrated tests of Bashforth on projectiles are described under the title "Ballistics" in several editions of the Encyclopaedia Britannica. It seems to the writer that viscosity and elasticity should explain all, and that it is more than likely that similarity would obtain in a Newtonian model of air and bullet. It could not obtain in air as a model of itself, unless the pressure and viscosity are properly adjusted, as in the writer's Appendix I.

(23) *Coefficient of Viscosity—Fundamental Error in Theory.*—The questions raised in the discussion relative to viscosity led the writer into investigation yielding prodigious results. The most consequential of these is the discovery of an error made by Maxwell in the use of momentum in the original deduction (1859)[94] of his formula, $\mu = \frac{1}{3} \rho \bar{c} l_*$ connecting the coefficient of viscosity of a gas with the density, molecular mean velocity, and molecular mean free path for the same gas and its molecules. This disclosure shows that the values of the mean free path which have since been calculated by

---

[94] *Philosophical Magazine*, June and July, 1860; "Collected Papers," Maxwell, Vol. I, p. 377.

Maxwell's formula from experimental observations of the coefficient of viscosity, must all be doubled, in order to effect the necessary correction. The last statement is founded also upon another disclosure of the investigation, showing that the error mentioned has never before been corrected. The full consequences of doubling the values of all the free paths hitherto calculated by the erroneous formula, and its more recent modifications, will be appreciated when it is recalled that these calculated values, of which there are a great many, should give the most reliable values of the sizes of the molecules of the various gases, since the diameters are known functions of the free paths, by a formula first deduced by Clausius and almost immediately afterward corrected, as to numerical coefficient, by Maxwell (1859).

The writer so concludes from the statements of Jeans[95] and Loeb. The latter states:[96] "The measurements of μ afford the best values of l obtainable."

Maxwell's law applied to Clausius' free path gives the relation, $l = \frac{1}{\sqrt{2}\pi\sigma^2 N}$, connecting free path, l, with molecular "diameter," σ, N being the number of molecules per unit volume ("molecular density"). Hence, it is clear that all previous values of σ calculated from the erroneous values of l must be reduced in the ratio of $\sqrt{\frac{1}{2}}:1$, since σ^2 must be changed inversely as l is changed, in order to effect the correction. All other values calculated from the erroneous free path will also be in error by corresponding amounts. Textbooks should be revised as to relations between the coefficients of viscosity, conduction, and diffusion.

This error, universally committed in the deduction of the formula for the coefficient of viscosity in terms of the free path, consists in the misuse of the concept of momentum and its transfer as previously discussed. Newton's law states that "change of motion is proportional to force applied, and takes place along the straight line in which the force acts," but it is not stated that force must result from every change of momentum. When Newton said "change of motion," he referred to motion, not momentum. For example, one may increase, or decrease, the momentum of a system by adding to, or abstracting from, that system amounts of mass without changing their velocities, as in the manner described in Article (19), "Momentum Transfer." No force, or impulse, results from such a change of momentum, that is, a change of mass with no change of motion.

Therefore, having careful regard for Newton's laws of motion, the coefficient of viscosity of a gas may be calculated as follows: Assume that the gas flows horizontally in the positive direction of the conformably chosen x-axis of right-hand rectangular co-ordinates, $x\ y\ z$, positive direction of z being upward. Suppose, furthermore, that the gas is limited by two horizontal planes, $z = z_1$ and $z = z_2$. The lower of the two planes, $z = z_2$, is considered at rest, the motion of the gas being created by the positive motion of the upper plane, $z = z_1$, on the theory that there can be no slip along a boundary surface as between that surface and the gas. Thus, molecules of gas in contact with the upper plane (face of a belt) must be dragged along with the plane until their "molecular motion" (heat motion) causes them to spring away with downward component velocity averaging perpendicular relatively to the upper plane for a distance equal to the "mean free path" before they can collide with another molecule. It is also a supposition of the theory, that each molecule traveling over a free path carries with it the horizontal motion ("mass-motion," as distinct from molecular or heat motion) appropriate to the point of beginning of the free path. Therefore, a particle springing on to the lower face of the upper plane will reach it with a deficient velocity, since the mass-motion is horizontal and must gradually decrease to zero at the lower plane, $z = z_2$.

---

[95] "The Dynamical Theory of Gases," p. 326.

[96] "Kinetic Theory of Gases," p. 188.

Under these circumstances, the transverse velocity gradient, $\frac{du}{dz}$, of the mass-motion of velocity, u, parallel to the planes and the x-axis, becomes constant from one plane to the other, and may be represented by a straight line sloping forward and upward in the positive direction of mass-motion. Molecules arriving in the lower plane, $z = z_2$, will have only the slight component mass-motion, $l\frac{du}{dz}$, due to an average elevation of one mean free path above the plane, while those in equilibrium in the plane, $z = z_2$, and also those traveling upward in the first free path, l, above that plane, will have no mass-motion, since the plane, $z = z_2$, is supposed to be at rest.

It is also necessary to understand why the velocity gradient, $\frac{du}{dz}$, will be constant under the circumstances supposed. (The mechanism is an ingenious device of Maxwell to simplify the analysis.) It is not only because the planes, $z = z_1$ and $z = z_2$, are infinite in their horizontal dimensions, but (which is much more important), because the gas pressure is tacitly assumed to be uniform in each horizontal plane; there is no pressure drop along the direction of flow. If there were, $\frac{du}{dz}$ could not be constant, for, otherwise, the shears on the upper and lower surfaces of a horizontal layer of the gas would be different, which cannot be the case for non-accelerated mass-motion. In other words, the only source of energy to keep the gas in motion is that supplied to the molecules of the gas which reach the upper plane (lower face of a moving belt) with deficient mass-motion, and which, therefore, must be accelerated by the contact with the upper plane. The mere assumption of a steady state of motion is not sufficient, by itself, to establish a constant transverse velocity gradient (the steady flow in a capillary tube is a practical illustration—the velocity gradient is a parabola).

By Joule's law of energy distribution, one-third the molecules of the gas, and, therefore, one-third its mass, may be considered to move parallel to each of the three rectangular co-ordinate axes, and with the mean molecular velocity, c; one-sixth the molecules, or mass, positively, and one-sixth, negatively. Moreover, each molecule, on the average, moves over one mean free path, l, between any two of its consecutive collisions. Hence, each time an upward moving molecule collides, it will, on the average, have its velocity increased by $l\frac{du}{dz}$ units. Correspondingly, a downward moving molecule will have its velocity decreased by $l\frac{du}{dz}$ units. By the principles pointed out under Article (19), "Momentum Transfer," no molecule, or molecules, can experience any change of mass-motion when any molecule leaves its position in any horizontal plane to pass to another parallel plane, for it is supposed to have acquired the mass-motion of the plane which it leaves, before taking its departure.

Now, to find the effective "shear" on any plane parallel to $x\ y$, one may proceed exactly as in finding the shear on any section of a rigid structure, as by the "free-body method." Hence, for a gas, this may consist in finding the "shearing stress" per unit area on the lower face of the portion of gas above the plane of shear, which may be at any elevation, $z = z_0$.

The mass passing up through the unit area of the plane, $z = z_0$, of shear must (by Joule) be $\frac{1}{6}\rho\bar{c}$ per unit time (ρ being the density), while its change of momentum in the x direction must be, by the ensuing action, that due to the increase, $l\frac{du}{dz}$, of velocity in passing over the distance, l, in the positive z direction. This change of momentum demands a "whole force" on the mass, $\frac{1}{6}\rho\bar{c}$, in the positive x direction of $\frac{1}{6}\rho\bar{c}\,l\frac{du}{dz}$, which, consequently, is the required negative effective "shearing stress" per unit area, exerted on the plane, $z = z_0$, and by similar reasoning, on any other parallel plane in Maxwell's particular mechanism herein used.

Therefore, considering the well-known formula, $S = \mu\frac{du}{dz}$, for the shearing stress on a plane in a viscous liquid, it is concluded that the coefficient of viscosity of a gas is, $\mu = \frac{1}{6}\rho\bar{c}\,l$, in which, the numerical coefficient is exactly one-half the value found by Maxwell and all other analysts since his time.

By similar reasoning, the shear on the same unit of area, considered as part of the upper face of the portion of gas lying below the horizontal plane of shear, will be found to be the same as before, but in the opposite direction, just as with rigid bodies.

The error which Maxwell and subsequent analysts have made, consists in adding the changes of momentum which are experienced by both the upward and downward moving molecules, just as though a molecule upon leaving the upper volume should require a change of motion, $l\frac{du}{dz}$, before it could depart; but this is evidently not true, for it is supposed by Maxwell that each molecule starting its free path has only the mass-motion appropriate to the starting point, just as a ball thrown laterally from a railway train has no mutual action and reaction with the train in the direction of train motion, as explained under Article (19), "Momentum Transfer." Therefore, it is an error to integrate the molecular impulses throughout the whole volume of the gas above and below the plane on which the shearing stress is required, since it is perfectly clear, by Newton's laws, that the integration should extend only throughout the volume on one side of the plane of shear, in order to find the shear on that plane.

In other words, as confirmed by the principles of statics, and as made clear by the free-body method (a most valuable aid to the elastician and structural engineer), the shear on the plane is in equilibrium with the forces on only one side of that plane. The integration in the volume above the plane gives the shear on the plane considered as the lower face of the free body above the plane; the integration in the volume below the plane gives the equal and opposite reactive shear on the plane considered as the upper face of the free body below the plane. It is simply an application of D'Alembert's principle enabling one to treat a problem in dynamics by the method of statics.[97]

This is a very simple matter, but very deceptive, owing to the fact that transfer of momentum, by itself, without reference to the circumstances of that transfer, is not associated with any definite impulse.

In pointing out the nature and amount of the error just disclosed, it was not at all necessary or desirable to introduce the detailed ideas connected with the distributions of random velocities, directions, and free paths, since the error consists merely in doubling the result of an integration involving such distributions, and does not consist in any error of statistical analysis, other than the errors in one set of limits of integration due to the erroneous doubling.

Of course, the foregoing does not relate in the least to those numerous corrections of the numerical coefficient of $\rho \bar{c} l$, which from time to time have been proposed or adopted by reason of changes in the method of averaging. The error herein disclosed is quite distinct from any of these others.

As mentioned in Article (19), "Momentum Transfer," the only way in which two or more bodies can be brought to a common velocity by their mutual impacts, is that the impacts be wholly inelastic, or have the precise effect of such inelastic impacts. Hence, it remains to be explained how it can be, that the supposedly "perfectly elastic" mutual actions of the molecules of the kinetic theory can become effectively inelastic when changes of mass-motion require consideration. A little reflection will soon convince one that the very existence of the kinetic theory depends upon a satisfactory explanation of this possibility. Otherwise, the kinetic theory must fall, because it would be impossible for molecules to be both elastic and inelastic at the same time. The explanation follows.

(24) Independent Verification of the Writer's Calculation.—Since the velocity of a given body cannot be brought to the common velocity of a stream of other bodies by their mutual actions and reactions, except by an impact, or aggregation of impacts, of resulting inelastic nature, it is neces-

---

[97] See Maurer's "Mechanics," First Edition, Article 146.

sary to explain the possibility stated in the proposition in Article (23), or the kinetic theory which connects mass-motion with molecular motions must collapse. This follows from the accepted fact that the mutual actions of the kinetic theory are "perfectly elastic," or, more properly described, wholly "conservative"; and, further, from the axiom that the action of a molecule cannot be conservative and non-conservative simultaneously.

It will appear that the proposition is true because of the presence of two mutually convertible types of motion—molecular (heat) motion and mass-motion. If, in a series of mutual actions between molecules, some of the mass-motion is converted into molecular motion, the energy of the latter may be regarded as having been dissipated, in so far as mass-motion is concerned. The convertibility of mass-motion into heat motion is the necessary mechanism which supplies to elastic molecules the property of effective inelasticity; the "dissipated" mass-motion thus becomes the energy "lost" by "inelastic impact."

The general problem of impact is usually treated in books on dynamics (see Routh's treatise on momentum,[98] previously cited), but the writer doubts that the problem here to be treated has received much attention; that is, the effect upon a molecule which is suddenly placed in a stream of other molecules. Detailed analysis agrees with the abbreviated method that follows.

When two bodies bring themselves to the same velocity in the same straight line by an impact (as, for example, during the "axial" collision of two perfectly elastic spheres at the instant when "restitution" begins), it is doubtless well understood that there must be dissipated, or stored, an amount of energy exactly equivalent to that exchanged between the two bodies in order to accelerate one and retard the other sufficiently to equalize their velocities. In the perfectly elastic axial impact of two equal spheres, therefore, the numerically equal variable acceleration of one body and variable retardation of the other, must continue after restitution begins, so that, owing to mechanical symmetry and the equality of action and reaction, the restoration of resilient energy must occur by a continuance of the respective variable acceleration and equal variable retardation, until the two equal spheres have exactly exchanged their original velocities which existed before the axial collision. At this instant the resilient energy has been fully restored to kinetic form. If the spheres are not equal, the statement is precisely the same if, instead of the word, "motion," or "velocity," the word, "momentum," be inserted, thus harmonizing the ideas of elastic collisions and "conservation of momentum." In using the word, "momentum," in this way, however, the greatest care must be taken not to violate Newton's laws of motion, as clearly explained under Article (18), "Momentum," and Article (19), "Momentum Transfer." Otherwise, the theorem of conservation of momentum does not apply at all. It is the eccentric collisions which cause dissipation.

In Maxwell's mechanism, described in Article (23), the number of molecules and the total kinetic energy at any level continue the same, since the density and motion of the gas are supposed not to change. Therefore, for every molecule which enters a level another must leave that level; and for every amount of energy, $\frac{1}{2} ma^2 = \frac{1}{2} m\left(l\frac{du}{dz}\right)^2$, deposited (or withdrawn) in any level, an equal amount must be rejected (or received) by that level. If, on the whole, Maxwell's mechanism supplies an excess energy to any or all levels, that energy must be rejected as mass-motion to re-appear as molecular motion.

---

[98] "Elementary Rigid Dynamics."

The upper plane (moving) delivers kinetic energy to the molecules impinging upon it from below. These molecules then spring downward, and, on the way down, have an excess velocity at every elevation they reach, owing to the fact that the excess velocity, a, is always dropped (Maxwell's hypothesis) during the passage of the molecule over each vertical mean free path, l, on the way down, or at the rate, $\frac{a}{l}$, per unit length of the vertical.

The molecule itself may not travel to the lowest plane on account of its frequent collisions with other molecules, but, since it transfers only its excess energy to other molecules, the amount retained by the molecule is always exactly appropriate to any level in which the molecule may linger.

Maxwell's mechanism clearly requires that, for every molecule which arrives at any level bringing with it the energy, $\frac{1}{2} m (v + a)^2$, from above, another molecule must arrive at that level bringing with it the energy, $\frac{1}{2} m (v - a)^2$ from below, and that, simultaneously, two other molecules, or these same two molecules, must leave the level carrying away with them the energy, mv^2. Therefore, for every molecule which reaches any given level from either above or below, but not from both directions combined, there will be delivered over every vertical mean free path an excess energy of $\frac{1}{2}m\left[(v + a)^2 + (v - a)^2 - 2v^2\right] = ma^2$, which, accordingly, must be dissipated in molecular (heat) motions. This dissipation is at the rate of a^2 per vertical mean free path per unit mass passing down, or up, but not both.

By Joule's rule, the rate of molecular flow of mass, in only one direction of the vertical, must be $\frac{1}{6}\rho\bar{c}$ per unit horizontal area per sec. Hence, the rate of dissipation, or power loss, is $\frac{1}{6}\rho\bar{c}a^2$ per vertical mean free path, l, or $\frac{\frac{1}{6}\rho\bar{c}a^2}{l}$ per unit volume per sec. Substituting the value of a, the time-rate of dissipation of energy per unit volume of Maxwell's device is, $\Phi = \frac{1}{6}\rho\bar{c}\,l\left(\frac{du}{dz}\right)^2$, in which, Φ is the dissipation as expressed by Stokes (1850).[99]

By substituting the proper values of the differential coefficients, appropriate to this analysis, in Lamb's Equation (8) (or in Stokes' expression, which is the same, when the density is made constant), to get the value of Φ, remembering that, in Maxwell's device, u is the velocity parallel to x, $2g = \left(\frac{du}{dz}\right)$, and $a = b = c = f = h = v = w = 0$ (see Lamb's Articles 30 and

---

[99] "Hydrodynamics," Lamb, Third Edition, p. 541, Equation (8), and footnotes. See, also, Stokes, "On the Effect of the Internal Friction of Fluids on the Motion of Pendulums," *Cambridge Transactions*, Vol. 9, p. 58, last expression.

317), involving different notation; that is, $a = (\frac{du}{dx})$, one easily finds $\Phi = \mu \left(\frac{du}{dz}\right)^2$, in which, μ is the coefficient of viscosity of the fluid of constant density.

Therefore, after comparing the two values of Φ, it is concluded that the coefficient of viscosity of a gas is, $\mu = \frac{1}{6} \rho c l$, which agrees exactly with the value deduced previously by the correct use of properties of momentum.

It is permissible to use the hydrodynamical equations as being rigorously exact in the foregoing method of deducing the formula for the coefficient of viscosity of a gas, since the problem treated does not lie within the region of the great lacuna of hydrodynamics.

If one does not wish to use hydrodynamics, the verification of the writer's calculation of the correct value and form for the coefficient of viscosity may be very easily effected by simple mechanical considerations. It follows from the simplest axioms of dynamics and statics that the shear on the face of the belt (upper plane, moving) is precisely the same as on any other horizontal plane within the fluid, and that the transverse velocity gradient must also be the same as at any level in the fluid. Therefore, the shearing stress, or friction, per unit area of the face of the belt is $\mu \frac{du}{dz}$, and, as the velocity of the belt is $Z \frac{du}{dz}$, in which, Z is the height of Maxwell's mechanism, the power supplied to the whole device, of length, X, and breadth, Y, is $\mu\, Z \left(\frac{du}{dz}\right)^2 \times XY$. Hence, since the whole volume is XYZ, and since the whole of the energy must be dissipated into molecular motion on account of the steady state of the mass-motion of the fluid, the time-rate of dissipation of energy per unit volume of Maxwell's device must be, $\Phi = \mu \left(\frac{du}{dz}\right)^2$.

Therefore, as before, $\mu = \frac{1}{6} \rho \bar{c} l$, which is another independent verification of the formula for the coefficient of viscosity of a gas, in terms of the density, molecular velocity, and mean free path. Both these verifications of the writer's calculations are entirely independent of any explicit considerations of momentum.

Such are the results to be expected by considering the effects of the collisions of spheres, or any other type of bodies of perfectly elastic quality. It is not stated by the writer that the collisions of elastic spheres are attended with an actual dissipation of energy. The only dissipation which occurs, is that of mass-motion when it is transformed into molecular, or heat, motion, and as that mass-motion is being replenished by the motion received from the upper plane, at a rate equal to that of its transformation into heat, the state of the gas will not become steady until the loss of heat by conduction and radiation balances the energy supply, so as to bring the temperature of the gas to a limit consistent with surrounding conditions.

It will be of interest to predict the result to be expected after correcting values which have been computed by the erroneous formulas connecting viscosity and free path. Jeans gives[100] the upper limit values for the molecular radii of sixteen different substances which the correct values should not exceed. In another table he gives corresponding lower limits. Of the sixteen supposedly correct values calculated by Jeans with the uncorrected formulas, eight exceed their upper limits.

Jeans states:

> "* * * the circumstance that some of the values of $\frac{1}{2}\sigma$ (molecular radius) given in the last column are greater than their upper limits is one that demands explanation. * * * If the molecules were known to be hard spheres the circumstances just mentioned would be perfectly incomprehensible."

After correcting the sixteen supposedly correct values by means of the factor, $\sqrt{\frac{1}{2}}$, previously deduced, corresponding to a reduction of about 30%, it will be found that all the corrected values fall between their upper and lower limits, as they should.

This, therefore, indicates that by applying the writer's correction (halving) to the numerical factors of the various modifications of Maxwell's formula, which correction is in accord with correct uses of momentum and Newton's laws of motion, there should be greater harmony between the kinetic theory and experiment than there has been in the past.

Lamb extends[101] Bernoulli's equation for an incompressible fluid to one for a gas by mere addition to the energy supply of the expansion work, $\int p\,dv$. If other energy supplies and friction, which were not included by Lamb, are disregarded, a number of well-known flow formulas may be deduced from Lamb's formula; but, to consider all kinetic and potential possibilities, the writer framed the following equation:

$$p_1v_1 + I_1 + h_1 + L_1 + \frac{u_1^2}{2g} + JH = pv + I + h + L + \frac{u^2}{2g} + F \ldots\ldots (123)$$

in which, I is any internal potential; h and L are sensible and latent heats; JH is the work equivalent of any heat which enters the gas through the pipe skin, or otherwise; and F includes all losses due to friction and other agencies. The ideal gas formula is $pv = Rt$, while u represents velocity. Since v is a specific volume, each term is a mere length, thus relating to 1 lb. of gas.

Equation (123) is perfectly general, taking account of all stores of energy, and of all heat transfers between the gas and its surroundings, including the three standard Bernoullian stores. Relative to the conservative relation between mass- and molecular-motions discussed previously, Professor Unwin has made a most cogent hypothesis for the flow of a gas by supposing all friction immediately returned to the gas as molecular-motion. Application of Unwin's hypothesis to Equation (123) leads to a rigorous solution of that equation for the flow of a gas in any conduit, which solution, however, contains a baffling integral, $\frac{dy}{dx} = \frac{xy + ax^2 + b}{xy - mx^2 + n}$. The particular case of isothermal flow, however, is readily soluble when the external and internal temperatures, and internal pressures at pipe ends, are observed. For a permanent gas, since pv, I, h, and L, become constant for isothermal flow,

---

[100] "Dynamical Theory of Gases," p. 330.

[101] "Hydrodynamics," Article 22.

$$JH = \frac{u^2 - u_1^2}{2g} + z - z_1 + F$$

in which, by Unwin's supposition, F may be cancelled, since there must be inserted on the left an increase of molecular-motion equivalent to F, and both must be dropped. Hence, the only extra energy supply necessary is that transferred through the pipe skin. Making the proper substitutions, and reducing,

$$Q^3 - \frac{2g(z - z_1)}{v^2 - v_1^2} Q - \frac{1}{900} \frac{gJ}{(v^2 - v_1^2)} \frac{\log(T - t)}{r^2 \sum \frac{1}{k} \log_e \frac{r+1}{r}} = 0 \ldots\ldots\ldots\ldots (124)$$

Equation (124) is a cubic, to be used for determining the weight-rate of flow, Q, per unit area of pipe section, in which, r equals the internal radius of pipe, while the well-known summation relates to the three consecutive layers: Gas film; pipe skin; and outer film. Coefficients of additional pipe coverings may be included in the summation. When the pipe is level, $z - z_1 = 0$, the central term vanishes, and the solution becomes a cube root. Cubics of this form are easily solved by means of tables[102]

(*25*) *Individual Discussions.*—All the important questions raised in the discussions may be reduced to two: Fluid dynamics; coefficients and viscosity and kinetic theory. The former class arises in most of the discussions, while the latter arises mainly from the remarks and reference by Professor Bateman and Lieut. Roop, questions which have seldom or never been connected with models, but which are herein explained in this connection.

By reference to Articles (4) to (12), (16), and (22), it will be seen that in Newtonian model engineering "dominance" is immaterial to the engineer, except as to economy. Referring to Articles (4) and (18) to (24), one should not be led astray by ill-defined, little used sciences, possibly involving serious fundamental errors. The aero-difficulties raised by Professor Bateman, can all be avoided by either of the artifices of Appendix I, which the writer suggested in 1918.[103] This suggestion has actually been used with great success in testing airplanes.[104] Mr. B. Melvill Jones has stated:

> "The highly practical importance of some of these critical flows has led to great efforts being made to devise laboratory experiments in which the Reynold's number will be the same as that of the full-scale flow to be represented. One way in which this has been successfully accomplished, though at great cost, is to enclose the whole wind tunnel in an air-tight chamber pumped up to a pressure of some 20 atmospheres; this increases ρ some 20 times * * *."

---

XXVI, Washington, 1909; Des Ingenieurs Taschenbuch der Hütte, Berlin, Eighteenth Edition. See Kennison's formula, *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 344.

[103] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), see footnotes, pp. 1179 and 1187.

[104] Encyclopaedia Britannica, Vol. 1, p. 236.

Evidently, this refers to the tests at Langley Field, but the writer does not know that his suggestion has ever been mentioned by any of these other writers. It would surely not be correct routine to enclose the whole wind tunnel, as mentioned, thereby creating excessive cost. This points to the probable fact that the original designers had no thought of such an artifice as similarity control by pressure in designing the wind tunnel.

Dr. Th. v. Kármán might easily have discovered Maxwell's error in deducing the coefficient of viscosity of a gas by the kinetic theory, had he recognized the consequences of his method of comparing $\rho\, c\, l$ with μ, in the article cited by Professor Bateman. However, the result would have been obtained by means of two compensating errors: (1) Use of momentum transfer ("impulstransport") regardless of Newton's laws of motion, as pointed out in Articles (18) to (24); and (2) use of one-half the mean free path instead of the whole.

The writer did not say: "Nothing has ever been added to any of Newton's theories." He referred only to specific theories, and re-affirms his statement. Relative to Lieut. Roop's assumption of Newton's ignorance of viscous friction, the best answer is given by O. E. Meyer in his "Kinetic Theory of Gases" (previously cited).[105] Meyer states:

> "Newton's theory will therefore be proved to be true if different measures of the internal friction, especially if made by different methods, give the same value for this constant. Such an agreement of measures has really been found, both for liquids and for gases, as will be described later in fuller detail. In gases a perfect agreement with experiment has also been found for those properties which, on the kinetic theory of gases, are connected with the coefficient of viscosity."

Newton's error in "Principia," when first applying his theory (as pointed out by Stokes[106] in 1845), as well as Maxwell's error, relates to viscosity.

It is idle to talk about reading a meaning into Newton's words before one has acquired the ability to get from those words the meaning really expressed, especially when read in the Latin. Lieut. Roop's remarks to the effect that a sphere would necessarily meet no resistance in an infinite frictionless fluid are most certainly wrong. If the velocity is high enough a cavity must form (just as Newton stated)[107] and resistance must occur, the dissipated energy resulting in accumulating kinetic disturbances in the fluid, which, however, may never be abated. (See Article (17).) Concerning frictional drag of a solid surface, the writer cautioned against making the error charged against him by Lieut. Roop (See "Historical Background" in the writer's paper). Relative to Lieut. Roop's remarks referring to Froude (see Articles (14) and (16)), there can be no greater mistake than to refer viscous resistances to an exponential power of the velocity. By so doing the two theoretically exact components of the coefficient of resistance in Article (14) are completely confused, thus blockading the development of the exact science of hydrodynamics as pointed out in Articles (4) to (11), and (14) and (15). Lieut. Roop is on the wrong "track" and will surely fail to secure results of permanent general value.

---

[105] In the section entitled, "Viscosity: Newton's Fundamental Law of Internal Friction," pp. 172-174.

[106] *Cambridge Transactions*, t. VIII, p. 303.

[107] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 836.

The writer was correct in stating that, if the over-all exponent of skin friction is 2, the scale of the model is immaterial. This fact was discovered many years ago by that most able analyst, M. J. Bertrand (see Articles (3) and (16)). If the exponent is not 2, a dynamic model cannot exist unless the scale is properly related to the constants involved with the model. It was to remove this inaccuracy from model technique that the writer adduced Equations (11), (12), (20), and (21), as fully explained in the paper (see particularly, Articles (4) to (13)). Lieut. Roop's models are not true dynamic models. Froude never claimed that they were anything but geometrical models. It is not the model method which excels, but Froude's ingenious method of correcting defective geometrical models by means of his tables of resistances applied to planks towed edgewise. The power of ships can be estimated nearly as well without such models, as Froude and others were amply able to do. In a true dynamic model it is never necessary to adjust the kinematic coefficient of viscosity, or any other coefficient, for various speeds, as that is properly cared for in the construction of the model to the specifications of the equations of similitude, Equations (11), (12), (20), and (21). (See Articles (4) to (13) as well as the main paper.) Lieut. Roop is wholly wrong in his idea that viscosity is not a dynamic phenomenon (see Articles (18) to (24)).

Mr. Karpov's methods seem to be similar to that of Eisner rather than to the new method which has been previously described by the writer.[108] The entire matter of elastic models arises very simply out of the equations of similitude, Equations (11), (12), (20), and (21). All one has to do is to see that any two independent elastic coefficients are properly installed in the materials of the model (synthesized materials) according to the specifications written from these equations, and he may then rest assured that every other elastic coefficient (excluding limit coefficients, which must be treated separately) will perform correctly. In the case of reinforced concrete, special materials must be found, or synthesized, so as to have these same two coefficients in the proper ratio to the other two in the concrete. When that is done, the entire reinforced structure will be in proper elastic regimen, assuming that the limit coefficients have also received proper attention throughout. The writer invites the attention of Mr. Karpov and other structural engineers, not only to his paper, but especially to the sections of this closure inclusive, from Articles (1) to (13), which will be found to give a generalization concerning coefficients and their classification.

In reply to Professor Draffin it may be stated that an immense amount of river flow and river-control engineering is done in the United States. The work on the Mississippi alone will compare favorably with all the rest of such work in the world during the past hundred years. Besides the work of the U. S. Army Engineers in general, only one name need be mentioned, that of the late James B. Eads, M. Am. Soc. C. E.

---

[108] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1186–1188.

Relative to the last two lines of Professor Draffin's discussion, the writer states confidently, that, in respect to similitude, the United States is actually in advance of the rest of the world. Since all hydraulic frictional resistance of every kind is primarily due to viscosity, it is the most important constant in hydraulic models of all sizes (see Article (14)).

Neither g nor G relates to the acceleration of gravity in problems of similitude. They relate merely to resultant accelerations at particular points in all similar systems, and frequently may each be zero at particular similar points, regardless of what the gravitational force may be. Mr. Smith confuses the law of similarity with the laws of gravitation, which error has been treated in Article (16). The idea that there is a material difference between the flow in open and closed channels is wholly wrong. They are identical, in so far as dynamical relations are concerned, the same general equations applying to both, indiscriminately. Newtonian similitude is much more easily applied to closed channels than to open ones. This results from the fact that the acceleration ratio, $\frac{G}{g}$, can be controlled in the case of closed channels, whereas, in the case of open channels, it is frequently necessary to make that ratio unity, thus limiting testing conditions considerably. The acceleration ratio in closed pipes may be controlled simply by adjusting terminal pressures, just as they were controlled, or observed, in Stanton and Pannell's experiments, and many others since. The case for gases is similar to that for liquids (see Example 2 and Appendix I, as well as Articles (2), (10), and (14)).

Reynold's number is just as important in open channels as in their "equivalent" closed forms. The acoustic ratio is self-eliminating from true dynamic models, since it depends solely upon well-known physical constants which may be properly treated by the theory presented, so that no attention whatever need be paid to it (see Article (10)). Appendix I, which involves all equations of similitude, corrects permanently for combined compressibility and viscosity, without requiring calculations, thus providing automatically for velocity of sound and resistances, as successfully applied in the airplane tests mentioned by B. Melvill Jones. Far from using the dimensional method of analysis, as inferred by Mr. Smith, the writer uses only elementary algebra, as, for example, Equations (11), (12), (20), and (21). Of course, dimensions of terms occur (and, alas, should appear) in all dynamical equations. Isotropic elasticity, as used in structural engineering, is a perfect science (see Article (1) to (15)) for safe conditions of loading. All the constants depend upon only two, with a few limit coefficients (see Articles (5) to (11)). Therefore, all the elastic properties mentioned by Mr. Smith, and some others also, are easily determinable. There is less trouble than with fluids. Mr. Smith mentions vectors in connection with elasticity, but not with fluids. As a matter of fact, the fundamental equations of elasticity and of fluid motion are mutually convertible (see Article (14)), one into the other, so that there is no fundamental difference between them. Vector analysis finds its best foundation in parts of hydrodynamics, as, for example, in Stokes' solutions of important vector problems in the papers cited, some of which problems are famous. E. B. Wilson's presentation of Gibbs' "Vector Analysis" includes some of Stokes' problems and theorems reduced to modern vector notation. Other good works are: Mason and Weaver's "Electromagnetic Field"; Abraham's Theorie der Electrizität"; and, of course, Maxwell's "Electricity." These citations, including Stokes' papers, will give a real view of vector analysis and its development. Dynamic models are independent of vectors (see "Corollary" in Article (4)). Reference to Rankine's "Applied Mechanics" and the treatises on elasticity previously mentioned, will clear up all questions in elasticity.

By referring to Mr. Smith's citation to a correct "air screw" theory, it will be found[109] that Professor Gibson has given the substance of the writer's demonstration of the accuracy of Newtonian models of viscous flow as described in his paper on "Ice Diversion, Hydraulic Models, and Hydraulic Similarity" previously cited. The resulting theorem was stated by the writer[110] as follows:

> "What we have done is to show that the conditions of geometric and dynamical similarity can be imposed simultaneously in a hydraulic model so that it will reproduce the prototype both in form and action, and that this possibility is in full accord with the generally accepted laws of turbulent stream flow, including viscosity resistances."

Dr. Eisner's discussion is very interesting, but discloses the fact that he is inadvertently confusing Newton's theorem of similitude with Newton's laws of motion. Of Newton's theorem of similitude, he says: "* * * it states only the fact that forces acting upon masses produce accelerations." This is merely a qualitative statement of the second law. Furthermore, Dr. Eisner states: "The introduction of density according to Newton's general statement assumes in advance the requirement of general dynamic similarity." This is another result of Dr. Eisner's confusion. Moreover, although he mentions Newton's implied reference to corresponding forces, he neglects to mention Newton's expressed statement concerning corresponding accelerations, corresponding velocities, and corresponding linear dimensions, which he later calls "Froude's law." Similitude cannot be understood until Newton's definitions and theorem concerning it are understood (see Article (16)).

The elementary practical essence of Newton's theorem of similitude is the adjustment by capable engineers of corresponding accelerations (in modern words, "accelerative force" = acceleration), corresponding velocities, and corresponding linear dimensions, in such manner that Equations (1) (or Equation (12)) shall be satisfied simultaneously with the other adjusted specified similar conditions. Independently of any materials contained by the systems, the theorem clearly states that if these adjustments are made by the engineer, who then starts the bodies with similar motions, the dynamical and kinematical similarity will continue. There is no tacit assumption in the theorem concerning initial similarity (see Article (12)).

---

[109] "Similarity and Model Experiments," by A. H. Gibson, *Engineering*, March 21, 1924, p. 327.

[110] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1188.

It makes no difference how the adjustments are effected (see Articles (1) to (16), and Article (26), Conclusion 10.)

Concerning Equations (11), (12), (20), and (21), the first is not to be independent. It is merely a specification of scale ratio (see Article (1)). The other three are solved for L, F, and T, using the physical constants of such materials as the engineer deems most appropriate. If resulting scales are not satisfactory, materials must be changed, treated, or synthesized, as now practised in the United States by the writer and others, so as to produce satisfactory testing conditions. The writer is advised by James W. Rickey, M. Am. Soc. C. E., that A. J. Ackerman, Assoc. M. Am. Soc. C. E., has put into execution this general idea of synthesizing concrete of proper ultimate strength (see Article (9), "Limit Coefficients") for the model of the obelisk at Chute à Caron.[111] This is "a step in the right direction." It is hoped that Mr. Ackerman may extend his control of materials so as to create proper values for all physical constants of his models by means of the equations of similitude (see Equations (11), (12), (20), and (21)).

Equations (20) and (21) represent as many equations as there are property constants to be introduced. When these property equations and Equation (12) exceed three in number, each additional property (in excess of two) must be "adjusted" by proper selection, treatment, or synthesis of the material. The problem is one of Newtonian model engineering. It is immaterial how adjustments are effected.

Dr. Eisner expresses Equation (40) in terms of "numbers," R, C, and F, which, indeed, can be done, the correct value in Example 2 being $\frac{\mathsf{R}^4\mathsf{C}^3}{\mathsf{F}}$. It is better to express characteristics by the constants, since they must be determined or given definitely, whereas, the "numbers" are not. If there are n property equations, there will be $n - 2$ characteristics, each containing property ratios. After using the first four properties, including the ratio, G, each new constant ratio is matched to its own dimensional ratio in terms of the previously found L, F, and T, to get its value. In solving the first four equations, the process may be inverted so as to find values of three property ratios instead of L, F, and T.

It is really a mathematical fact that Equation (40) (eliminant), or its inverted form, sets up the condition that any four property ratios (scales, inverted form), including G, determine consistent scales (properties) for a model, based upon the corresponding solution of Equations (12) and (20) and the two Equations (21). Consequently, it is easily shown that the individual factors satisfy $\mathsf{F}_1 = \mathsf{F}_2$, $\mathsf{R}_1 = \mathsf{R}_2$, $\mathsf{C}_1 = \mathsf{C}_2$ (etc., *ad infinitum*, in general). It is much simpler by ratios; for example, $\mathsf{C} = \frac{k}{L\rho v^2} = 1$, since $E = \frac{k}{L}$. Thus, $\mathsf{C}_1 = \mathsf{C}_2$ etc. Although this alone is a necessary condition that elasticity may enter a model, it does not alone necessarily establish similarity, unless Newton's theorem of similitude is also satisfied, which may not be the case, as in the first part of Example 3. The same is true of properties in general. The writer's treatment of history covers about all there is of Newtonian models. The problem of providing suitable materials is not the main difficulty of Newtonian model engineering. The real difficulty is that caused by the novelty of the methods, and the scarcity of engineers who know anything about it. No criticism of past methods is intended, as Newtonian model engineering has played no part in them. Article (3), "Bertrand's Models," contains a discussion of Froude's law; the writer has treated the subject of accelerations in his reply to Mr. Smith; and the subject of properties is treated in Article (4), "Corollary, Fundamental."

---

[111] *Civil Engineering*, December, 1930.

Ratios L and T are not necessarily confined to narrow limits (see Article (2) and Example 3, in which, $G = 125$, in the part where similarity exists, by a very simple artifice; see, also, all other remarks on pressure). The writer uses mercury in small models with satisfaction. As stated in Article (4), Newtonian models are independent of functionality of physical properties, so that adhesion can be eliminated from relations between similar systems as treated by the writer. As a matter of fact, adhesion is probably a mere phenomenon of viscosity. Besides pressure, acceleration may be controlled as explained in a paragraph preceding Equation (44). It seems to the writer that Dr. Eisner's models are used empirically. They really do not constitute dynamic models. Newtonian models are exact, thus avoiding empiricism.

The object of deducing Equations (29), (30), and (31), was to show that the writer's equations of similitude, Equations (11), (12), (20), and (21), were capable of producing Newton's form for the velocity of sound in any medium, Equation (31). Laplace's correction of this formula was not, in reality, a correction of the formula, but an insertion of the correct value of the elasticity, when the formula was used to determine the velocity of sound in a gaseous medium. Dr. Eisner's method, especially by making transferability depend solely on linear scale, leads to difficulties such as mentioned in connection with the section on "Reynolds' Similarity" in the main paper. Thus, if a model of an airplane with a 75-ft. wing spread and a 1 000-h.p. motor, capable of attaining a speed of 200 miles per hour, is to be built to one-twenty-fifth of the full size, the model would need to have a wing spread of 3 ft. and its power plant would have to generate 25 000 h.p. so as to permit traveling 5 000 miles per hour. Newtonian model engineering avoids such impractical requirements because of its flexibility. It gives an engineer opportunities to use his technical skill.

Recently, there have been some very interesting experiments to determine internal elastic stresses by means of a condenser internally inserted, the effects being amplified by a radio tube. There have also been some tests by means of a magnetic needle. The measurement by polarized light is well known.

(*26*) *Conclusions.*—The following will summarize this paper and its discussion:

1.—All former conclusions are re-affirmed.

2.—The principle of momentum transfer, as it has been applied in the kinetic theory of gases, is invalid.

3.—The mean free paths which have been calculated by the erroneous formulas based upon momentum transfer, are all of just one-half their correct magnitude. It will be necessary to correct all these values by doubling them.

4.—Other magnitudes of the kinetic theory which have been calculated by means of the erroneous free paths, of which magnitudes there are many, will require correction by suitable alterations of formulas and values.

5.—All textbooks and handbooks, and all books of chemical and physical tables, should be carefully examined and revised, with reference to the errors mentioned. Such necessity for revision will be found to extend to tables, sections, and chapters on viscosity, heat conduction, and diffusion, if not elsewhere.

6.—Use of the kinetic theory of gases is not necessary, or desirable, in ordinary Newtonian model engineering.

7.—The first paragraph of "Conclusions" in the paper, is general as to physical properties and characteristic numbers, when appropriate interchanges of properties, numbers, dimensions, and notation are made. Similarity exists only in Newtonian form, regardless of physical properties, which must all be adjusted to the system in which they occur, as required by Newton's theorem of similitude.

8.—Froude's law is merely a corollary[112] of Newton's theorem of similitude, which corollary results by making the ratios of corresponding accelerations all equal to unity. Correctly stated, it is: "As between model and prototype, squares of corresponding velocities must vary directly as corresponding linear dimensions." M. J. Bertrand (1848) anticipated Reech, Froude, and Helmholz in stating it. This law holds rigorously only in true Newtonian similitude.

9.—Stanton and Pannell's experiment indicates most satisfactorily the truth of the hypothesis which the writer now makes, namely, that the great lacuna of hydrodynamics, including aerodynamics, is due wholly to the fact that hydrodynamics is not yet fully equipped with the complete mechanism and functionality of viscosity.

10.—Newton's theorem of similitude is one of adjustment of ratios of homologues. It is independent of dynamical laws of all kinds, with which the theorem has nothing to do directly. That is to say, any of the dynamical physical laws, including Newton's laws of motion, may be changed at will without destroying the similarity, provided the acceleration ratio is kept in adjustment, or is continuously re-adjusted, as required by the theorem. If materials and general conditions are unchanged, the original adjustment is permanent, even if the form and action of the model is changed.

11.—By Conclusions 9 and 10 and Articles (4) and (22), Newtonian model engineering stands proved as the only existing method which will yield a theoretically correct solution of every problem in rigid dynamics, hydrodynamics, aerodynamics, elasticity, and capillarity, either separately, or in any combination, without an actual construction and test in place of the full-sized prototype.

---

[112] "History of Mathematics," Cajori, p. 380.

12.—By far the greater portion of the writer's closure results from his equations of similitude, Equations (11), (12), (20), and (21). These equations express the entire theory of similarity, and represent any kind of true dynamic model that can be devised, because they are the mathematical expression of Newton's theorem of similitude.

In a paper[113] entitled "Misuse of Postulations in Theory of Viscosity," the writer has elaborated this subject further and has treated aspects of it not included herein.

TESTS OF BROAD-CRESTED WEIRS [1]

By James G. Woodburn,[2] Assoc. M. Am. Soc. C. E.

With Discussion by H. W. King, Sherman M. Woodward, David L. Yarnell, Boris A. Bakhmeteff, D. D. Curtis, Erik G. W. Lindquist, Ralph L. Parshall, and James G. Woodburn.

Synopsis

This paper gives the results of 305 tests made during 1928-29 at the University of Michigan, Ann Arbor, Mich., on broad-crested weirs of various designs in a rectangular wooden flume 2 ft. wide. The crests varied in breadth from 10 to 15.5 ft., and in slopes and combinations of slopes from level to 0.085. The range of head was from 0.5 ft. to 1.5 ft. and of volume of flow from 2.0 to 11.0 cu. ft. per sec.

The purpose of the tests was to obtain experimental data in regard to certain advantages suggested in favor of the broad-crested weir over the sharp-crested weir as a device for measuring flowing water. One advantage established by the tests is that the tail-water can be backed up to an elevation only slightly lower than the water surface at the down-stream end of the weir without changing appreciably the relation between head-water elevation and discharge. Moreover, if the slope of the weir is such that a hydraulic jump can be made to occur on the crest, nearly all the initial head can be recovered, still without changing the head-water-discharge relation.

This ability to operate when submerged adapts the broad-crested weir for use under conditions where head is at a premium, as, for example, in the measurement of irrigation water. The broad-crested weir, moreover, even when operating under a considerable degree of submergence, requires the measurement of head at only one point and is thus preferable to the submerged sharp-crested weir and the Venturi flume, which require the measurements at two points.

Another advantage is the possibility of causing flow to occur at critical depth at some predetermined point on the crest at which the depth can be readily measured. The discharge is then a simple function of the depth, independent of the confusing effects of velocity of approach.

Previous discussions of this subject had indicated that critical depth might be expected to occur at the change in grade between slopes of channel, one of

---

[1] Published in September, 1930, *Proceedings*.

[2] Associate Prof. of Hydr. Eng., State Coll. of Washington, Pullman, Wash.

which would maintain flow above, and the other below, the critical depth. To investigate this theory tests were made of weirs formed of 10 ft. of level crest followed by 3½ ft. of apron with a small down-stream slope, the entrance to the weir being rounded.

These tests showed that the location of critical depth is affected by waves on the crest. The conformation of these waves is, in turn, affected by the volume of flow. With flows up to about 8 cu. ft. per sec., critical depth in a number of tests occurred at the change in grade, provided the slope of the apron was not too steep; but in other tests the waves caused the position of critical depth to move short distances up or down stream. When the flow was increased to more than 8 cu. ft. per sec. the position of critical depth moved from 1 to 3 ft. up stream from the change in grade.

Waves occurred at certain volumes of flow with every weir model tested in which part or all of the crest was level. If the crest was given a slope sufficient to maintain flow without waves, critical depth was found to occur, as a rule, only at some point of the initial drop at the entrance to the weir, at which the water surface sloped steeply and a small error in selection of the point of measurement would cause considerable error in the measured depth.

The tests showed that there was no single location of critical depth for all volumes of flow. Some interesting relations, however, were brought out between the design of the weir, the number of waves on the crest, and the location of critical depth.

Much information was obtained in regard to weir coefficients and to the factors affecting their variation. Coefficients as high as 3.08 were reached with a weir with rounded entrance followed by a down-stream slope of 0.026. This slope of crest permitted the formation of the hydraulic jump and the recovery of nearly all the initial head.

INTRODUCTION

Few previous tests have been made of broad-crested weirs of the designs described in this paper. Experiments have been made by Bazin, Blackwell, Fteley and Stearns, the U. S. Geological Survey, and others, on many designs of dams and weirs not sharp-crested, but only a small part of their investigations has dealt with weirs with broad level crests or with broad crests having a small down-stream slope.

However, recent discussions and tests on the subject of the critical depth and hydraulic jump[3] have suggested certain advantages which the broad-crested weir may have over the sharp-crested weir as a device for measuring flowing water. These suggested advantages are:

E., Vol. LXXX (1916), p. 338; "Theory of Hydraulic Jump and Back-Water Curves," by S. M. Woodward, M. Am. Soc. C. E.; also "The Hydraulic Jump as a Means of Dissipating Energy," by R. M. Riegel and J. C. Beebe, The Miami Conservancy Dist., Tech. Repts., Pt. III, 1917; "The Hydraulic Jump and Critical Depth in the Design of Hydraulic Structures," by Julian Hinds, M. Am. Soc. C. E., *Engineering News-Record*, November 25, 1920; "The Improved Venturi Flume," by Ralph L. Parshall, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), particularly discussions by Julian Hinds and J. C. Stevens, Members, Am. Soc. C. E., p. 841 *et seq.*; "Berechnung der Wasserspiegellage," by P. Boess, *Karlsruhe Forschungsheft No. 284*, Verein Deutscher Ingenieure, Berlin, 1927; "The Hydraulic Design of Flume and Siphon Transitions," by Julian Hinds, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1423.

1.—Its adaptability to the use of the hydraulic jump to reduce to a minimum the head lost in the weir; and

2.—The possibility of producing flow at critical depth with a resulting simple relation between depth and discharge which is independent of the confusing effects of velocity of approach.

Purpose and Scope of the Tests

The purpose of the tests was to obtain experimental data in regard to these two suggested advantages of the broad-crested weir. The breadth of crest of the weirs tested varied from 10 to 15.5 ft., with various down-stream slopes and combinations of slopes from level to 0.085. The range of heads was from 0.5 ft. to 1.5 ft. and of volume of flow from 2 to 11 cu. ft. per sec. These and other details of the tests will be given in the summaries of the experiments.

Coefficients of discharge of various weir models were determined both with free over-fall and with the weir submerged. The data thus obtained permitted a study of the effect of submergence, of the effect on the coefficient of various factors in the design of the weir, and of the variation of the coefficient with the head. Profiles of the water surface were made with different weir models to permit a study of the factors affecting the position of critical depth, with a view to suggesting if possible a design of weir which would produce flow at critical depth at the same point on the crest for all volumes of flow.

Notation

The following notation is used in the paper:

H = head on the weir, in feet.
H_a = total head, in feet, at any point in a flowing stream.
h_v = head due to velocity of approach, in feet.
D = depth, in feet.
D_a = depth in channel of approach, in feet.
D_c = critical depth, in feet.
V = velocity, in feet.
v_a = velocity of approach, in feet.
Q = discharge, in cubic feet per second.
Q_1 = discharge, in cubic feet per second, per foot of width.
C = weir coefficient.
g = acceleration due to gravity, = 32.16 cu. ft. per sec. per sec.
α = velocity-head coefficient, correcting for unequal distribution of velocities in cross-section; here considered = 1.0.

Review of Critical Depth Theory

The total head in any point of a flowing stream is:

$$H_a = D + \alpha \frac{V^2}{2\,g}$$

Considering $\alpha = 1.0$.

$$V = \sqrt{2\,g\,(H_a - D)}$$

Then,

$$Q_1 = D\sqrt{2\,g\,(H_a - D)}$$

Critical depth, by definition, is the depth at which, for any given total head, the discharge is a maximum. Differentiating Q_1 with respect to D and equating to zero,

$$H_a = \frac{3}{2} D$$

Substituting,

$$Q_1 = \sqrt{g}\ (D_c)^{\frac{3}{2}}$$

The discharge is, therefore, a simple function of the critical depth; the velocity of approach is not involved. Thus, if the critical depth can be made to occur at any known point where it can be measured accurately, a simple method of determining the discharge is available.

The effect of error in measurement of D_c may be shown by differentiating Q_1 with respect to D_c and dividing; that is,

$$d\,Q_1 = \frac{3}{2} \sqrt{g}\ (D_c)^{\frac{1}{2}}\ d\,D_c$$

$$\frac{d\,Q_1}{Q_1} = \frac{3}{2}\ \frac{d\,D_c}{D_c}$$

Thus, for any percentage, p, of error in D_c, the computed Q is in error 1.5 p per cent. This degree of accuracy is the same as that of the usual equations for rectangular weirs (aside from velocity of approach) and is greater than that of the equations for V-notch weirs, where an error of $p\%$ in measuring the head results in an error of $2.5p\%$ in the computed Q.

The Laboratory

Details of the hydraulic laboratory are shown in Figs. 1 and 3. The quantity of water flowing in the system was controlled by the gate valve at the upper end of the 15-in. pipe line.

The 90° V-notch weir by which the discharge was measured, was calibrated by means of the weighing tanks. The methods and results of this calibration are described under "Measurement of Discharge".

Weir.—At a point 32 ft. from the head end of the flume, the bottom was stepped up 1.75 ft. (Fig. 1), and carried for 10 ft. at this elevation. This formed a weir crest 10 ft. broad, with square-cornered entrance. Series *A* includes the tests of this weir. Rounded entrances of various curvatures were obtained by means of laminated wooden blocks set on bases of proper height and thickness against the up-stream end of the weir.

Variation in slope was obtained by a false bottom 12 ft. long. This bottom was given the desired slope by laying it on shims on the 10-ft. level section. Series *D D* and *D E* give the results obtained with two different slopes of crest.

Combinations of level and sloping crests were obtained by means of a platform 3½ ft. long, used with either the permanent level section or the sloping false bottom. With the former the platform was used as a down-stream apron with three different slopes (Series *DA*, *DB*, and *DC*) while with the sloping bottom the platform was placed ahead to form a level section of crest (Series *DF* and *DG*).

The flume and weir were built in August, 1928. Just prior to the tests which began in November, the crest of the permanent weir was planed to a true level surface, and the sides of the flume, as well as the weir crest, were scraped and sand-papered to give as smooth a surface as possible. The surfaces of the false bottom and short platform were also made smooth.

CROSS SECTION OF FLUME
DETAIL OF FLUME LINING

FIG. 1.—DETAILS OF EXPERIMENTAL FLUME.

Aeration.—Five 1-in. holes to provide aeration of the nappe were bored in the wooden bulkhead forming the down-stream end of the permanent weir section. These holes were in a horizontal line 5 in. below the weir crest. Wooden plugs were used to stop the holes when required. As a general rule, the plugs were removed and the nappe was aerated in tests in which the back-water from the fall did not rise high enough to cause leakage through the holes. The nappe was thus aerated for flows up to about 7 cu. ft. per sec.

Measuring Elevation of Water Surface.—The elevation of the head water was measured by a point-gauge mounted in the center of the flume on the cross-cap of one of the bents (Figs. 1 and 3). The distance from the up-stream edge of the weir to the gauge was 7 ft. When the weir was extended up stream by the addition of the 3½-ft. platform, the gauge was moved up to the next bent. Profiles of the water surface over the weir were taken with another point-gauge mounted on a light channel iron. This movable gauge was supported by parallel channels attached to the tops of the posts.

Measurement of Discharge.—The discharge over the broad-crested weir was measured by means of a 90° V-notch weir which was calibrated gravimetrically just previous to the tests. The methods and results of this calibration will be discussed here briefly.

The flying-start-and-stop method was used in measuring the water. With the flow steady and the water discharging through the weighing tank, the weight on the scale-beam was set to a small initial reading and the outlet valves of the weighing tank were closed. At the instant the beam rose to the cross-bar the two watches were started. The weight was then set ahead to the desired final quantity, and the watches were stopped when the beam rose to the bar again. The average of the watch readings, corrected for initial error, was used in computing the coefficient. The watches were checked for initial error at the start of each test.

The hook-gauge was read as many times as possible during the course of the tests. The length of test for the smaller flows was made about 4 min., enabling twenty or more gauge readings to be taken. At the larger flows the length of the test was determined by the capacity of the weighing tank, and was sometimes as short as 50 sec., permitting only seven or eight gauge readings.

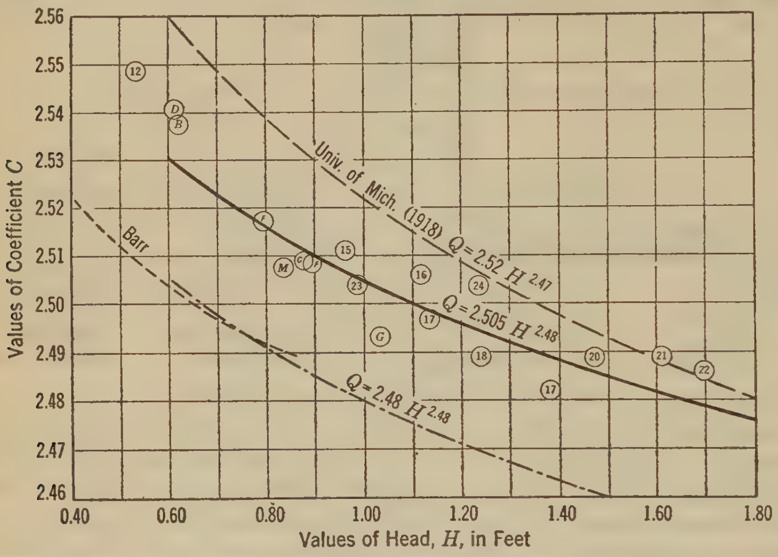

FIG. 2.—CALIBRATION TESTS OF 90° V-NOTCH WEIR: VARIATION OF C WITH H IN $Q = CH^{2.5}$ FOR THE EQUATIONS SHOWN.

The volume of flow, in cubic feet per second, was obtained by using 62.40 lb. as the weight of 1 cu. ft. of water. The computed volume of flow and the observed head on the weir corrected for zero reading of the gauge, were used to compute the coefficient, C, in the equation, $Q = CH^{\frac{5}{2}}$. Values thus obtained for C are plotted against values of H in Fig. 2, which shows the usual decrease in coefficient with increase in head. The equation, $Q = CH^{\frac{5}{2}}$, is awkward to use because it involves two variables. By making a slight change in the exponent of H, a suitable equation can be derived in which C is constant. The equation best fitting the points on the graph was adopted for use, namely, $Q = 2.505\,H^{2.48}$. The curve representing this equation (Fig. 2) was obtained by plotting values of C against H. C is computed from the equation, $C = \frac{Q}{H^{\frac{5}{2}}}$,

Q having been computed from the equation, $Q = 2.505\ H^{2.48}$. Thus, the curve and the test results are comparable graphically.

Curves of two other series of experiments with 90° V-notch weirs are also shown on Fig. 2. The equation, $Q = 2.52\ H^{2.47}$, was obtained as the result of experiments performed at the University of Michigan in 1918. In Scotland, some years previously, Barr made some experiments with results as also shown on Fig. 2. Barr's coefficients fit quite closely the equation, $Q = 2.48\ H^{2.48}$. The curve corresponding to this equation is drawn on the graph to serve as an extension of Barr's results to higher heads.

The writer's equation is seen to lie between the Barr experiments and the University of Michigan equation, but approaching more nearly the latter at the higher heads. The care taken in calibrating the V-notch weir and the agreement with former V-notch weir tests offer reasonable assurance that the subsequent measurement of discharge over the broad-crested weir was correct at least within 1 per cent.

TEST PROCEDURE

The usual method of making a test required four observers. One man read the hook-gauge which showed the head on the V-notch weir by which the discharge was measured. Another read the fixed point-gauge up stream from the broad-crested weir. These two gauges were read regularly at 30-sec. intervals. Twenty readings constituted the usual test.

A third observer operated the movable gauge to obtain the profile of the water surface (Fig. 3). Cross-sections were taken, proceeding down stream, at as many points as were required to permit drawing an accurate profile. The usual cross-section consisted of three readings, one at the center and one 3 in. from each side. The average of these readings was used in plotting the profile.

The fourth man kept notes for the second and third observers. The man reading the hook-gauge recorded his own notes.

A number of tests were made merely to determine coefficients of discharge without taking profiles of the water surface. These tests required an observer on the hook-gauge, one on the fixed point-gauge, and a recorder.

METHOD OF COMPUTING WEIR COEFFICIENTS

The weir coefficient for each test was computed by the method outlined by Horton in his treatise on "Weir Experiments, Coefficients, and Formulas."[4] The steps in the computation will be given briefly.

The average reading of the hook-gauge, corrected for the zero reading of the gauge, was used to find the discharge, Q, from a table prepared by the writer, based on the formula already stated, $Q = 2.505\ H^{2.48}$.

The average reading of the fixed point-gauge, corrected for the zero reading, was used as the observed head, H, on the weir.

The depth of water in the channel of approach is,

$$D_a = H + \text{the height of the weir}$$

---

[4] *Water Supply and Irrigation Paper No. 200,* U. S. Geological Survey, pp. 66-67.

Then,

$$v_a = \frac{Q}{2\ D_a}$$

$$h_v = \frac{v_a^{\ 2}}{2\ g}$$

$$H_a = H + h_v$$

$$C = \frac{Q}{2\ H_a^{\frac{3}{2}}}$$

$$D_c = \left(\frac{Q_1}{\sqrt{g}}\right)^{\frac{2}{3}} = \left(\frac{Q}{2\sqrt{g}}\right)^{\frac{2}{3}} = 0.1982\ Q^{\frac{2}{3}}\ \text{(see page 390)}.$$

D_c was found from a table prepared by the writer for a rectangular flume, 2 ft. wide, giving critical depths for values of Q from 0 to 12 cu. ft. per sec.

Outline of Tests

An outline of the 305 tests of broad-crested weirs, with the series designations, in the chronological order of their performance, is as follows:

Tests of weirs with level crest, 10 ft. broad, with varying curvature of entrance:

Square cornered entrance	37 tests,	Series *A*
Rounded entrance, 2-in. radius	13 tests,	Series *B*
Rounded entrance, 3-in. radius	11 tests,	Series *C*
Rounded entrance, 6-in. radius	26 tests,	Series *D*
Rounded entrance, 3 by 6-in. ellipse, long axis horizontal	10 tests,	Series *E*
Rounded entrance, 8-in. radius	12 tests,	Series *F*
Rounded entrance, 4 by 8-in. ellipse, long axis horizontal	12 tests,	Series *G*

Tests of weirs from 12 to 15.5 ft. broad, with various slopes and combinations of slopes. Entrance rounded on 6-in. radius:

10-ft. level, followed by 3.5 ft. of 0.015 slope	25 tests,	Series *DA*
10-ft. level, followed by 3.5 ft. of 0.004 slope	36 tests,	Series *DB*
10-ft. level, followed by 3.5 ft. of 0.085 slope	8 tests,	Series *DC*
12 ft. of 0.004 slope	33 tests,	Series *DD*
12 ft. of 0.026 slope	36 tests,	Series *DE*
3.5-ft. level, followed by 12 ft. of 0.026 slope	33 tests,	Series *DF*
3.5-ft. level, followed by 12 ft. of 0.004 slope	13 tests,	Series *DG*
Total tests	305	

Analysis of Results

The results will be discussed under three heads:

1.—Effect of submergence on the weir coefficient.

2.—Location of critical depth.

3.—Variation of coefficient with head for different weir models.

Effect of Submergence on Coefficient.—The results of fifty-four pairs of tests which show the effect of submergence on the weir coefficient, are sum-

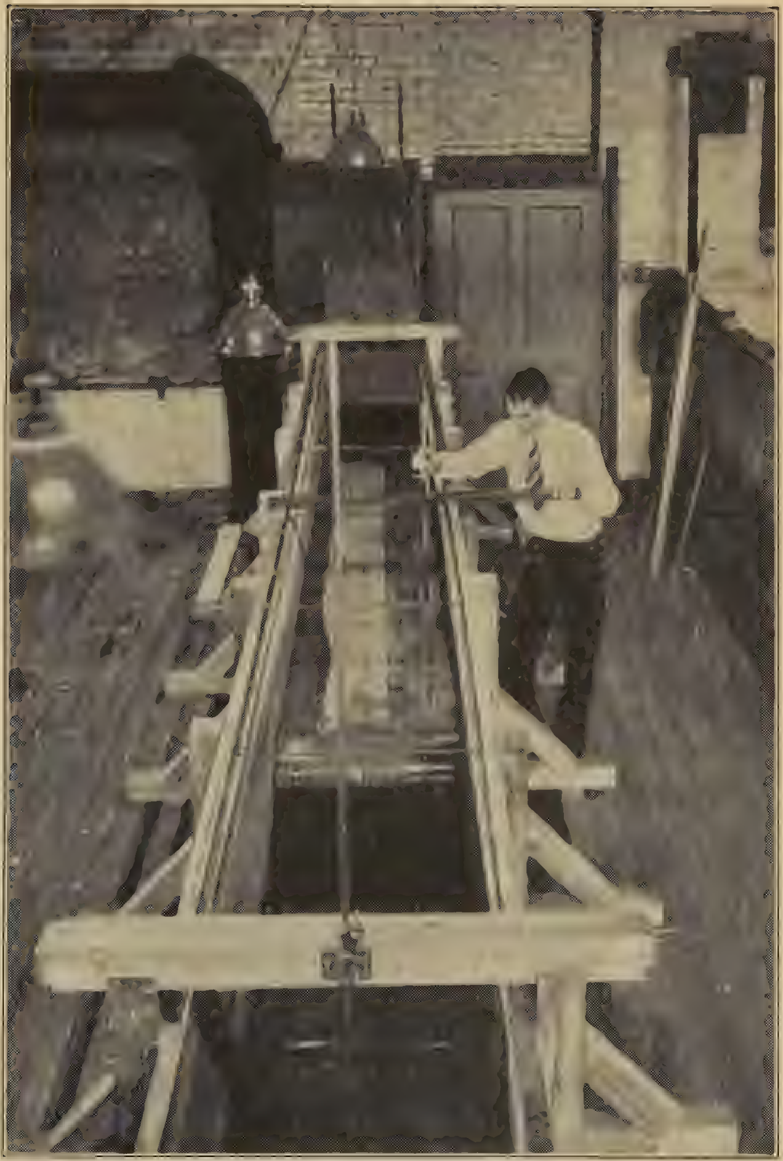

FIG. 3.—SET-UP AND DETAILS OF HYDRAULIC FLUME.

marized in Table 1. These tests were made on eight different weir models and covered the entire range of head from 0.5 ft. to 1.5 ft. Each pair, in nearly every case, was performed consecutively with no change between tests in the quantity of water flowing.

Either with or without the hydraulic jump, the average difference in the coefficients of the weirs submerged and with free over-fall was found to be inappreciable. In thirty-two pairs of tests in Table 1 (Part I), in which the jump could not be produced when the weir was submerged, the coefficient for the submerged weirs was, on the average, 0.219% less than for the weirs with free over-fall; while in twenty-two pairs of tests in Table 1 (Part II), in which the jump was formed on the crest when the weir was submerged, the coefficient for the submerged weirs was, on the average, 0.081% less than for the weirs with free over-fall. In the fifty-four pairs of tests in both parts, the average coefficient for the submerged weirs was 0.163% less than for the weirs with free over-fall.

The depths of submergence are shown in the profiles of water surface in Fig. 4. In the tests in which the slope of the crest was steep enough to permit the formation of the hydraulic jump (Series *DE* and *DF*), the loss of head over the weir was limited to about 0.2 ft. at the smallest flow and about 0.3 ft. at the largest flow. In the tests of weirs with slopes so flat that the jump could not be formed (Series *DA*, *DD*, and *DG*), the tail-water could be raised only to an elevation somewhat below the water surface at the down-stream end of the weir without noticeably affecting the conditions of flow over the weir, and the loss of head was from about 0.3 ft. for the smallest flow to about 0.6 ft. for the largest flow.

The attempt was made at the start of each test with the weir submerged to back up the tail-water to an elevation just under the maximum which would leave the weir coefficient unchanged. If at the start of a test, however, the tail-water was very close to the permissible elevation, slight fluctuations in volumes of flow might have caused this elevation to be exceeded momentarily with a resulting change in the conditions of flow over the weir and a decrease in the weir coefficient. The permissible elevation of the tail-water was purposely approached more closely in the tests in which the jump could not be formed than in those in which it could be formed, and as a result was probably exceeded more often in the former case than in the latter. This fact is reflected by the averages of Table 1 (Parts I and II) which show a difference in coefficients of weirs submerged and with free over-fall somewhat larger when the jump could not be formed than when it could be formed.

A typical example of the change in conformation of the water surface over a submerged weir without the jump when the tail-water rises through this permissible elevation is shown by Tests 4 and 5 of Series *DD* (Fig. 4). The volume of flow in the two tests was practically the same; but a small closure of the down-stream gate between tests caused a rise in the tail-water, with a marked change in profile of the water surface over the weir and a rise in the head-water. A change of this nature, although much smaller in extent and caused by a slight fluctuation in the volume of flow instead of by closure of the gate, doubtless occurred during those six tests of Table 1 (Part I) in

which the coefficient submerged was more than 0.5% less than the coefficient with free over-fall. If these six pairs of tests are disregarded, the remaining twenty-six pairs give coefficients for the submerged weirs only 0.09% less on the average than for the weirs with free over-fall.

With the jump formed on the crest, the largest difference in coefficients submerged and with free over-fall was 0.39 per cent. Various positions of the jump were tried, but none closer to the entrance of the weir than about 5 ft., at which distance a slight fluctuation in volume of flow merely caused a small movement of the jump up or down stream with no other visible effect on the conditions of flow.

LOCATION OF CRITICAL DEPTH

Profiles of the water surface over the weir for each weir model tested, both submerged and with free over-fall, and with a range of head from 0.5 ft. to 1.5 ft., are shown in the series of graphs in Fig. 4; also the points at which the measured depth equals the computed critical depth for each flow.

The graphs show that none of the weir models tested produced flow at critical depth at any fixed location throughout the entire range of heads. At points where previous discussions had indicated that critical depth might be expected to occur, as, for instance, at the change from level crest to a small down-stream slope (Series *DA*, *DB*, *DF*, and *DG*), the depth of flow was found to be affected by waves on the crest of the weir. On the other hand, with crest slopes sufficient to maintain flow free of waves (Series *DE*), critical depth occurred, as a rule, only on the initial drop in water surface at the entrance to the weir. One series of tests in which the crest had a down-stream slope of 0.004 (Series *D D*) showed for the smaller flows a depth very near the critical through a distance of 3 or 4 ft. at about the center of the crest; but for flows larger than about 6 cu. ft. per sec., the depth was distinctly less than the critical at all points except on the initial entrance drop.

Although for the models tested no one location was indicated at which critical depth may be expected to occur at any flow, nevertheless, the profiles show some interesting facts in regard to the manner in which it varies with the number of waves on the crest; and also the manner in which the width and slope of the crest, the rounding of entrance, and the volume of flow affect the number and position of the waves.

Waves occurred at certain flows with every weir model tested in which part or all of the crest was level. The profiles of Series *B* to *G* show typical conditions of flow over a weir with a level crest, 10 ft. wide, with rounded entrance. The locus of the points of critical depth in the profiles of this group is a series of disconnected straight lines, apparently with about the same slope, each line containing the points of critical depth accompanying a particular number of waves on the crest. Thus, all profiles showing only one wave on the crest have their points of critical depth on Line *BB*; profiles with two waves have their points on Line *CC*; those with three waves, on Line *DD*; with four waves, on Line *EE*; and with five waves, on Line *FF*. Test No. 6 in Series *B* appears to be a border-line case between one wave and two waves, since its profile shows points of critical depth on both Line *BB* and Line *CC*. Line *AB*, containing critical depth points for flows of about 11 cu. ft. per sec. and greater, appears, from the few tests made at those flows, to slope up to the left instead of up to the right like the other loci.

The same arrangement of the points of critical depth is apparent also in the profiles in Series *DA* and *DB* for free over-all. A majority of the points of critical depth for the lower flows in these two series lie at, or very close to, the change in slope. However, even with these smaller flows, the effect of the waves is apparent in the variations of some of the points from the change in slope. At the larger flows, the points of critical depth all occur from 1 ft. to 3 ft. up stream from the change in slope, and their locus is similar to that of the points on the profiles with one wave in Series *B* to *G*.

The profiles show the variation of the number of waves on the crest with the volume of flow and with the breadth and slope of the crest. At the smallest flows tested (Series *B* to *G*, and *DA*), five distinct waves appear. With increasing flow, the number of waves decreases consecutively until at the largest flows the profiles present a smooth curve free from waves. Moreover, it is apparent that at least within the limits of these tests, the waves on a level crest continue to occur until smoothed out by sufficient increase in the slope

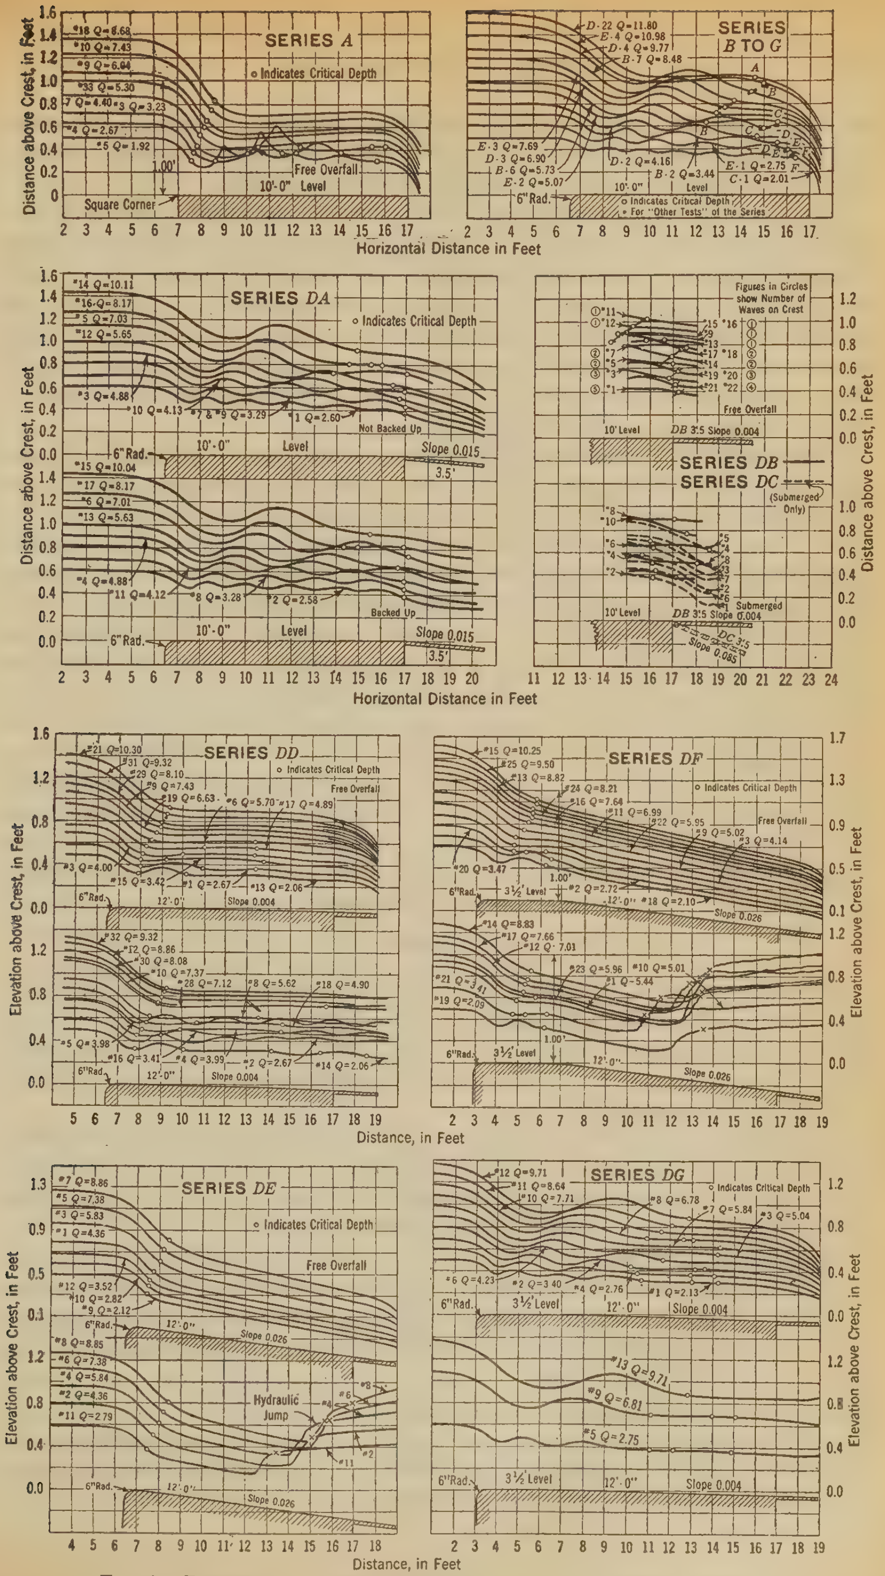

FIG. 4.—PROFILES OF WATER SURFACE AND LOCI OF CRITICAL DEPTH.

or by a fall at the down-stream end of the level section. Narrowing the weir would thus obviously result in fewer waves at the smaller flows and in a reduction of the volume of flow at which the last wave disappears.

The effect of an increase in slope is shown by the profiles of Series *DF* and *DG*. The weir in Series *DF* consisted of a level section 3½ ft. long, with rounded entrance, followed by 12 ft. of 0.026 slope. Waves occurred singly and only at the two smallest flows. The narrow section of level crest and the steepness of the down-stream slope combined to smooth out the flow quickly. The slope of crest in Series *DG*, however, was not sufficient to smooth out the flow quickly and the profiles show at least one wave for all heads tested and as many as three waves for the smallest flow.

The foregoing discussion of the position of critical depth pertains to the weirs in which the entrance was rounded. With a square-cornered entrance the conformation of the water surface over the weir was quite different, as is seen by comparing the profiles of Series *A* with those of Series *B* to *G*. The initial drop in the water surface was greater with the square-cornered entrance than with the rounded entrance preceding a level crest 10 ft. broad. With the square-cornered entrance the water surface dropped to a point below the critical depth and then commenced to rise gradually. This rise continued either until it approached the critical depth, when the surface became wavy and turbulent, or until it reached the vertical curve caused by the fall. The critical depth was reached and waves were formed only with flows of less than about 4 cu. ft. per sec. The waves formed with the rounded entrance were smooth in profile, and the water surface was practically level in cross-section at all points. With the square-cornered entrance the waves reached more of a peak, being considerably higher in the center of the stream than at the sides; and there was more surface turbulence.

VARIATION OF WEIR COEFFICIENT WITH HEAD

The variation of the weir coefficient, C, with the total head, H_a, in the equation, $Q = C L H_a^{\frac{3}{2}}$, for thirteen different weir models tested, is shown by the series of graphs in Fig. 5. A longitudinal section of the weir model is shown with each graph. The points on the graphs include only tests of weirs with free over-fall.

To facilitate comparisons of the coefficients for the different weir models, all thirteen curves are shown on one graph in Fig. 6; also, two curves obtained by Bazin and three by the U. S. Geological Survey for weirs of the same general type as those reported in this paper.

One important comparison (Fig. 6) is that for the weirs with the broader part of the crest level, with rounded entrance, and either with or without a narrow sloping down-stream apron, the coefficient increases with the head up to values of H_a of about 1.10, after which it is approximately constant (Series *B* to *G*, *DA*, and *DB*); while for weirs with the broader part of the crest sloping down stream, with rounded entrance, and either with or without a narrow level platform preceding the sloping section, the coefficient decreases with the head and shows a tendency to become constant at values of H_a of about 1.30 (Series *DD*, *DE*, *DF*, and *DG*).

Series *B* to *G* (Fig. 6) also indicate that for the breadth of weirs tested, varying the curvature of the weir entrance between a 2-in. and an 8-in. radius has practically no effect on the weir coefficient. The graphs obtained with six different curvatures—four circular and two elliptical—all lie within 0.5% of one another at all points. The graph for a square-cornered entrance (Series *A*), however, is considerably lower, showing values of the coefficients from 6 to 8% less than for rounded entrances. Apparently, the entire advantage of rounding the entrance is obtained with the change from the square corner to the 2-in. radius, and further increase in the radius does not appreciably increase the coefficient.

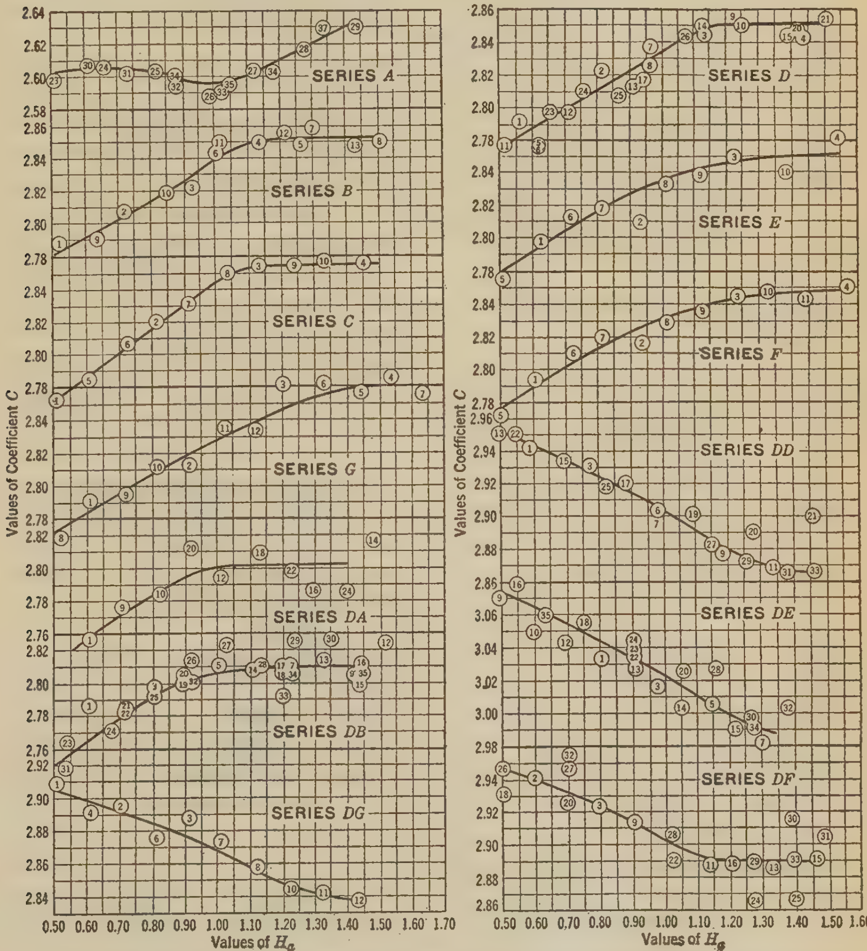

FIG. 5—VARIATION OF COEFFICIENT OF DISCHARGE, C, WITH TOTAL HEAD, H_a, IN FORMULA, $Q = C L H_a^{3/2}$. H_a = OBSERVED HEAD + VELOCITY HEAD; L = 2.0 FEET.

A definite increase in coefficient with increase in slope of the crest is also shown. A comparison of the curves of Series *DE* and *DD* for the same width of crest, but with different slopes, shows that the coefficients for the weir with a crest slope of 0.026 are about 4% higher throughout the range of heads tested than the coefficients for the weir with a crest slope of only 0.004. Tests in Series *DF* and *DG*, in which a 3½-ft. level section preceded the sloping

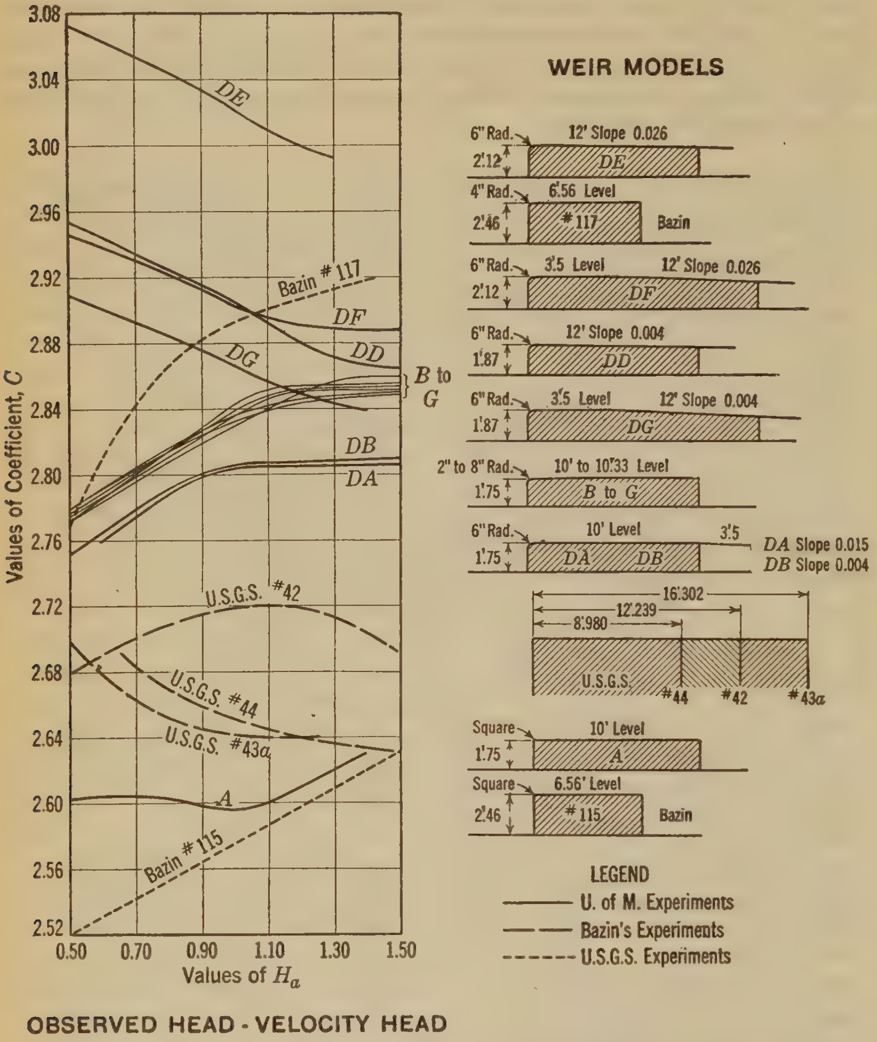

FIG. 6.—VARIATION OF COEFFICIENT OF DISCHARGE, *C*, WITH TOTAL HEAD. H_a. BAZIN CURVE AND U. S. GEOLOGICAL SURVEY CURVES ARE TAKEN FROM *Water Supply Paper No. 200,* PLATES IV, XXIX, AND XXX.

section, also show higher coefficients for the weir with steeper slope. The difference is not so great, however, as in the narrower weirs of Series *DE* and *DD*, indicating that a greater width tends to reduce the effect of a change in slope.

The tests show a reduction in coefficient with an increase in the width of the weir. Comparison of Series *DA* and *DB* with Series *B* to *G* shows that a decrease of about 1% in the coefficient resulted when a 3½-ft. downstream apron with a slight slope was added to the weir with level crest. Moreover, comparison of Curves *DE, DF,* and *DD* shows that the coefficients were reduced about as much by the addition of 3½ ft. of level section ahead of the sloping section as by reducing the slope from 0.026 to 0.004. The height of these weirs varied from 1.75 to 2.12 ft., but there is little probability that the conclusions are appreciably in error on this account, especially since the variation in height was largely compensated for by including the correction for velocity of approach in the head used to compute the weir coefficients.

All the tests show fairly good agreement with those obtained by other experimenters on weirs of the same general type. The results of Series *B* to *G* are comparable with Bazin's Test No. 117 (Fig. 6) on a weir with level crest, 6.56 ft. broad, with rounded entrance. As might be expected with a narrower weir, the curve of Bazin's results lies somewhat higher than the curves of Series *B* to *G*. For a sharp-cornered entrance, the curve of Series *A* for a weir with a crest 10 ft. broad agrees in general location with the curves of Bazin's Test No. 115 and of the U. S. Geological Survey Tests Nos. 42, 43A, and 44 (Fig. 6).

An inspection of the individual graphs of Fig. 5 shows that in 201 tests of the 13 weirs, only one point, No. 21 in Series *DD,* is more than 1% off from its curve, while the large majority are well within 0.5% of the curve.

Since H_a enters the broad-crested weir equation to the three-halves power, an error of 0.5% in the computed value of C is caused by an inverse error of approximately one-third of 1% in observing the head on the broad-crested weir. At the lowest head tested, 0.5 ft., this error would be produced by an actual error in reading the head of 0.0017 ft.; while at the highest head, 1.5 ft., the error in reading the head would have to be only 0.005 ft. to produce an error of 0.5% in the coefficient.

CONCLUSIONS

The tests furnished experimental verification of the theory that a broad-crested weir can be properly designed to operate submerged with small loss of head, and with the same coefficients as for a weir of the same design with free over-fall. Measurement of head, moreover, is required at only one point. The minimum loss of head occurs when the weir is designed to produce a hydraulic jump on the crest. As long as the jump does not approach too close to the weir entrance, its position does not affect the coefficient. Proper design of the weir, therefore, can provide for considerable fluctuation in discharge, with resulting variation in position of the jump, without change in the head-water-discharge relation.

In addition, the tests brought out difficulties which must be overcome in producing flow at critical depth at some predetermined point on the crest of the weir. The chief difficulty is the formation of waves on the crest which affect the location of critical depth. Tests of other types of entrance with different alignment of the sides of the channel may lead to a design of weir which will maintain the flow at the desired depths without these disturbing waves. The measurement of flowing water with a broad-crested weir of this type would require only a determination of the depth at the predetermined point and would not involve velocity of approach, which has been a continued source of uncertainty in measurements with sharp-crested weirs.

PERSONNEL

The tests were performed by the writer under the leadership and guidance of H. W. King, M. Am. Soc. C. E., and with the assistance of C. O. Wisler, Assoc. M. Am. Soc. C. E., and Messrs. H. A. Seaman, J. G. Jobes, C. L. Palmer, A. J. Paddock, P. Singh, and C. Li, graduate students and seniors at the University of Michigan. Most of the drawings were by Mr. Seaman.

APPENDIX

SUPPLEMENTAL TESTS—WEIRS WITH APRONS INCLINED UP STREAM AND DOWN STREAM

By ALEX. R. WEBB,[5] M. AM. SOC. C. E.

SCOPE

This Appendix describes experiments conducted in continuation of Mr. Woodburn's work on broad-crested weirs. The object was to determine if possible a form of weir crest which would cause the locus of critical depths to lie in a vertical line. The general dimensions of the weir used are illustrated in Fig. 7. The apex of the two sloping aprons forms the highest section of the weir crest.

Results are given for 235 separate experiments. The down-stream apron was set at slopes of 1 in 15.4, 1 in 24.8, 1 in 25.0, 1 in 25.5, and 1 in 46.4. The slope of the up-stream apron was varied between 1 in 7.5 and 1 in 98.5. The heads ranged from 0.12 to 1.33 ft. and the discharges from 0.22 to 9.33 cu. ft. per sec.

The experiments show that for the flatter slopes waves formed on the up-stream apron and that the location of critical depth changed with the position of the wave. This condition was less marked for the smaller discharges. Except for these very flat slopes it was found that for each slope of the down-stream apron there was a corresponding slope of the up-stream apron, which caused critical depths for all discharges to lie in a vertical straight line near, but not necessarily above, the apex of the crest.

The effect of submergence on the relation of head to discharge was investigated by making parallel runs both with and without submergence. In all, fourteen pairs of comparative tests were made. The value of the coefficient, C, in the weir formula, $Q = C L H_a^{\frac{3}{2}}$, was also investigated. In addition, a series of experiments was conducted to check the formula for the V-notch weir which was used to measure discharges.

LABORATORY

With slight modification the equipment used is the same as that described in the paper. The horizontal broad-crested weir was modified by building a small bulkhead at the up-stream end and attaching the sloping aprons, shown in Fig. 7. The down-stream apron, the false bottom referred to by Mr. Woodburn, was fixed for each set of experiments. The up-stream apron was attached by hinges to the bulkhead so that the slope could be easily changed.

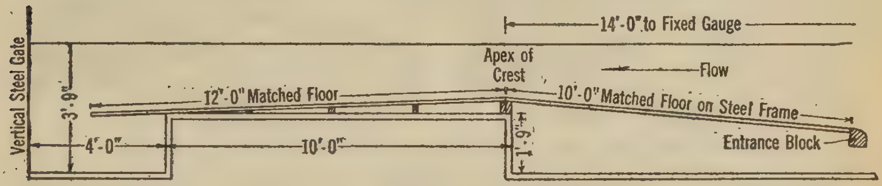

FIG. 7.—LONGITUDINAL SECTION OF WEIR.

During the first experiments, Series *WA* to *WH*, uplift pressure caused the floor to pull away from the joists, forming a slightly convex surface instead of a plane. Thereafter, matched flooring attached to a welded steel frame ensured a plane surface under all conditions.

For all experiments except Series *WA*, *WB*, and *WC*, a 3 by 6-in. elliptical laminated block was bolted to the up-stream apron to give a rounded entrance.

TEST PROCEDURE

An outline of conditions to which the experiments conform is given in Table 2. In making each run, the profile of water surface over the weir was determined from observations 2 ft. or less apart. At the time of taking readings along the center line of the channel, simultaneous readings were made for the fixed gauge and the V-notch weir gauge. Six readings were taken across the apex of the weir while simultaneous readings were being taken at the fixed gauge. While these observations were being made, as many readings as possible of the V-notch weir gauge were taken. (See Table 3.) One reader attended each of the three gauges, and one man acted as recorder for the fixed gauge and the movable gauge.

ANALYSIS OF RESULTS

The results of the investigation will be discussed under several heads.

Location of Critical Depth.—A profile of water surface was plotted for each run. Usually 6 to 8 runs (constituting a series of experiments) were conducted for each setting of the aprons. In all there were 37 series. The point of critical depth was determined from the formula, $Q = \sqrt{g}\ L\ D_c^{\frac{3}{2}}$, or, for length of weir, $L = 2, D_c = 0.1981\ Q^{\frac{2}{3}}$. This depth was plotted on each profile.

Profiles for each series of experiments were plotted on a single sheet. Typical examples are shown in Fig. 8. Five sets of experiments containing, respectively, 8, 10, 9, 6, and 4 series were performed. In each set the slope of the down-stream apron was kept constant and that of the up-stream apron was varied. Profiles of each set of experiments plotted to a larger scale on a

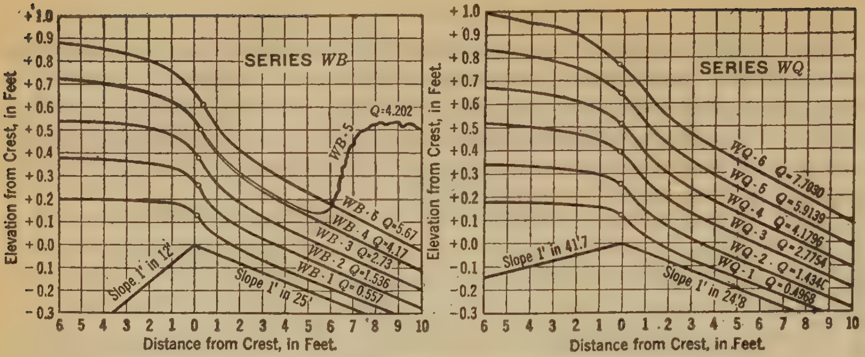

FIG. 8.—EXAMPLES OF WATER PROFILES, SHOWING CRITICAL DEPTHS.

single diagram and showing water surfaces 1.5 ft. up stream and down stream from the apex (Fig. 9), indicate that while there are individual variations, in general the points of critical depth lie on well-defined curves. These curves plotted to a greatly distorted scale are shown in Fig. 10.

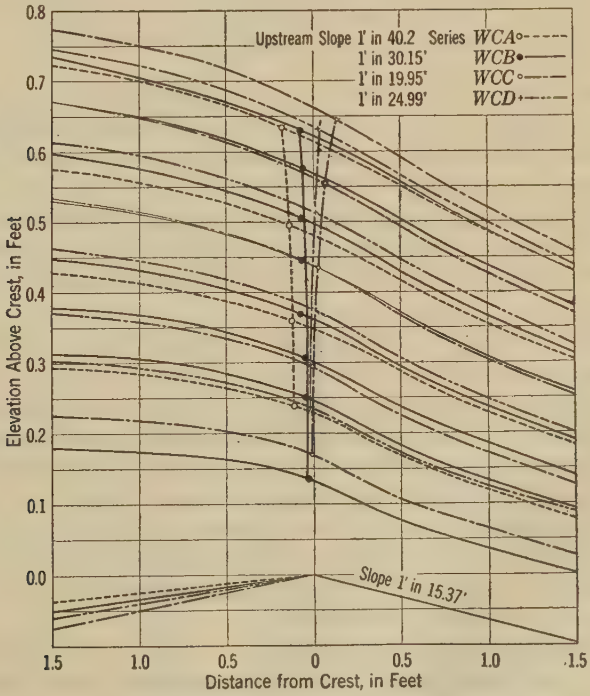

FIG. 9.—ENLARGED PROFILES, SHOWING CRITICAL DEPTHS.

In one series of experiments, where the slope of the down-stream apron was 1 in 25.5 and that of the up-stream apron, 1 in 40.3, the points of critical depth for all discharges fell on a vertical straight line over the apex. This condition was not duplicated for any other combination of slopes. With down-stream and up-stream slopes, respectively, 1 in 24.8 and 1 in 39.8, critical depths fell in a vertical line, 0.08 ft. up stream from the apex. Experiments on a much steeper down-stream slope (1 in 15.4) indicate that critical depths would lie in a vertical line about 0.04 ft. up stream from the apex when the up-stream slope was about 1 in 28.

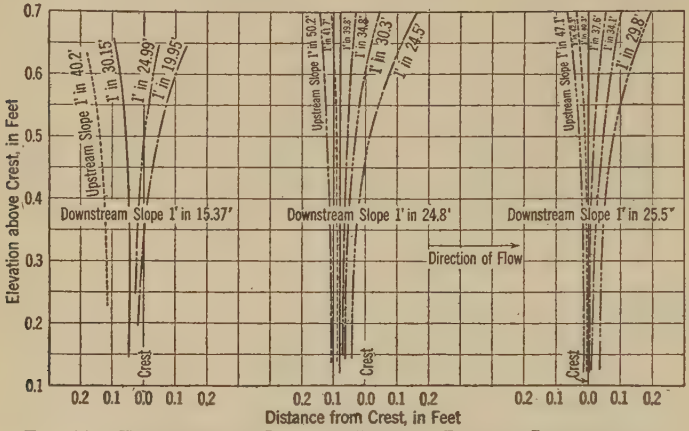

FIG. 10.—VARIATIONS IN LOCI OF CRITICAL DEPTHS CORRESPONDING TO SLOPES OF WEIRS.

In all cases where the up-stream apron was given a very flat slope, waves formed on the crest of the weir. The position of critical depth then became variable, depending more or less on the location of the waves. The condition for an up-stream slope of 1 in 98.5 is illustrated in Fig. 11(*a*). The tendency of waves to form on the up-stream apron was less marked for the smaller discharges. There were slight indications of waves for slopes of about 1 in 50. No waves were observed when the slope of the up-stream apron was 1 in 40, or less.

Calculations were made to determine the percentage of error that would result from computing discharges by the formula, $Q = \sqrt{g}\ L\ D_c^{\frac{3}{2}}$, substituting the measured depth over the apex D_c. The results of the computations for Series *WAA* and *WP*, in which the critical depths were approximately in verticals, over the apex and 0.08 ft. up stream from the apex, respectively, are shown in Table 4. In the first case the percentages of error that would result from using the measured depth over the apex as the critical depth, lie between the limits, — 0.7% and + 0.5 per cent. In the second case the corresponding percentages range from — 2.1 to — 7.4. These results show clearly the sensitive character of this type of structure.

Effect of Submergence on Head-Discharge Relation.—One of the advantages of weirs with broad crests is that the down-stream water surface may be at an elevation materially higher than the crest of the weir without affecting the relation between head and discharge. Weirs having this characteristic per-

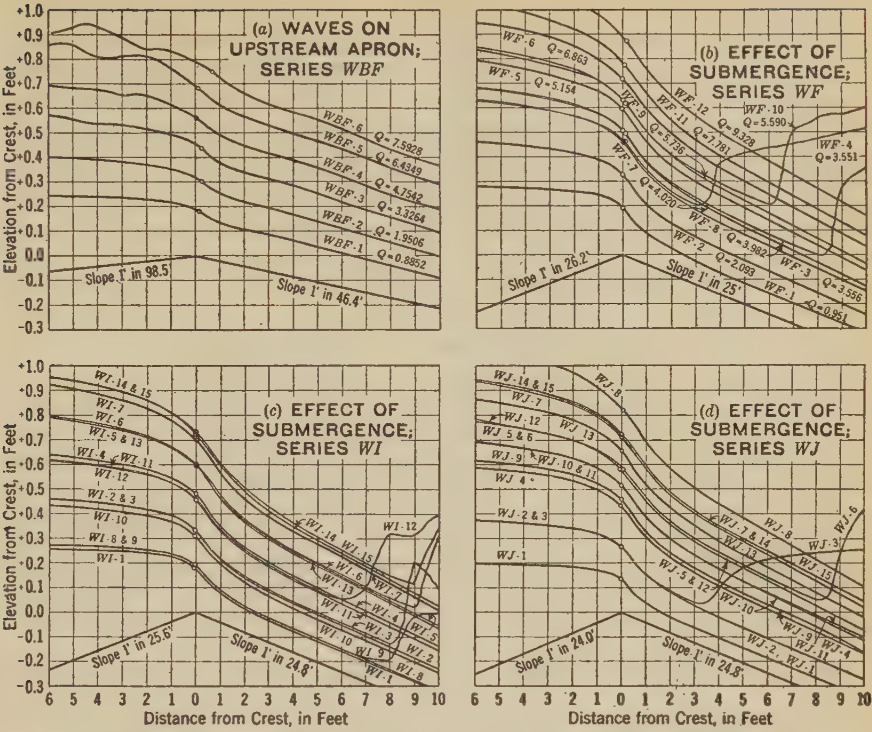

FIG. 11.—EXAMPLES OF WATER PROFILES AND INFLUENCE OF WAVES.

mit the measurement of discharges without great loss of head. Fourteen pairs of experiments were conducted to study the effects of submergence. In so far as practicable the discharge for both runs of any pair was kept constant. One run was made with free discharge and the other with the water backed up so as to cause a hydraulic jump on or just below the down-stream apron. Since the down-stream end of the apron was only 2 ft. from the outlet of the flume, it was not possible to determine the effect of a jump farther down stream.

In all these experiments it was found that backing up the tail-water caused a slightly increased depth over the apex and a slight increase in head at the fixed gauge. Table 5 gives comparative discharges for each pair of experiments computed from the formula, $Q = \sqrt{g}\ L\ D^{\frac{3}{2}}$, D being the depth over the apex. These values compared with measured discharges show that submergence affects the discharge by 0.31 to 2.81 per cent. In all the experiments the slope of the down-stream apron was approximately 1 in 25, but the slope of the up-stream apron varied from 1 in 7.5 to 1 in 30. (See Fig. 11.)

THE VARIATION OF WEIR COEFFICIENT WITH HEAD AND SLOPE

Values of the coefficient, C, in the weir formula, $Q = C\ L\ H_a^{\frac{3}{2}}$, show a wide variation for comparatively small changes in discharges and in slopes of aprons. This variation is indicated quite clearly in Fig. 12. In determining Q and H, gauge readings for a complete run were averaged.

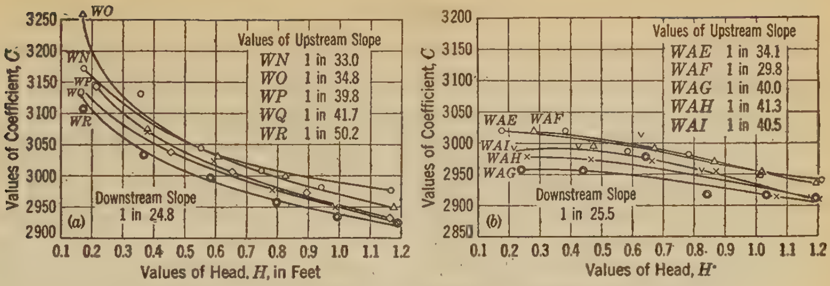

FIG. 12.—VARIATION IN VALUES OF COEFFICIENT, C.

CHECKING V-NOTCH WEIR FORMULA

Preliminary to beginning the experiments, an examination of the V-notch weir used by Mr. Woodburn for determining discharges, showed the face of the weir to be quite heavily coated with mineral deposits. A series of experiments was made with the weir in this coated condition and another series after it had been cleaned. The quantity of flow was obtained by weighing as described in the paper. The results of these experiments (Table 6) show average discrepancies with Mr. Woodburn's formula before and after cleaning, of 0.44 and 0.33%, respectively. In view of this close agreement Mr. Woodburn's formula was accepted as being substantially correct.

CONCLUSIONS

The following conclusions are drawn relative to a weir consisting of two connected aprons sloping upward to form a peak along the line of junction:

1.—It is possible, with proper slopes of the aprons, to cause the points of critical depth to lie in a vertical straight line. The position of this vertical is sensitive to slight changes in the two slopes. Further study will be required to determine whether a form of weir crest can be devised which will assure a fixed position for the vertical.

2.—Backing up the tail-water in an amount sufficient to cause the hydraulic jump to occur upon the apron increases the depth of water on the weir.

3.—Values of the coefficient, C, in the weir formula, $Q = C L H_a^{\frac{3}{2}}$, are very sensitive to small changes in the slopes of the aprons.

ACKNOWLEDGMENTS

The experiments were performed under the direction of H. W. King, M. Am. Soc. C. E. Harry Larson, Assoc. M. Am. Soc. C. E., collaborated in conducting the experiments and in computations. The following students in the College of Engineering, University of Michigan, assisted in the laboratory, Messrs. E. V. Schulhauser, V. K. Ipe, M. Mortenson, D. W. Richardson, I. Curtis, F. F. Smalla, and C. O. Bloom.

During the past year (1929-30) the Society's Special Committee on Irrigation Hydraulics has co-operated in the experiments. In particular, D. C. Henny, and J. C. Stevens, Members, Am. Soc. C. E., Chairman and Secretary, respectively, of the Committee have made valuable suggestions.

DISCUSSION

H. W. KING,[6] M. AM. SOC. C. E. (by letter).—Critical-depth devices for measuring flowing water are being used to a limited extent, particularly by the Bureau of Reclamation in the irrigated districts of the Western United States. The discharge has been considered to be a function of the up-stream head. For this method the theoretical discharge per foot of width of a rectangular cross-section is:

$$Q_1 = 3.087\, H_a^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Since H_a is the sum of the static head and velocity head the problem of correcting for velocity of approach is the same as for the weir. Moreover, all the tests in the paper and in the Appendix show that the coefficient varies considerably from the theoretical value of 3.087. Used in this manner the critical-depth device, therefore, does not provide a precise means of measuring flowing water. It is useful, however, for approximate measurements such as are satisfactory for apportioning irrigation water.

If a structure could be designed so that it would be known in advance that flow at critical depth would occur at a definite cross-section for all discharges, the discharge could be determined by measuring the critical depth, D_c, at this section and then making proper substitution in a simple rational formula. For a rectangular cross-section the discharge per foot of width is:

$$Q_1 = \sqrt{g}\, D_c^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

With such a device there would be no coefficient to apply for velocity of approach, nor any other corrective factor to consider, and the measurement of discharge would be reduced to its simplest terms. Another advantage is that it provides for measuring discharges with a minimum loss of head, as the tail-water can be nearly as high as the head-water without changing the position of critical depth.

If a channel is sufficiently constricted either by elevating the bottom, or by drawing in the sides, or by combining the two so as to form a short reach which has a gently sloping bottom, flow at critical depth will occur near the upper end of this slope. The position of critical depth can be predicted approximately, but not with the accuracy required if discharges are to be determined from measurements of this depth. Investigations of several types of structures by the Society's Special Committee on Irrigation Hydraulics, and by others, have failed to produce a design for which the position of critical depth could be predicted accurately.

Professor Woodburn began an investigation of this problem in the fall of 1928. His experiments on a broad-crested weir with rounded entrance and gently sloping crest showed that critical depths for the different discharges lie in quite regular lines down stream from the upper edge of the weir. The law affecting their position could not be determined. Since critical depths on this structure, as well as on other structures with which the writer is familiar, occur where the water surface has a comparatively steep slope, it is necessary that their positions should be known within very narrow limits. An error of ½ in. up stream or down stream in the point of measuring critical depth results in an error of several per cent. in the discharge determined by Equation (2).

---

[6] Prof. of Hydr. Eng., Univ. of Michigan, Ann Arbor, Mich.

An unsuccessful attempt was made to flatten the water surface near the point of critical depth by attaching an apron with a gentle slope to the up-stream end of the weir. Too flat a slope of the apron, by producing flow in the unstable condition existing near critical depth, causes waves to form on the weir crest with one or more points of critical depth occurring most irregularly. It appeared, therefore, that to assure the occurrence of critical depth at a fixed section very flat slopes on the weir crest should be eliminated.

Since Professor Woodburn's experiments with a single sloping crest showed critical depth to occur down stream from the upper edge of the weir, while with a level apron attached to the up-stream edge critical depth moved up stream and over the level apron, it appeared that the point of critical depth could doubtless be moved up stream or down stream by changing properly the respective slopes of the two aprons. Professor Webb's experiments were undertaken for the purpose of investigating this principle. (See Appendix I.)

He was successful in finding slopes for the two aprons which caused the critical depths for all discharges to lie very close to vertical lines. It was found, however, that slight changes in the slope of either apron would displace points materially from these verticals and also that the position of the vertical when it was obtained was not precisely the same for the different combinations of slopes. One series of experiments in the Appendix shows the vertical to be over the apex; another shows it to be 0.08 ft. up stream from the apex; while a third indicates a position about midway between the other two. In view of the steep slope of water surface that obtains, if a device of this type is to be useful for precise measurement of water the position of critical depth must be known between much narrower limits than these.

The investigations of Professors Woodburn and Webb give much additional and useful information regarding flow at critical depth. They have not completely accomplished the original purpose of devising a structure which will produce critical depth at a predetermined cross-section. They have made progress, however, and by bringing to light conditions which affect the stability of flow as well as the position of critical depth, they have paved the way for intensive investigations in the future. In the writer's opinion it is quite probable that a design satisfactory for measuring flowing water by this method may yet be devised.

SHERMAN M. WOODWARD,[7] M. AM. SOC. C. E. (by letter).—Whenever flow is near the critical depth and critical velocity, the depth is in a condition of peculiar unsteadiness, leading easily to the formation of standing waves by some very slight disturbing factor. On this account, it will probably be difficult to devise any arrangement of the channel which will insure that at some prescribed point the depth shall be exactly the critical depth. This state of uncertainty does not extend, however, to the quantity of flow, since for a given total head it is at a maximum value during critical flow, and, therefore, independent of slight changes in depth. The result is that the very same conditions which are most unfavorable for an experimental measurement of critical depth are most favorable for the prediction of quantity of flow.

---

[7] Prof. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

Compared with many other hydraulic phenomena, the flow over weirs is nearer stream-line flow and is, therefore, relatively more stable and less subject to accidental and erratic disturbance. Through a careful exploration of the velocity distribution throughout the sheet flowing over the weir crest it may be expected that the effect of each separate factor influencing the flow can be determined. After such an analysis it may be possible to know how the flow over the weir is influenced by the shape and angles of the approach channel, by the dimensions and curvature of the crest, by the friction on the crest, and by the nature of the exit conditions from the crest. The phenomena are particularly well adapted to study by the laws of similarity.

The ideal should be to accumulate experimental data sufficiently comprehensive and precise so that the exact flow over any full-sized overflow weir can be predicted in advance of its construction. The author and Professor Webb have made a most commendable contribution toward the realization of this ideal.

The paper opens up a series of fascinating questions, and it is to be hoped that it will be followed by further studies. This field appears to be particularly favorable for intensive studies designed to show the fundamental nature of stream flow.

DAVID L. YARNELL,[8] M. AM. SOC. C. E. (by letter).—This paper presents interesting data on various types of broad-crested weirs both in regard to coefficients of discharge and the location of the critical depth.

During 1929 the U. S. Bureau of Public Roads, in co-operation with the State University of Iowa, conducted a series of experiments on the flow of water over full-sized sections of railway and highway embankments for the purpose of developing formulas for use in calculating the quantity of flood water flowing over such embankments.

Full-sized sections of single and double-track railway embankments, 10 ft. in length, were built in the laboratory testing canal. With the rails removed the embankments resembled somewhat the weir for Test Series *B* to *G*, Fig. 4.

The single-track railway test embankment with rails removed is shown in Fig. 13 (*a*). Profiles of the water surface are shown for free flow for quantities of from 12 to 78 cu. ft. per sec. The position of critical depth (indicated by circles) has been computed for each quantity of flow. It will be noted that, with certain exceptions, the locus of critical depth is approximately a vertical line. Fig. 13 (*b*) shows a check series of tests run on the same embankment for quantities of flow of from 15 to 74 cu. ft. per sec. The locus of critical depth was again found to be practically a vertical, as is also the case in Fig.

---

[8] Senior Drainage Engr., Bureau of Public Roads, U. S. Dept. of Agriculture, Iowa City, Iowa.

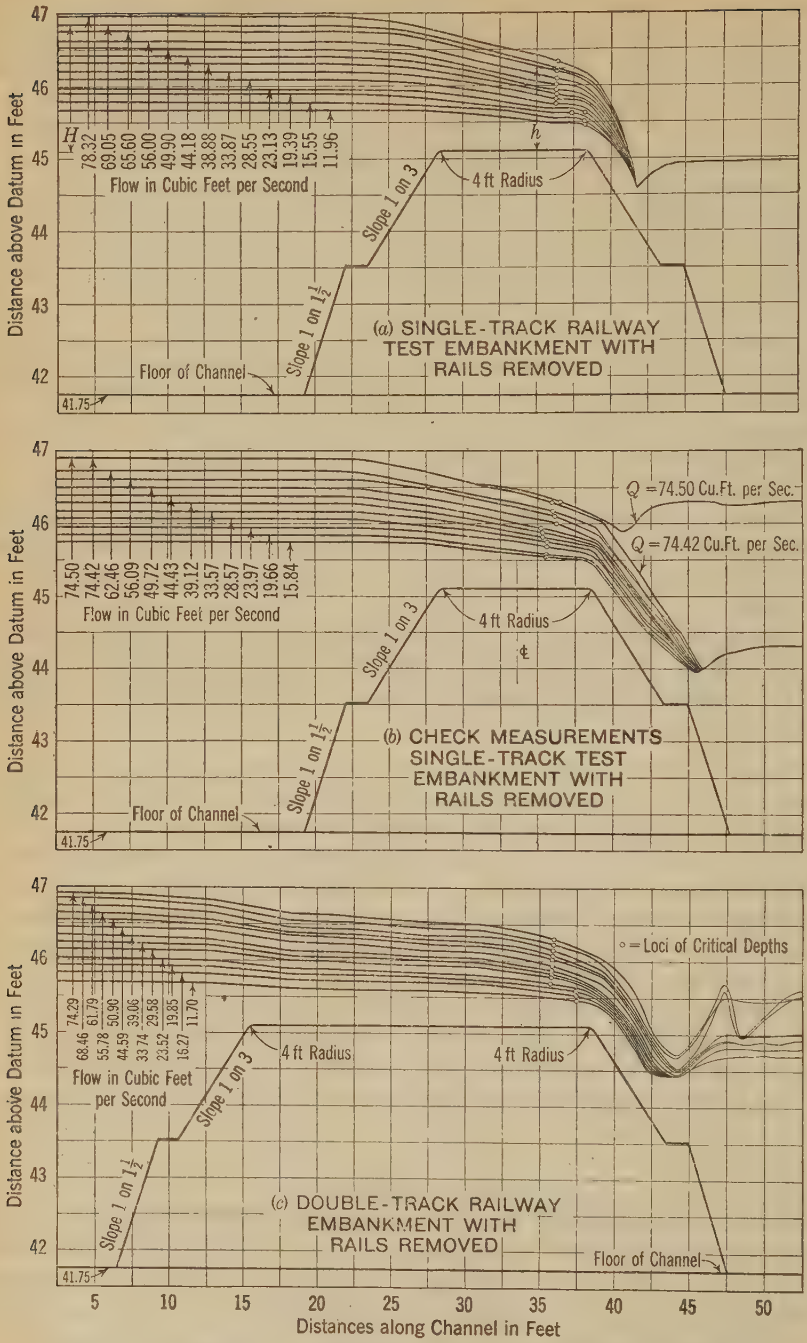

FIG. 13.—PROFILES OF WATER SURFACE AND LOCI OF CRITICAL DEPTH.

13 (*c*) which shows a series of tests on a double-track railway embankment (with rails removed) for quantities of flow of from 11 to 74 cu. ft. per sec.

The water-surface profiles were obtained from a series of staff gauges placed along both walls of the testing canal. Due to the continual pulsation of the water surface at the various gauges, the surface profile may be a few hundredths of a foot in error. This error is of great importance in locating exactly the position of critical depth. Hence, it is believed that for Fig. 13, all the loci of critical depths in each case would lie in verticals if the surface profiles could have been obtained more accurately.

Attention is called to the position of the tail-water for a flow of 74.50 cu. ft. per sec. in Fig. 13 (*b*). For this experiment the hydraulic jump occurred at Station 41, while the point of critical depth lies practically in the same vertical as in the case of the tests with free flow.

In connection with some tests on the hydraulic jump on sloping floors the writer had an opportunity to make a series of experiments on a weir with aprons inclined up stream and down stream. These experiments were made in a glass-walled channel, 2.5 ft. wide. The quantities of flow ranged from 3 to 8 cu. ft. per sec. The surface profiles and the loci of critical depths are shown in Fig. 14. In this case the locus of critical depth is in a vertical approximately at the crest of the weir.

Apparently, the author made no velocity traverses at the critical section. This would have added much value to the experimental work. The critical velocity as obtained from the formula, $V_c = \sqrt[3]{g\ Q \text{ per unit of width}}$, is the mean value for the critical section. Vertical velocity curves for the two largest discharges shown, Fig. 14, indicate that the greatest velocity is next to the crown of the weir and that the velocity decreases toward the surface of the water. This velocity distribution is characteristic of that existing in bends of pipes.

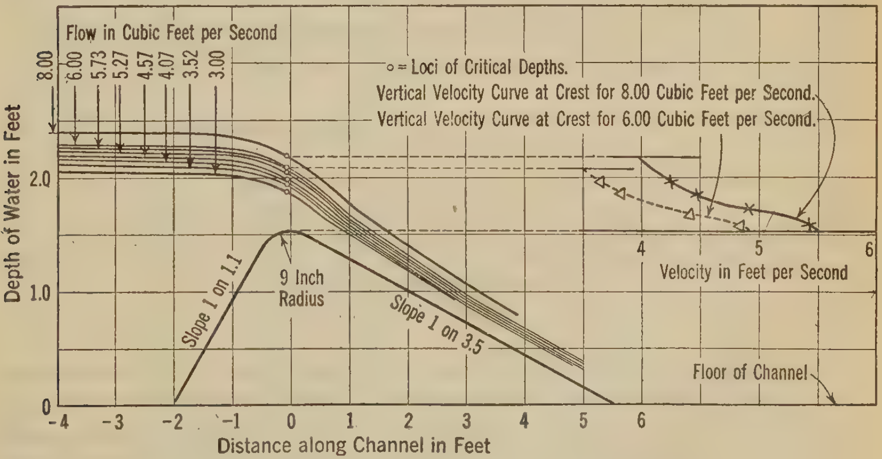

FIG. 14.—PROFILES OF WATER SURFACE AND LOCI OF CRITICAL DEPTH, AND VERTICAL VELOCITY CURVES FOR TWO DISCHARGES.

In Fig. 15 the coefficients obtained for the single and double-track railway embankments (without rails) are shown for the tests with free flow.[9] The standard American Railway Engineering Association railway embankments may be considered to have aprons inclined up stream and down stream, the slope being joined to the crown by a curve with a 4-ft. radius. Comparison of these coefficients with those given in Fig. 6 shows some differences, due no doubt to the fact that none of the weir models shown in Fig. 6 approaches the shape of a railway embankment. The coefficients for the weir with the rounded crest are given in Fig. 16.

If h (Fig. 13), represents the critical depth, and H, the head on the embankment, then $h = \frac{2}{3} H$. In an actual test, however, this relation does not always exist, the constant generally being less than two-thirds. The difference between the actual ratio and the theoretical, 0.666, is used up in overcoming friction on the up-stream face and crown of the embankment and may also be partly due to losses within the mass of moving water, such as eddies.

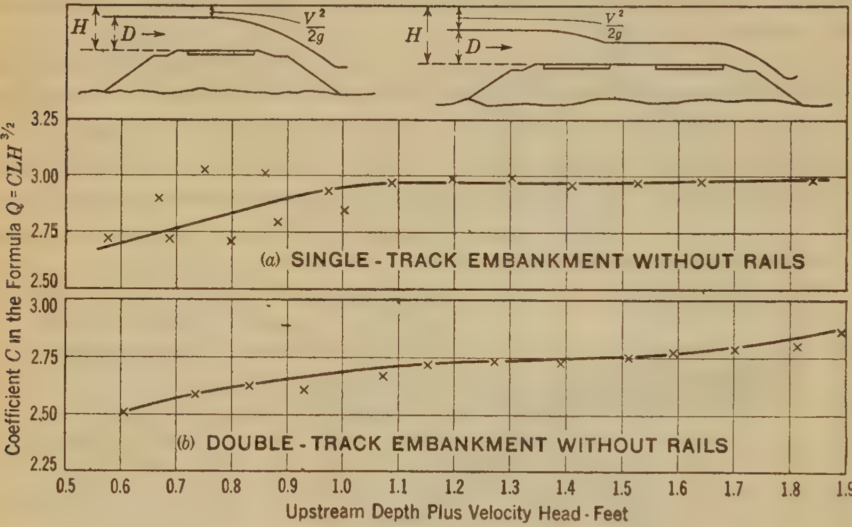

FIG. 15.—CURVE SHOWING VARIATION OF COEFFICIENT WITH HEAD.

In Table 7 the actual ratios for the single-track (Fig. 13 (a)) and double-track (Fig. 13 (c)) embankments are given as well as the amount used up in friction, etc. A comparison of the two sets of data shows that a little greater loss occurs, on the average, in the double-track than in the single-track embankment. This is to be expected since the double-track embankment is the wider.

---

BORIS A. BAKHMETEFF,[10] M. AM. SOC. C. E. (by letter).—The remarks that follow are offered with the sole purpose of further elucidating the phenomenon described in Professor Woodburn's valuable paper.

"Theory" of Flow.—The author defines the critical depth as one "at which, for any given total head, the discharge is a maximum". It was Bélanger who,

---

[10] Prof. of Civ. Eng., Columbia Univ., New York, N. Y.

nearly a hundred years ago, first suggested the postulate of "maximum discharge" as a basis for the "theory" of flow over broad-crested weirs. Given the total head, $H = H' + \frac{v^2}{2\,g}$, and a crest sufficiently wide so that flow may become parallel (Fig. 17), the depth, d, is supposed to establish itself in such a manner that the discharge will be a maximum. This method of treatment has since been invariably followed by hydraulicians, notwithstanding the fact that the deductions from the "maximum discharge theory" do not hold in the face of experimental evidence.

In fact, designating the relation of the depth, d, to the head, H, as

$$K = \frac{d}{H} \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and introducing a "velocity coefficient", ϕ, to take account of the hydraulic losses which occur between Sections A and B, the velocity, v, and the discharge, q, per unit width in Section B will be:

$$v = \phi\sqrt{2\,g\,(H - d)} = \phi\sqrt{2\,g\,H}\sqrt{1 - \frac{d}{H}} = \phi\sqrt{1 - K}\sqrt{2\,g\,H} \ldots (4)$$

and,

$$q = d\,v = K\,H\,v = \phi\,K\sqrt{1 - K}\,H^{\frac{3}{2}} \ldots\ldots\ldots\ldots (5)$$

Designating the "discharge coefficients" in the usual weir formula by m and $M = m\sqrt{2\,g}$,

$$q = m\sqrt{2\,g}\,H^{\frac{3}{2}} = M\,H^{\frac{3}{2}} \ldots\ldots\ldots\ldots (6)$$

by comparison with Equation (5),

$$m = \phi\,K\sqrt{1 - K} \ldots\ldots\ldots\ldots (7)$$

and

$$M = \phi\,K\sqrt{1 - K}\sqrt{2\,g} \ldots\ldots\ldots\ldots (8)$$

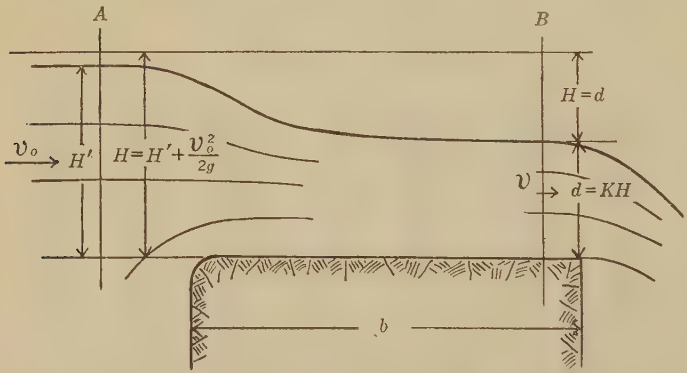

FIG. 17.—PARALLEL STREAM FILAMENTS IN UNIFORM FLOW.

Obviously, the "maximum discharge" is reached whenever m in Equations (6) and (7) is a maximum. For a given form of the entrance edge, ϕ may be assumed to be unchangeable. By writing,

$$\frac{dm}{dK} = \phi \sqrt{1 - K} - \frac{1}{2} \frac{\phi K}{\sqrt{1 - K}} = 0$$

the maximum discharge is found to occur at $K = \frac{2}{3}$ irrespective of ϕ. In other words, if the maximum discharge were to govern, the depth, d, near the end of the crest would be $d = \frac{2}{3} H$ for any type of crest, irrespective of its length, roughness, or the form of the entrance edge.

This deduction is in contradiction to observed facts. Professor Woodburn's profiles (Fig. 4), and other experiments,[11] show K to be less than two-thirds. Moreover, the value of K varies with the conditions of flow. For rounded entrance edges, under average conditions, K is nearly 0.63. For sharp entrance edges and relatively long crest, the value of K is nearly 0.6 and eventually less.

Cognizant of the discrepancy between the traditional theory and experiment, the writer suggested some years ago that investigators should approach the problem from a different angle. "Energetic" considerations were to be applied. For a given total head, H, the depth, d, and the resulting discharge were assumed to be such as to make the contents of energy in Section B the smallest possible minimum.[12]

If a discharge, Q, flows with a uniform depth and with parallel stream filaments in a canal of given form, such as Fig. 18, and if the depth of flow, d, varies, there is a certain "specific energy of flow" that corresponds to each depth of flow:

$$\varepsilon = d + \frac{v^2}{2\,g} = d + \frac{Q^2}{2\,g\,a^2} \quad \text{......................} (9)$$

which is the energy head (energy per unit weight) referred to the bottom line of the cross-section. The factor, a, in Equation (9) is the cross-sectional area at the depth, d. The graph of ε, which features the contents of specific energy as it changes under varying depth, has the shape illustrated in Fig. 19. The energy curve is tangent to the horizontal axis and to a straight line, drawn through 0 at 45%, and passes through a minimum point at C.

The ordinate, d_{cr}, at Point C is the critical depth. From this point of view critical flow acquires a definite physical meaning, namely, that at which the discharge in the canal flows with the smallest possible minimum content of energy per unit of weight. The energy curve, as shown in Fig. 19, and which has proved to be of incalculable service in considering different problems of varied flow, has been discovered and presented in different countries by different hydraulicians seemingly independent of each other. In the United States a lucid exposition has been given[13] by Julian Hinds, M. Am. Soc. C. E. In Germany, Professor Rehbock alludes[14] to a similar curve. In Russia, the energy curve was introduced by the writer[12] in 1912 and, as far as he is aware, that was its first appearance. For a canal of any form, the critical depth is determined by the equation, $\left(\frac{a^3}{b}\right)_{cr} = \frac{Q^2}{g}$, in which, a is the cross-sectional area, and b, the width of the surface at the depth, d_{cr}. For a rectangular canal, the critical depth is related to the discharge per unit width by the well-known formula used by Professor Woodburn, $d^3_{cr} = \frac{q^2}{g}$.

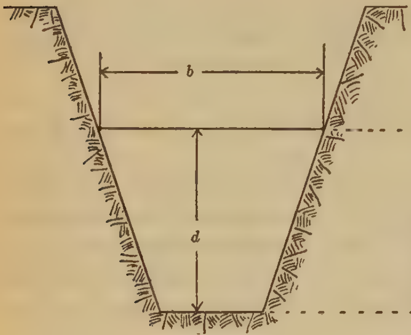

FIG. 18.

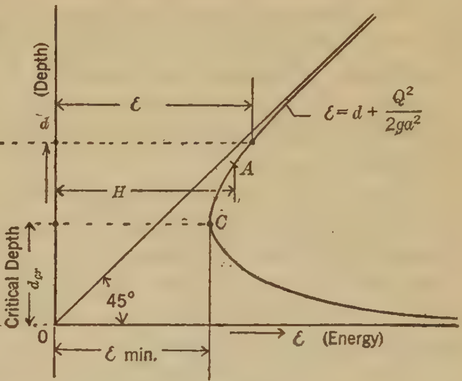

FIG. 19.

On the energy diagram, Fig. 19, flow over a broad-crested weir is shown by the movement from an initial point, A, corresponding to the energy content, H, down along the energy curve toward C. Obviously, in its natural tendency to become lower with a corresponding loss of energy, the level on the crest may not fall below Point C, as a further lowering of the depth could take place only through an increase, an addition of energy from outside, which is obviously impossible.

Thus, the critical depth (that at which flow takes place with a possible minimum content of energy), appears to be the natural limit, to which the surface level may lower, and which will establish itself at the end of the crest. The analytical relations between the different parameters of flow may be determined, as follows: The discharge in Section B, in accordance with Equation (5) and Equation (6), is:

$$q^2 = m^2\, 2\, g\, H^3 = \phi^2\, K\, (1 - K)\, 2\, g\, H^3 \ldots\ldots\ldots\ldots (10)$$

The condition of minimum energy (critical depth) is expressed, as follows:

$$q^2 = g\, d^3 = g\, K^3\, H^3 \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Hence,

$$m^2\, 2\, g\, H^3 = g\, K^3\, H^3 \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

and,

$$\phi^2\, K^2\, (1 - K)\, 2\, g\, H^3 = g\, K^3\, H^3 \ldots\ldots\ldots\ldots\ldots (13)$$

From Equation (12), $m = \sqrt{\frac{K^3}{2}}$; $K = \sqrt[3]{2\,m^2}$; and,

$$M = \sqrt{2\,g}\,m = \sqrt{g\,K^3} = 5.67\,K^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots (14)$$

On the other hand, the relation between K and the velocity coefficient may be expressed in the form:

$$\frac{2\,\phi^2\,(1 - K)}{K} = 1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

which gives, $K = \frac{2\,\phi^2}{2\,\phi^2 + 1}$, and $\phi = \sqrt{\frac{K}{2\,(1 - K)}}$.

It should be noted that this analysis applies to crests that are horizontal or inclined at a slope not exceeding the "critical slope." For slopes beyond the critical, the very nature of the phenomenon changes, as outlined subsequently. Curves for various numerical values of Equations (14) and (15) are plotted in Fig. 20.

The factor, 3, is a "resistance coefficient", obtainable from the relation,

$$\frac{v^2}{2\,g}\,(1 + \zeta) = H - d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

which, in view of Equation (3), gives, $\zeta = \frac{1}{\phi^2} - 1$.

In contradistinction to the "maximum discharge" theory, K is no longer constant. In the "ideal" case, with $\phi = 1$ (no losses), K is two-thirds. Under actual conditions, with $\phi < 1$, K is less than two-thirds. The greater the losses the smaller the relative value of K. Preliminary experiments, carried out during 1913 in the Hydraulical Laboratory of the Polytechnical Institute of St. Petersburg, gave results, which on the whole appeared consonant with the foregoing theory. The principal difficulty in comparing theoretical deductions with observations, lies in the fact that flow over a weir, unless the relative length of the crest, $\left(\frac{b}{H}\right)$, is considerable, is seldom "parallel" in the sense of the paragraph to follow. A large part of the surface is covered with waves. Moreover, the surface at the end of the weir is usually marked by pronounced curvature.

Effect of Curvature on the Critical Depth.—Professor Woodburn and Professor Webb both seek to determine the locus of the critical depth as a means of establishing a simple and reliable method of measuring the volume of flow. This locus is assumed by them to lie in a section, such that the depth of flow corresponds with the relation,

$$d'_{cr} = \sqrt[3]{\frac{q^2}{g}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which, d'_{cr} is the "apparent" critical depth.

The main point to be taken into account in this connection is that the critical depth as defined by Equation (17) is determined under the assumption of parallel flow; that is, flow in which the stream filaments are practically parallel, having "no appreciable curvature nor divergence". These requirements for flow being "parallel", which underlie the whole theory of varied flow, were formulated by Bélanger as early as 1828. In this case, and only in such a case, the potential energy, $y + \frac{P}{\Delta}$, in the Bernoulli equation is identical for all and every point of the cross-section and is everywhere equal to the depth, d, which accounts for the simple expression of specific energy of flow as given in Equation (9). The physical characteristic of parallel flow is, that the pressures within a cross-section are distributed according to hydrostatic law, the pressure diagram being the hydrostatic triangle *abc* (Fig. 21).

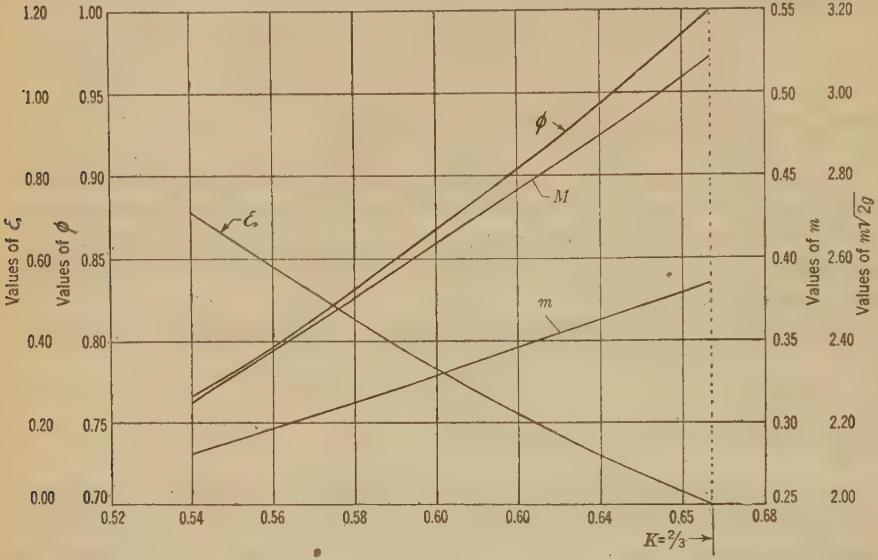

FIG. 20.

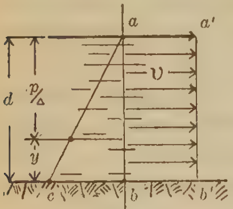

FIG. 21.

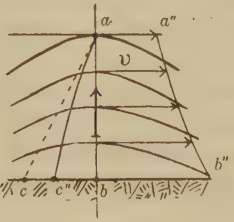

FIG. 22.

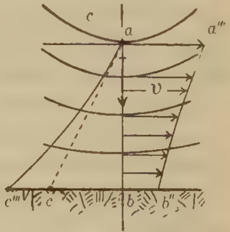

FIG. 23.

Now, if the surface and the stream filaments are curved, the pressure diagram is no longer a triangle. Centrifugal forces come into action, which for concave filaments (Fig. 22) bear downward, thus adding to the hydrostatic pressure and changing the triangle into abc'''. For convex filaments (Fig. 23), the centrifugal forces are directed upward; the hydrostatic pressure is diminished and follows the curve, abc'''. If the velocities and the curvature are substantial enough, the pressure at the bottom may change into a vacuum.

In general, additional pressure caused by curvature results in a lowering of the velocities and *vice versa*. Therefore, the "ideal" rectilinear velocity diagram of Fig. 21 is modified into $a'' \, b''$ and $a''' \, b'''$ in Figs. 22 and 23.

The specific energy varies from point to point. The average contents per unit weight will be:

$$\varepsilon = \frac{\int_0^d \left(\frac{P}{\Delta} + y + \frac{v^2}{2\,g} \right) v \, dy}{\int_0^d v \, dy} \qquad \text{(18)}$$

To determine the energy, one must know the distribution of pressures and velocities over a cross-section, a problem usually requiring recourse to methods of hydrodynamics.

To get a concrete appreciation of the effect of curvature, consider the elementary case of a canal, the bottom of which is laid on a circle of radius, R_0 (Fig. 24), under the further assumption that in the vicinity of the vertical section, Oab, the filaments form concentric circles with a common center of curvature in O; and, moreover, that the motion occurs in conformity with the law of the so-called "free vortex". In this case, as is well known, the velocity is inversely proportioned to the radii, so that $v\,R$ is a constant. In the case of concave streaming (Fig. 24 (a)), designating the surface velocity by v_a, the formula, $v\,(R_0 - y) = v_a\,(R_0 - d)$ is obtained, or,

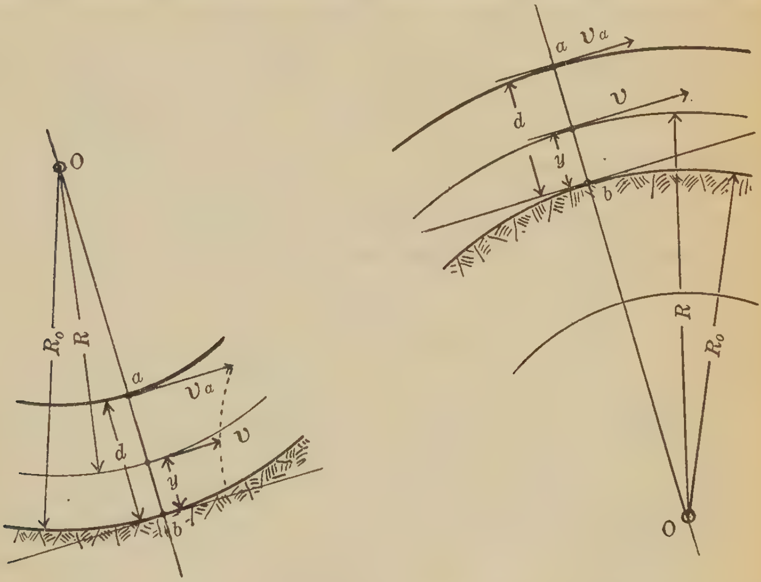

FIG. 24.

$$v = v_a \frac{R_0 - d}{R_0 - y} \qquad \text{(19)}$$

The discharge is:

$$q = \int_0^d v\, dy = \int_0^d v_a \frac{R_0 - d}{R_0 - y}\, dy = v_a (R_0 - d) \log \frac{R_0}{R_0 - d} \ldots (20)$$

Furthermore, designating the average velocity over the cross-section by v_m so that $q = v_m d$,

$$v_m d = v_a (R_0 - d) \log \frac{R_0}{R_0 - d} \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

or,

$$v_a = \beta\, v_m = \beta \frac{q}{d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

in which, the coefficient, β, is equal to,

$$\beta = \frac{1}{1 - \frac{d}{R_0}} \times \frac{1}{\log \frac{1 - d}{R_0}} \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

In the case of convex streaming (Fig. 24 (*b*)), analogous reasoning gives:

$$v = v_a \frac{R_0 + d}{R_0 + y} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

$$q = v_a (R_0 + d) \int_0^d \frac{d\, y}{R_0 + y} = v_a (R_0 + d) \log \frac{R_0 + d}{R_0} \ldots\ldots (25)$$

and,

$$v_a = \beta\, v_m = \beta \frac{q}{d} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

in which, the value of the coefficient is,

$$\beta = \frac{\frac{d}{R_0}}{1 + \frac{d}{R_0}} \times \frac{1}{\log \left(1 + \frac{d}{R_0}\right)} \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

Numerical values of β are given in Table 8.

TABLE 8.—NUMERICAL VALUES OF β

$\frac{d}{R_0}$	0.10	0.20	0.30	0.40	0.50	0.60	0.75
β for concave streaming……	1.063	1.12	1.20	1.303	1.44	1.64	2.16
β for convex streaming……..	0.953	0.925	0.88	0.848	0.82	0.795	0.77

The specific energy of the surface filament (at *a*) is $d + \frac{v^2_a}{2\,g}$. For any point within the stream, the energy is $y + \frac{P}{\Delta} + \frac{v^2}{2\,g}$. Now, free vortex is irrotational flow with a velocity potential. In such case the Bernoulli constant, $y + \frac{P}{\Delta} + \frac{v^2}{2\,g}$, has an identical value for the entire body of moving liquid. Hence, in the section, *Oba* (Fig. 24(*b*)), the specific energy at all points is the same, and thus is equal to the energy of the surface stream line. The specific energy, therefore, is:

$$\varepsilon = d + \frac{v^2_a}{2\,g} = d + \beta^2 \frac{q^2}{2\,g\,d^2} \qquad (28)$$

The critical depth may now be determined as the depth at which ϵ is a minimum. It is found by making

$$\frac{\partial\,\varepsilon}{\partial\,d} = 1 - \beta^2 \frac{q^2}{g\,d^3} + 2\,\beta \frac{q^2}{2\,g\,d^2} \frac{\partial\,\beta}{\partial\,d} = 0 \qquad (29)$$

The value of $\frac{\partial\,\beta}{\partial\,d}$ being comparatively small, one may, in a first approximation, neglect the third member in Equation (29), with the result that,

$$d_{cr} = \sqrt[3]{\beta^2\,\frac{q^2}{g}} = \beta^{\frac{2}{3}} \sqrt[3]{\frac{q^2}{g}} = \beta^{\frac{2}{3}}\,d_{cr} \qquad (30)$$

The actual critical depth in concentric curvilinear motion is thus larger or smaller than the apparent critical depth, d'_{cr}, defined in Equation (17), by the value of the coefficient, $\beta^{\frac{2}{3}}$.

In curvilinear motion, as it occurs in actual practice, the various stream filaments usually have different centers of curvature. For example, at the extremity of the weir in Fig. 25, the surface point, *C*, has the greatest curvature while the bottom filament is parallel to the floor at $R = r$. The average energy of flow and the critical depth may still be represented by an expression similar to Equations (28) and (30), but the value of β will be different from that of Equation (23) or Equation (27), and will obviously lie between the value of β, corresponding to the extreme curvature of the surface filaments, and $\beta = 1$, corresponding to the bottom point. Finding the exact value of β presents in most cases a complicated and thankless venture. The foregoing analysis, however, clearly shows, that whenever the surface is curved, the real

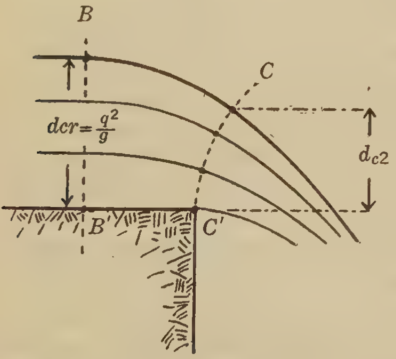

FIG. 25.

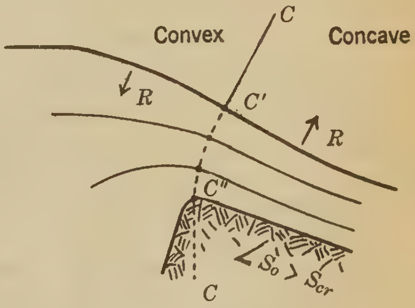

FIG. 26.

value of the critical depth is substantially different from the "apparent" depth corresponding to parallel movement and that such apparent value may not be used in hydraulic reasoning without due regard to the actual circumstances of flow. Combining Equations (28) and (30), the result with $d = d_{cr}$ is the value of $\varepsilon_{\text{min.}}$, the minimum possible contents of energy, which a discharge, q, carries in critical flow in curvilinear motion; in fact,

$$\varepsilon_{\text{min.}} = d_{cr}\left(1 + \beta^2 \frac{q^2}{2\,g\,d^3_{cr}}\right) = 1.5\,\beta^{\frac{2}{3}} \sqrt[3]{\frac{q^2}{g}} \ldots\ldots\ldots\ldots (31)$$

The minimum energy in parallel flow, $\varepsilon'_{\text{min.}} = 1.5 \sqrt[3]{\frac{q^2}{g}}$, is derived from Equation (31), assuming $\beta = 1$. Equation (31) shows that, in curvilinear motion, $\varepsilon_{\text{min.}}$ is different from $\varepsilon'_{\text{min.}}$ in parallel flow. It is greater with $\beta > 1$, when the streaming is concave, and less with $\beta < 1$ when the elementary filaments are convex.

With reference to the energy diagram, Fig. 19, this means, for example, that for convex flow the location of the point, C' (determined by d_{cr} and $\varepsilon_{\text{min.}}$), will be to the left and below Point C corresponding to parallel flow. Because of convex streaming, critical flow will occur with a smaller depth and with a smaller minimum contents of energy.

In this light, one may reconcile the apparent contradiction between the theory, according to which the minimum contents of energy were to be reached at the very end of the crest, and the observed fact, shown, for example, in Professor Woodburn's profiles, Series *A-B-C*, (Fig. 5), namely, that the critical depth, $d'_{cr} = \sqrt[3]{\frac{q^2}{g}}$, is found to lie at some distance from the end of the crest. Referring to Fig. 25, it is seen that $d'_{cr} = \sqrt[3]{\frac{q^2}{g}}$ will be properly reached in Section *B*, where the parallel flow is supposed to end, but that flow may continue with a further loss of energy between Sections *B* and *C*, at the expense of a further reduction of energy, made possible by the fact that the surface becomes convex, with the curvature increasing as it approaches the end section, *C*.

Equations (13), (14) and (15) will properly apply to Section *B*, which usually is very close to the end of the crest.

It is further evident, in the light of the foregoing reasoning, that any device which may reduce the curvature, will result in bringing the locus of the apparent critical depth nearer the end of the crest. Thus, Professor Woodburn's profiles, Series *D A* (Figs. 4 and 5), show how the addition of an apron, and particularly the backing up of tail-water, has the effect stated in the foregoing remarks.

Another instance, which may be usefully considered, is the fact well known from the theory of varied flow, namely, that whenever the surface passes the critical depth, there is an inversion of curvature. For example, in Fig. 26, *C-C* divides the upper convex from the lower concave part of the surface curve. At the point, C', where the inversion of surface curvature takes place, the radius of curvature is infinite. Assuming that the inversion of curvature inside the stream takes place in close proximity to the section, C'-C'', the movement at the intersection of the stream lines with C'-C'' will be close to parallel, and β for such section will approach $\beta = 1$. This explains, to some extent, the location of the critical depth in Fig. 8.

Waves on the Surface Over the Crest.—Under the caption, "Location of Critical Depths", Professor Woodburn records interesting data relating to the formation of waves on the surface over the weir. The theory of varied flow gives a sufficiently definite answer to this question. In general, it may be stated, that waves will form or will not be present, depending on whether the slope of the crest is smaller or larger than the so-called critical slope:

$$S_{cr} = \frac{g}{c^2} \times \frac{P}{b} \quad \text{.......................(32)}$$

Equation (32) determines S_{cr} as dependent on the depth, d, P being the wetted parameter, b, the top width, and c, the Chézy coefficient corresponding to a given depth of flow. For the rectangular flume with b = 2 ft., experimented upon, with C computed by means of the Ganguillet-Kutter formula with n = 0.011, the critical slope for the different depths is, as follows:

d, in feet.	S_{cr}.
0.1	0.0055
0.2	0.0044
0.4	0.0039
0.6	0.0039
0.8	0.0040
1.0	0.0043

The rule, as stated, follows from the study of the forms, which a surface assumes in the process of establishing a flow, given by Boussinesq.[15] With reference to the particular case under consideration, the deductions to be drawn from Boussinesq's most ingenious analysis, which are known to accord well with observation, would be as follows:

1.—When S is less than S_{cr} so that the movement which establishes itself is "tranquil", meaning a flow which, with the slope as given, would lead to a uniform movement with a depth greater than the critical, then the surface in the transition section will be undulated.

2.—When on the other hand, with S greater than S_{cr}, the movement which is in process of establishment is "rapid" (meaning that with the slope as given, the depth in uniform movement will be less than the critical), then the transition section will feature one inflected curve with no further undulations.

In Fig. 4, the slope in Series *D E*, is S = 0.026, far in excess of S_{cr}, as determined in the foregoing tabulation. Accordingly, there are no undulations.

On the other hand, Series *B G*, with a horizontal floor ($S = 0 < S_{cr}$), and partly Series *D D* and *D G*, register undulations. By coincidence the slope,

---

[15] "Essai sur la théorie des eaux courantes," Paris, 1877; also, "Théorie de l'écoulement tourbillonant," etc., 1897.

0.004, used in Series *D D* and *D G* is practically identical with the critical slope as given in the foregoing list. Therefore, the movement, which is in process of establishment, is a uniform movement with a depth equal to the critical. That is the reason why in these series the surface curve pendulates around the critical depth, and seems to appear repeatedly in the same profile in different locations.

D. D. Curtis,[16] Assoc. M. Am. Soc. C. E. (by letter).—The importance of various forms of weirs as means of measuring discharge is manifest. In particular, broad-crested weirs—because of several advantages, and perhaps more because of the comparative scarcity of data available—furnish especially interesting topics for investigation. This paper, therefore, is timely.

The writer was engaged in an experimental study of a round-crested weir, operated chiefly under condition of submergence, in the Hydraulic Laboratory of the University of Iowa during the summer of 1930. Although the work was undertaken for purposes different from those of Professors Woodburn and Webb, a comparison may prove of interest.

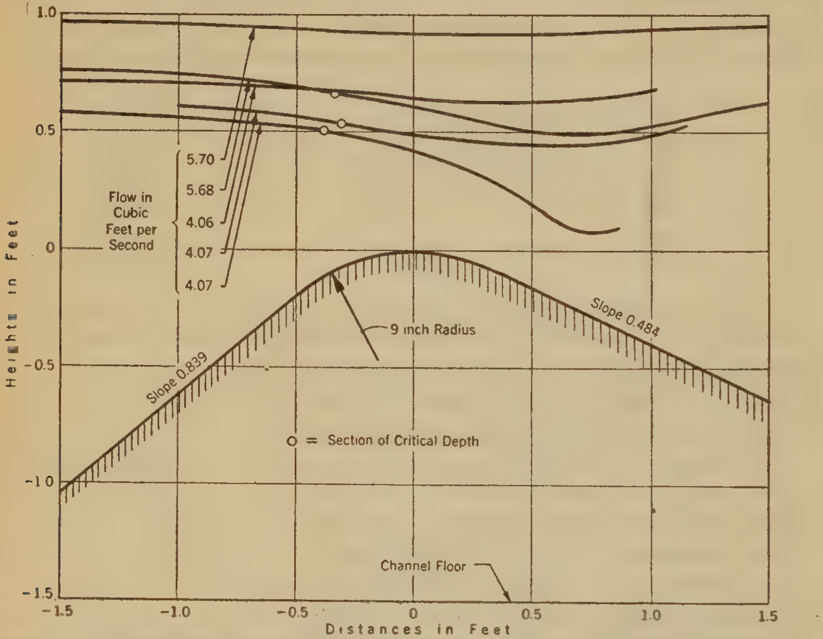

Fig. 27.—Water-Surface Profiles for One Set of Runs on Round-Crested Weir, with Location of Critical Depth.

A weir, 18 in. high with a circular crest of 9-in. radius, was installed in a glass channel 2½ ft. wide. The up-stream face had a slope of 40°, and the down-stream face was a movable apron, set at angles varying from 10 to 45 degrees. The quantity of water was determined from readings of the head on a sharp-crested rectangular weir which had been previously calibrated volumetrically by Mr. M. E. Nelson, of the U. S. Army Engineer Office, at

---

[16] Prof. of Mechanics, Clemson Agri. Coll., Clemson College, S. C.

St. Paul, Minn. Velocity readings were taken with a Pitot tube designed and made in the laboratory. Water surface elevations were read with a movable point-gauge.

Fig. 27 shows the water surface profiles for a typical series of runs. In this set, two runs show depths greater than the critical and three were adjusted so that flow occurred at the critical depth in each. Sections at which critical depth existed are indicated by small circles.

With the steepness of the aprons used in these experiments, it is indicated that the error in discharge, due to assuming critical depth to exist at the mean of the actual positions, might range up to ± 6 per cent. This, of course, is too inaccurate to be of value except where the most approximate results would be sufficient, and it demonstrates that this type of weir is not suitable for the determination of discharge from measurement of depth in one vertical plane if this depth is assumed to be the critical one.

Manipulation of tail-water height and quantity led the writer to believe that a condition of flow might persist through a greater degree of change on rising stage than on falling stage. For example, the unstable conditions accompanying critical flow might not become apparent so quickly when the water stage was rising as when it was falling, apparently indicating greater stability under rising than under receding waters. If this is true it is necessary for the experimenter to exercise some caution in adjusting the flow to meet any definite condition he desires, particularly if what he is attempting is a stage bordering on the critical.

Erik G. W. Lindquist,[17] M. Am. Soc. C. E. (by letter).—If the measurements of water surface profiles in this paper had been accompanied by simultaneous measurements of pressure on the deck of the weir and within the flowing masses, as well as simultaneous measurements of the velocity distribution up stream from the weir, the paper would have been a notable contribution to the study of the flow of water over dams. It would have been possible then to analyze and discuss every conclusion from a theoretical point of view. Nevertheless, the author is entitled to the appreciation of the profession for his laborious work, which will certainly direct the way to future experiments.

If measurements of pressure had been made, the author would have found that the ordinary formula for computing the critical depth is not always applicable to a dam. This statement is made on the basis of the following analysis. In addition to the notation given by Professor Woodburn, the following must be introduced:

Let B = length of the crest, perpendicular to the direction of flow.
z = distance above some horizontal plane of reference.
p = internal pressure.
k = velocity head.
h_e = loss of head due to friction.
r = radius of curvature.
w = specific weight.

---

[17] Capt., Royal Swedish Corps of Civ. Engrs.; Office Engr., Stockholm City Water Supply, Stockholm, Sweden.

Consider a vertical section at the crest of a dam with the form illustrated in Fig. 28. The discharge is expressed by,

$$Q = B \int_0^D v_z \, d\, z \dots\dots\dots\dots (33)$$

For a section, *a-a*, Bernoulli's equation of energy is,

$$H = z_0 + h_0 + \alpha \, k_0' \dots\dots\dots\dots (34)$$

and for a section, *b-b* (assuming that the stream lines, or filaments, are perpendicular to the sections),

$$H = z_0 + z + p_z + k_z + h_e \dots\dots\dots\dots (35)$$

Hence, since $k_z = \frac{v_z^2}{2\,g}$, Equations (34) and (35) may be solved simultaneously to produce,

$$v_z = \sqrt{2\,g\,(h_0 + \alpha\,k_0) - z - p_z - h_e} \dots\dots\dots\dots (36)$$

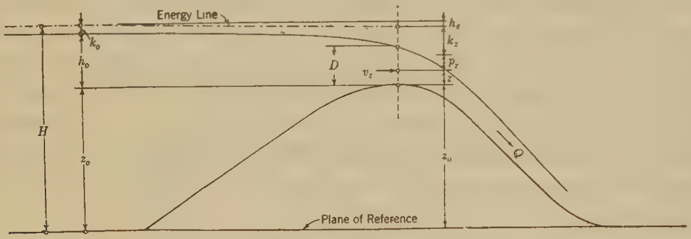

FIG. 28.

The discharge then (from Equation (33)) is equal to,

$$Q = \psi\,B\,\sqrt{2\,g} \int_0^D \sqrt{(h_0 + \alpha\,k_0) - z - p_z}\, dz \dots\dots\dots\dots (37)$$

in which, the coefficient, ψ (less than 1), has been inserted instead of h_e to account for friction. A pressure, p_z, is a function of the curvature of the stream line; that is, its value depends on the height of the dam and on the shape of its cross-section as well as on the head.

Assuming, first, that $p_z = D - z$ (see Fig. 28), and integrating Equation (37),

$$Q = \psi\,B\,D\,\sqrt{2\,g}\,\sqrt{(h_0 + \alpha\,k_0) - D} \dots\dots\dots\dots (38)$$

In 1848, Belanger introduced the principle that the critical depth is that at which the discharge is a maximum for any given head. In other words, for $\frac{\partial Q}{\partial D} = 0$,

$$D_c = \frac{2}{3}\,(h_0 + \alpha\,k_0) \dots\dots\dots\dots (39)$$

and,

$$Q = \frac{2}{3}\,\frac{\psi}{\sqrt{3}}\,B\,\sqrt{2\,g}\,(h_0 + \alpha\,k_0)^{\frac{3}{2}} \dots\dots\dots\dots (40)$$

Next, assume that $p_z = 0$, and again integrate Equation (37):

$$Q = \frac{2}{3} \psi B \sqrt{2g} \left\{ (h_0 + \alpha k_0)^{\frac{3}{2}} - (h_0 + \alpha k_0 - D)^{\frac{3}{2}} \right\} \ldots\ldots (41)$$

Applying Belanger's principle, as before, $D_c = h_0 + \alpha k_0$, and:

$$Q = \frac{2}{3} \psi B \sqrt{2g} (h_0 + \alpha k_0)^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots (42)$$

Thus, it is demonstrated that the discharge depends upon the pressure in the overfalling sheet. For equal values of energy head, the discharge is lower when the pressure has a hydrostatic distribution from the surface to the crest, that is, when $p_z = D - z$. This condition is fulfilled only on a broad-crested weir with a very smooth entrance end.

Assuming, finally, that $p_z = m (D - z)$, and again integrating Equation (37),

$$Q = \frac{2}{3} \frac{\psi B}{1 - m} \sqrt{2g} \left\{ (h_0 + \alpha k_0 - m D)^{\frac{3}{2}} - (h_0 + \alpha k_0 - D)^{\frac{3}{2}} \right\} . (43)$$

Once more Belanger's principle indicates that, for $\dfrac{\partial Q}{\partial D} = 0$,

$$\frac{3}{2} m (h_0 + \alpha k_0 - m D)^{\frac{1}{2}} + \frac{3}{2} (h_0 + \alpha k_0 - D)^{\frac{1}{2}} = 0 \ldots\ldots\ldots (44)$$

which reduces to the form,

$$D_c = \frac{1 + m}{1 + m + m^2} (h_0 + \alpha k_0) \ldots\ldots\ldots\ldots\ldots (45)$$

For D, in Equation (43), insert the value of D_c, given in Equation (45) and simplify. The result is,

$$Q = \frac{2}{3} \psi B \sqrt{2g} (h_0 + \alpha k_0)^{\frac{3}{2}} \frac{1}{\sqrt{1 + m + m^2}} \ldots\ldots\ldots (46)$$

The ordinary discharge formula is,

$$Q = \frac{2}{3} \mu B \sqrt{2g} (h_0 + \alpha k_0)^{\frac{3}{2}} \ldots\ldots\ldots\ldots\ldots (47)$$

Combining Equations (46) and (47), for purposes of comparison,

$$\mu = \frac{\psi}{\sqrt{1 + m + m^2}} \ldots\ldots\ldots\ldots\ldots\ldots (48)$$

in which, ψ is a coefficient the value of which depends upon the loss of head due to friction. Assuming that $\psi = 1$, the values of μ in Table 9 are compared with the values of D_c for the range from $m = +1$ to $m = -1$. Only when the stream filaments are parallel and straight can m equal $+1$, and m can equal zero only in a freely falling sheet of water, in which the stream filaments are concentric and in which the contours of the nappe are exposed to the air or to some other surrounding medium of constant pressure. When the contours of the escaping stream begin to converge, the internal pressure becomes higher than the pressure in the air or other medium surrounding the nappe.

TABLE 9.—COMPARISON OF CRITICAL DEPTHS

m	$\frac{D_o}{h_o + \alpha\, k_o}$ (Equation (45))	μ (Equation (48))	m	D_o	μ
+1.0	0.667	0.578	0.0	1.0	1.0
+0.9	0.702	0.610	−0.1	0.999	1.049

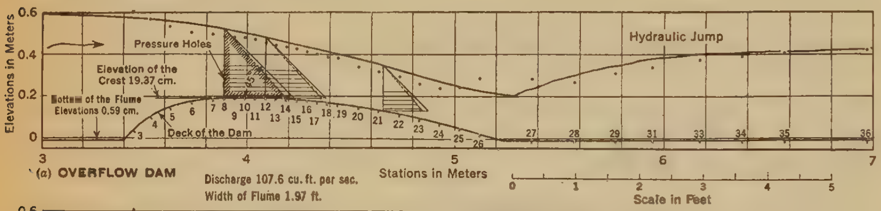
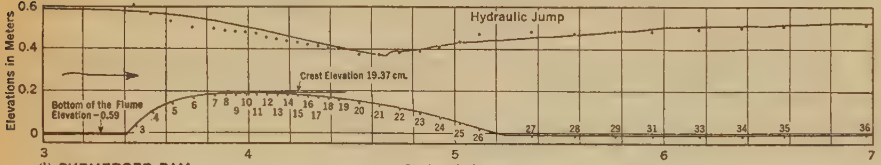
The linear pressure distribution given by the expression, $p_z = m\,(D - z)$, is only an assumption. However, it has proved itself applicable in some cases as will be explained subsequently.



(a) OVERFLOW DAM



(b) SUBMERGED DAM

FIG. 29.—DISCHARGE OVER A LOW WEIR, WITH SMOOTH APPROACH CHANNEL.

For the weir shown in Fig. 29, the pressure distribution, which is measured by holes in the side wall of the experimental flume, is nearly linear. The value of m for this case was 0.87 and the value of μ as computed by means of Equation (47) was 0.62. For a value of ψ equals 0.99, Equation (48) produces a value of μ equal to 0.61.

The results of measurements on weirs with a semi-circular cross-section, are as listed in Table 10.

TABLE 10.—EXPERIMENTS ON A SEMI-CIRCULAR DAM, 800 MILLIMETERS HIGH

Q, in liters per second. (1)	Total head, m. (2)	Observed pressure at the crest, m. (3)	m, observed. (4)	μ, experimental Equation (47). (5)	μ, computed by Equation (48). (6)	m, computed by Equation (53) (7)
253.4	0.361	0.172	0.69	0.648	0.666	0.70
151.7	0.262	0.139	0.78	0.625	0.627	0.78
78.7	0.159	0.092	0.87	0.606	0.607	0.87
26.2	0.085	0.052	0.93	0.594	0.598	0.93

The values of μ, computed by Equation (48) (see Column (6), Table 10) in which, ψ equals 0.98, agree very closely with those determined by Equation (47) (see Column (5) Table 10).

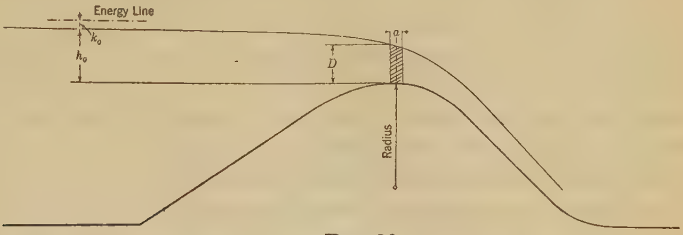


FIG. 30.

The internal pressure close to the deck at the crest can be computed approximately as follows: In Fig. 30, consider the mass element, $a\,D\,B$, in motion. The vertical forces acting are the weight of the element, $w\,a\,D\,B$, the pressure on the deck, $-w\,p\,a\,B$, and the centrifugal reaction, $-a\,D\,B\,\frac{w\,v^2}{g\,r}$. Hence,

$$w\,a\,D\,B - w\,p\,a\,B - a\,D\,B\,\frac{w\,v^2}{g\,r} = 0 \dots\dots\dots\dots\dots (49)$$

or,

$$p = D\left(1 - \frac{v^2}{g\,r}\right) \dots\dots\dots\dots\dots (50)$$

Since $m = \frac{p}{D}$,

$$m = 1 - \frac{v^2}{g\,r} \dots\dots\dots\dots\dots (51)$$

The mean velocity above the crest is approximately,

$$v = \sqrt{2\,g\,\frac{(h_0 + \alpha\,k_0)}{3}} \dots\dots\dots\dots\dots (52)$$

For v, in Equation (51), insert the value of v in Equation (52) and,

$$m = 1 - \frac{2}{3}\left(\frac{h_0 + \alpha\,k_0}{r}\right) \dots\dots\dots\dots\dots (53)$$

The values of m, in Column (7), Table 10, were computed by means of Equation (53). Although the method used is very approximate the observed and computed values are very close; but this does not prove that the method used is always applicable. As soon as the path of the particles flowing near the deck does not agree with the contour of the dam, the problem becomes very much complicated. This is the condition that exists for the dams tested by Professor Woodburn. Cushions or eddies will be found on the crest near the entrance end.

Fig. 29(*b*) illustrates that position of the hydraulic jump when the dam is submerged. As soon as this condition occurs, small waves are formed on the surface and are propagated up stream, with the result that the up-stream level is raised.

Ralph L. Parshall,[18] Assoc. M. Am. Soc. C. E. (by letter).—The study of the possibilities of measuring the rate of flow over broad-crested weirs of different types, based on the principle of critical depth, has been given attention at various times since November, 1925, at the hydraulic laboratories of the Colorado Agricultural Experiment Station, at Fort Collins, in co-operation with the Division of Agricultural Engineering, Bureau of Public Roads, U. S. Department of Agriculture. The Society's Special Committee on Irrigation Hydraulics has been especially helpful in its suggestions and criticism, and more particularly in proposing different forms of weir crests thought best suited to the investigation of such a measuring device.

The first studies were made on a setting consisting of a rectangular flume, 2 ft. wide, 2½ ft. deep, and about 10 ft. long. Near the up-stream end, on the floor of this flume, a metal convex-shaped hump was placed so that the up-stream and down-stream faces curved in an easy transition to the crest line, which was level and normal to the axis of the flume. This crest, or hump, was 10 in. high. A secondary humped crest of similar design, but only 4 in. high, was placed at a distance of 4 ft. down stream. It was soon discovered, however, that this secondary crest was of no effect. The principal feature involved was the application of the critical depth in the formula,

$$Q = L \sqrt{g}\; H_c^{1.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \tag{54}$$

in which, Q is the rate of flow, in cubic feet per second; L, the length of crest, in

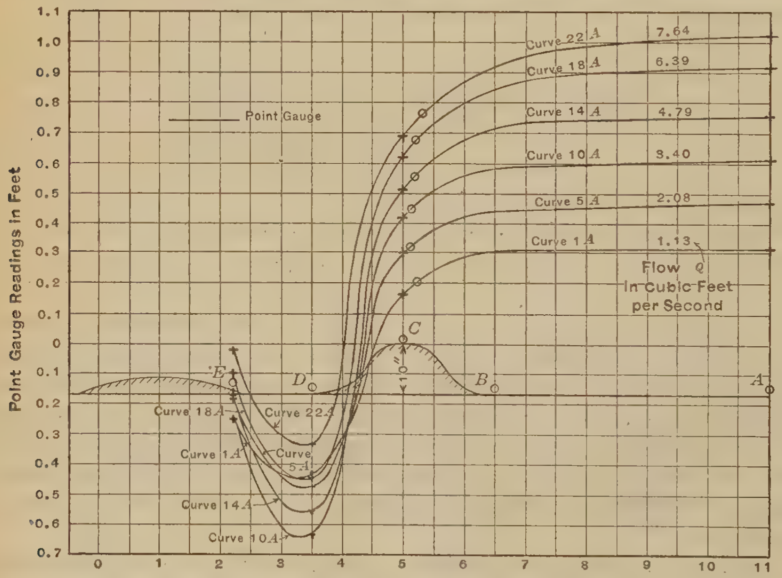

Fig. 31.—Profiles of Water Surface with 10-Inch Crest and Free Flow, Fort Collins Laboratory, November, 1925.

---

[18] Irrig. Engr., U. S. Dept. of Agriculture, Fort Collins, Colo.

feet; g, the acceleration of gravity; and H_c, the critical depth, in feet. From a theoretical standpoint, this critical depth should occur at the crown or crest of the hump, but the preliminary investigation of this setting indicated that the location of this particular depth was not over a fixed point.

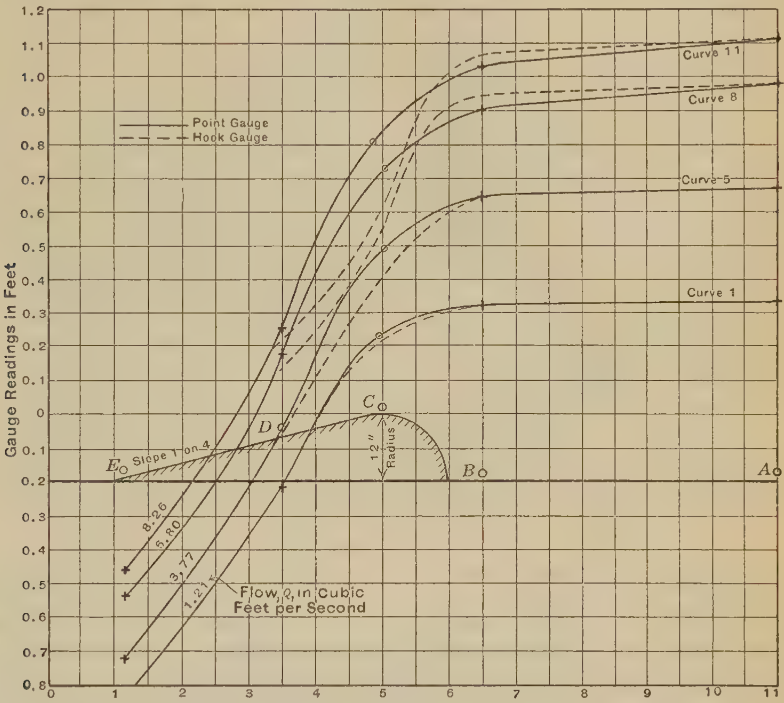

FIG. 32.—PROFILES OF WATER SURFACE, WITH RADIUS OF 12 INCHES UP STREAM AND SLOPES OF 1 ON 4 BELOW CROWN (FREE FLOW), FORT COLLINS LABORATORY, JUNE, 1926.

The profiles of the water surface along the axis of the flume with the double hump (Fig. 31) show, for a limited number of tests, that this point of critical depth shifts up stream from the vertical through the crest as the rate of discharge increases. This arrangement was changed and a single crest substituted, having a radius of 12 in. up stream, with a slope of 1 on 4 inclined downward from the crown. It will be noted in Fig. 32 that the actual location of the point of critical depth substantially agrees with the vertical through the crest.

In October, 1926, experimental apparatus consisting of a flume similar to that just described, having a single crest, 13 in. high, placed about 5 ft. down stream from the upper end of the channel, was installed at the laboratory in Bellvue, Colo. The up-stream face of this weir was of an ogee shape, in section, curved from the floor line with a radius of 31 in., with a transition from a concave to a convex surface, having a radius of 24 in. Just down stream from the crest line it was made tangent to a plane surface, inclined downward with a slope of 1 on 10. For this setting, under a free-flow discharge, the point of critical depth shifted down stream as the rate of discharge increased. The profiles of the water surface along the axis of the flume and the location of the point of critical depth are shown in Fig. 33. This setting was altered later, to the arrangement shown in Fig. 34. The height of the crest is 13 in.

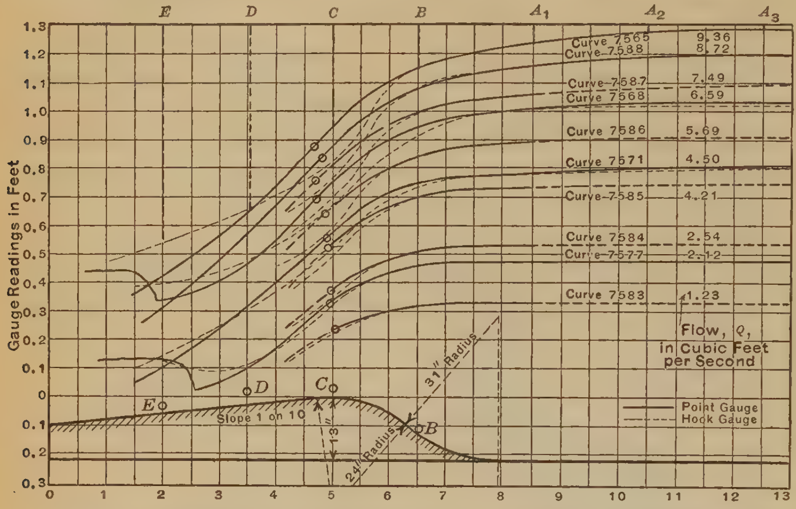

FIG. 33.—PROFILES OF WATER SURFACE, WITH RADIUS OF 24 INCHES UP STREAM AND SLOPES OF 1 ON 10 BELOW CROWN (FREE FLOW), BELLVUE LABORATORY, OCTOBER, 1926.

This general plan of the control weir was suggested by J. C. Stevens, M. Am. Soc. C. E.[19] For this setting, the point of critical depth appears to fall to the down-stream side of the vertical through the crest. The laboratory setting of this arrangement is shown in Fig. 35, with a discharge of 7.68 sec-ft.

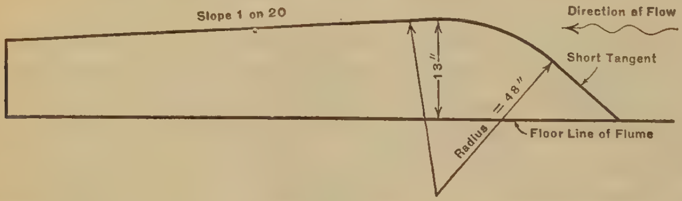

FIG. 34.

Fig. 36 is the laboratory setting for the double hump previously described (see Fig. 31). The head, as measured by the hook-gauge at the crest (where a piezometer tube to the stilling-well was set flush with the inside face of the flume wall) was consistently less than the actual depth as determined by a point-gauge. This variation in the two gauges, intended to give the head or depth over the crest, is believed to be due to the effect of cavitation or negative pressure existing just down stream from the crown of the weir. Profiles of the water surface over this type of weir are shown in Fig. 37.

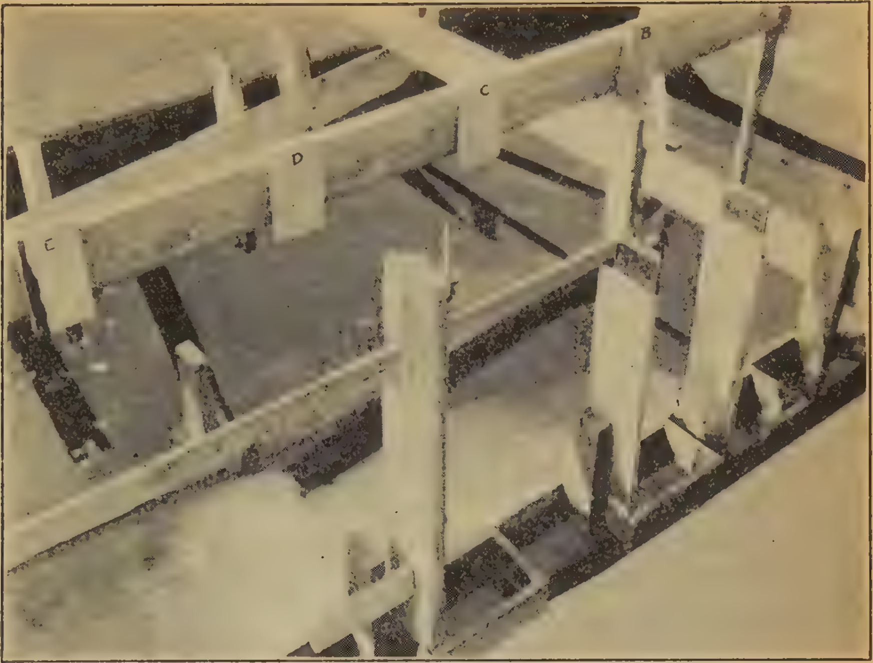

FIG. 35.—FLOW OF 7.68 SECOND-FEET OVER CREST WITH CONVEX CURVED UP-STREAM FACE (SEE FIG. 34)

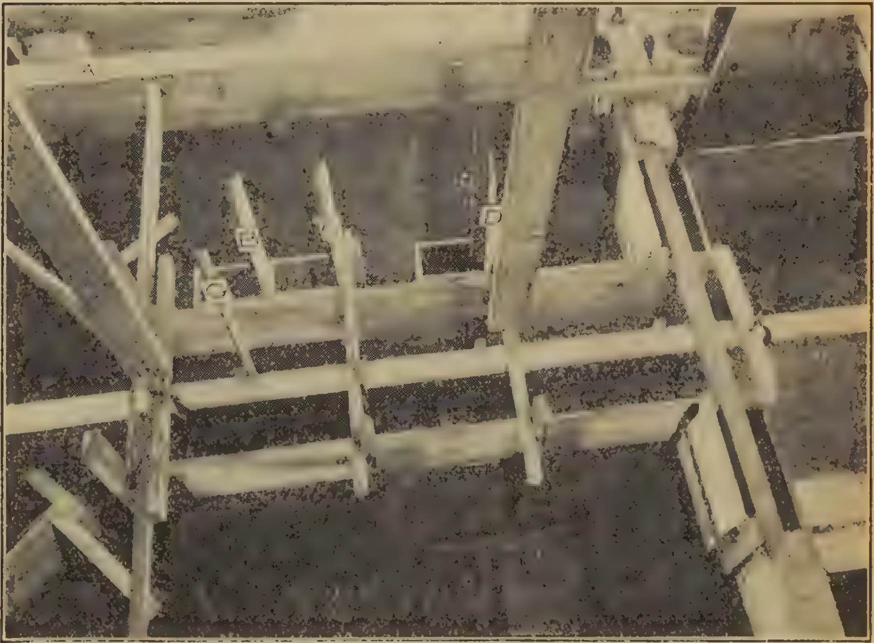

FIG. 36.—DOUBLE-CREST SETTING OF CONTROL WEIR, DISCHARGE 2.08 SECOND-FEET. POINT-GAUGE *G* LOCATING WATER SURFACE AT SECTION *B*.

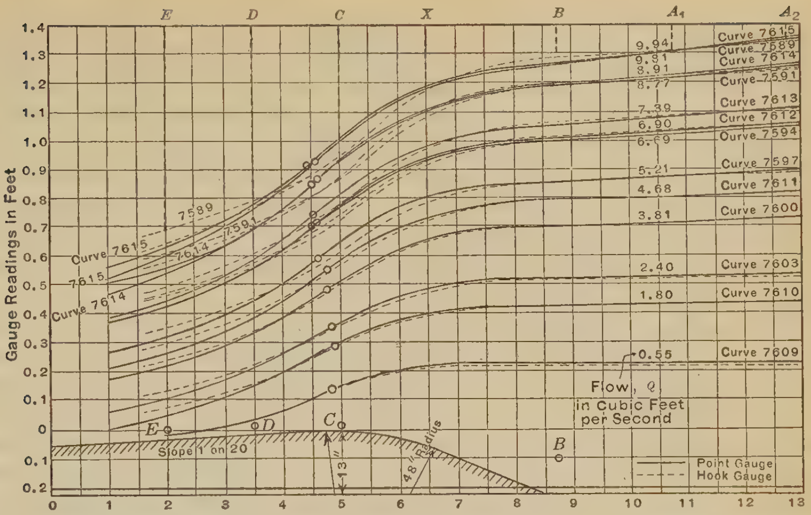

FIG. 37.—PROFILES OF WATER SURFACE WITH RADIUS OF 48 INCHES UP STREAM AND SLOPE OF 1 ON 20 BELOW CROWN (FREE FLOW), BELLVUE LABORATORY, OCTOBER, 1926.

In June, 1927, a special setting of the critical-depth flow meter, as suggested by Mr. Stevens (Fig. 38), was installed at the Bellvue Laboratory. It is essentially the same as the Herschel hollow-crest weir.[19] In this setting the pressure head on the crest, observed by the hook-gauge, was communicated to the stilling-well through a water-tight compartment placed beneath the

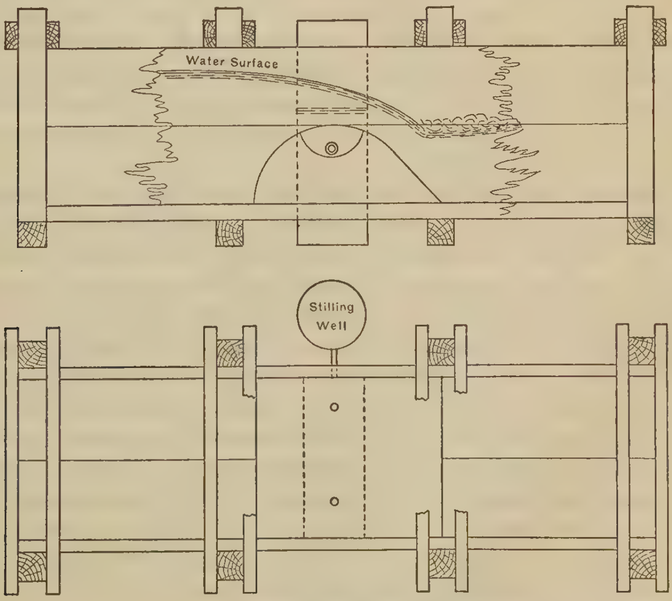

FIG. 38.—CRITICAL-DEPTH FLOW METER.

curved surface forming the crest. This pressure head was transmitted to the compartment through two ¼-in. holes normal to the crest line of the weir. Tests on this device were quite conclusive, particularly as to the effect of cavitation. The difference between the depths at the crown of the weir, as determined by the point-gauge and that observed by the hook-gauge in the stilling-well, was greater than that found for the previous different settings of the control weir. For a head of 1 ft. over the crest, as determined by the point-gauge, it was found that the hook-gauge showed only about 0.35 ft., and, as before, the true critical depth was found not to be in the vertical through the crown of the weir.

The various profiles shown by the author in Fig. 4, clearly indicate that the point of critical depth is not fixed at a definite place, but is dependent on the discharge. It is noted that when the critical depth occurs near the up-stream edge of the broad-crested weir, the variation in the position of this depth is moved down stream about 1 ft., in a range of discharge from approximately 2 to 9 sec-ft. The long level crest, where waves are present, results in a poor condition from the standpoint of using the critical depth as a criterion of the rate of flow.

Unfortunately, the data, as given in Table 1, do not show the degree of submergence for the tests thus indicated. By inspection of Fig. 4, it is estimated that for Series *D E* and *D F*, where the hydraulic jump occurs, this submergence may reach 75 to 80% as a maximum, with no material change in the coefficient, *C*. It is found that for the 2-ft. Parshall measuring flume for the head, H_a, ranging from 0.8 ft. to 1.4 ft., and with the submergence varying between 74 and 77%, the observed and computed free-flow discharges agree within about 3 per cent. Observations on submerged flow through large flumes of this type seem to indicate that this limiting submergence may equal or exceed 80 per cent. It is believed that the ability of this flume to withstand a high degree of submergence, without affecting the range of discharge, is practically equal to the possibilities indicated by broad-crested weirs under conditions of critical depth flow.

The investigations made by the writer on various forms and settings, and also the form of weir adopted by the author, are subject to criticism from the viewpoint of practical design, in regard to the stilling-basin or depressed section up stream from the crest. In the field, this up-stream section, from the standpoint of irrigation practice, will readily fill with sand, silt, and possibly gravel, to a level approaching the elevation of the weir crest. This rise in the bottom of the channel will decrease correspondingly the entrance drop at the up-stream edge of the weir, which, at the limit, will entirely eliminate the control at this point. This condition may best be obviated by providing a lateral constriction, or converging section, similar to that in the Parshall measuring flume, which provides a control. Observations relative to the point of critical depth near the crest of a 4-ft., Parshall measuring flume (free-flow), show this point to be about 0.8 ft. up stream from the crest for discharges of 17 to 34 sec-ft. When the submergence is about 77%, this point is found about 0.3 ft. up stream for like flows.

JAMES G. WOODBURN,[20] ASSOC. M. AM. SOC. C. E. (by letter).—The able discussions which have been called forth by this paper are greatly appreciated. These discussions emphasize the varied and complex nature of the phenomena connected with flow over a broad-crested weir. As Professor Woodward points out, this type of weir presents many fascinating problems for study. Among the infinite variety of crest forms there must be certain designs which best combine a simple and constant head-discharge relation with minimum obstruction to flow and with ruggedness of construction and durability of crest. The ability of a broad-crested weir to operate at least 50% submerged (possibly 80% in some cases, as mentioned by Mr. Parshall) with practically no change in coefficient, gives it an advantage over a sharp-crested weir where head is at a premium; and the fact that it can be built without sharp edges to wear round and thus materially alter the discharge coefficient, recommends it for use in measuring the discharge of débris-carrying streams.

As a closing discussion of this first part of an extended study, the writer offers the following summary of the characteristics of flow over a broad-crested weir and of the outstanding points which require further study and explanation.

Since any weir not sharp-crested is, in effect, a short open channel, most of the phenomena of flow in open channels can also be observed in flow over broad-crested weirs. The chief cause of complications in broad-crested weir studies, as in any open-channel studies, is that the simple conditions of uniform, parallel flow are almost always absent. The problem is usually one of accelerated or retarded flow, of back-water or down-drop curves, and of wave formation, a complete explanation of which leads far into physics and hydrodynamics.

In considering the broad-crested weir as a short open channel, it is apparent that friction losses in flow across the weir must not be neglected. These losses reduce the discharge below the theoretical, frictionless maximum by an amount which depends on the location of critical depth.

Critical depth, or depth at maximum discharge for a given height of energy gradient, always occurs at some point in non-submerged flow over a broad-crested weir. It may be expressed both as a fraction of the total head and also as a function of the discharge. From these relations the discharge at the point of critical depth, which is the largest possible discharge for the channel in question, can be expressed as a function of the total head. It should be noted that the head referred to in the case i the total head at the section of critical depth.

The location of critical depth in flow over a broad-crested weir is usually not easy to determine. Two cases arise for consideration.

1.—Parallel Stream Lines.—In this case the relations between depth, discharge per unit width of channel, and total head, are: $D_c = \frac{2}{3} H_a$, $D_c = \sqrt[3]{\frac{Q_1^2}{g}}$, and $Q_1 = 3.087\, H_a^{\frac{3}{2}}$ (English units).

---

[20] Associate Prof. of Hydr. Eng., State Coll. of Washington, Pullman, Wash.

The total head is represented by the elevation of the energy gradient above the stream bed, and with parallel flow it is obtained by adding the velocity head, $\alpha \frac{V^2}{2g}$, to the elevation of the water surface, since the pressure head at any point in the cross-section of the stream equals the height of the column of water above the point.

2.—Vertically Curving Stream Lines.—Since there is seldom any point at which flow over a broad-crested weir is parallel, it is necessary to consider the effect of vertical curvature of the stream lines, and to modify the equations for discharge and critical depth to take care of the change in pressure caused by centrifugal forces. The effect of vertical curvature of the stream lines has been treated fully in the discussions by Professor Bahkmeteff and Dr. Lindquist. Another treatment of this subject, applied particularly to down-drop curves, was published in 1929 by Dr. P. Boess, in reporting on some experimental studies in the Karlsruhe Laboratory.[21]

The curvature of the stream lines may be either downward or upward with respect to the stream bed. If they curve down toward the stream bed, centrifugal action reduces the pressure at all points in the cross-section below true hydrostatic pressure. Dr. Boess found by tests that it could usually be assumed with sufficient accuracy that this reduction in pressure is in straight-line variation with the depth. Since friction losses in accelerated flow are usually small, the energy gradient is very nearly horizontal. Thus, a reduction in pressure head causes an increase in velocity head, with resulting increase in velocity, in discharge, and in critical depth, for a given height of energy gradient.

With downward curving stream lines, therefore, D_c is larger than $\frac{2}{3} H_a$, and Q_1 (max.) is larger than $3.087 H_a^{\frac{3}{2}}$. Conversely, also, with upward curving stream lines, D_c is less than $\frac{2}{3} H_a$ and Q_1 (max.) is less than $3.087 H_a^{\frac{3}{2}}$.

The application of these relations to a study of the coefficients of discharge of broad-crested weirs may be made through the equation for maximum unit discharge,

$$Q_1 \text{ (max.)} = C\, H_a^{\frac{3}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (55)$$

The largest possible value of C in this equation is equal to, greater than, or less than, 3.087, depending on whether the stream lines are parallel, downward curving, or upward curving with respect to the stream bed. Furthermore, H_a in Equation (55) is the total head at the section of critical depth. Because of the continual loss of energy in a flowing stream, if the head at any point up stream from the point of critical depth is used in the equation, $C = \frac{Q_1}{H_a^{\frac{3}{2}}}$, the value obtained for C is less than the maximum value by an amount depending on the loss of head between the two points. This loss of head varies with the distance, with approximately the square of the velocity of flow, and probably also with the number of waves, between the two points.

---

[21] Berchnung der Abflussmengen und der Wasserspiegellage bei Abstürzen und Schwellen," *Wasserkraft und Wasserwirtschaft*, 1929, No. 2-3. The writer's translation of this work has been filed for reference in Engineering Societies Library, 33 West 39th Street, New York, N. Y.

Herein lies an explanation of why the coefficient of discharge of some of the weirs tested increased as the head increased, while that of other weirs decreased. In the former class are all the weirs with level crest. Critical depth occurred well down the crest at or below a point of approximately parallel flow, signifying a limiting value of C of about 3.087. Movement of critical depth up stream and decrease in the number of waves with the increase in head tend to reduce the losses between the point of measurement on the weir and the location of critical depth. Increasing velocity, on the other hand, tends to increase the loss. The increase in the coefficient with increasing head indicates that the resultant of the three factors was a reduction in the loss of head.

The writer's weirs with crests sloping slightly down stream, and Professor Webb's weirs which sloped slightly both ways from a crest line, show the coefficient decreasing as the head increases. Critical depth occurred usually near the entrance or highest point, and was either nearly constant in location or moved down stream as the head increased. This increase in distance and the increasing loss of head due to increasing velocity combine to cause a decrease in the coefficient.

Of course, the limiting value of C is not necessarily constant for a given weir, but may change with the head. This change becomes more pronounced as the down-stream slope of the crest increases. Thus, the pressure on the round-crested weir described by Mr. Yarnell (Figs. 14 and 16) is evidently reduced further below true hydrostatic pressure as the head increases, with resulting increase in C.

This reasoning with regard to the weir coefficient suggests the possibility of designing a broad-crested weir having a constant coefficient. The general requirements apparently are that there be approximately parallel flow at some point on the weir so that the coefficient shall have a definite limiting value; and that the resultant loss between the point of measurement of head and the location of critical depth shall be constant. It appears to the writer that the design of a weir of constant coefficient presents fewer difficulties than the design for which critical depth occurs at the same location at all heads.

Further progress in the study of flow over broad-crested weirs requires first an accurate experimental determination of the energy gradient. The height of the energy gradient at any point can be computed accurately only when the distribution of pressures and velocities over the cross-section is known. The accumulation of data regarding pressures and velocities on many different forms of weir crest is to be desired.

With the energy gradient drawn, and the pressure distribution known, the position of true critical depth can be located and the variation of this position can be studied with varying head and with different shapes of crest.

Further study is needed of the coefficient of discharge of broad-crested weirs of many different designs. An interesting question is to determine the boundary point in design between weirs which show a coefficient increasing as the head increases and weirs which show a coefficient decreasing as the head increases. Another point to be studied is the effect on the coefficient of small changes in the slope of the weir crest. There are also few data available regarding the effect of various degrees of rounding of the entrance to the weir.

The writer is continuing the experimental study of the flow over broad-crested weirs in the Hydraulics Laboratory of the State College of Washington. Following certain lines of investigation suggested in the discussion, and from other sources, preliminary tests are being made of a number of different weir crests in a glass-walled flume, 1 ft. wide. The first three weirs tested have been made of wood, with level crest 2 ft. broad, and 4 in., 8 in., and 12 in. in height, with rounded entrance. Comparison will be made with the results of the tests described in the writer's paper in order to study the application of the laws of similarity. A number of other crest designs will then be tested to study in a general way the coefficient of discharge and profile of the water surface so that certain designs may be selected for more accurate construction and study.

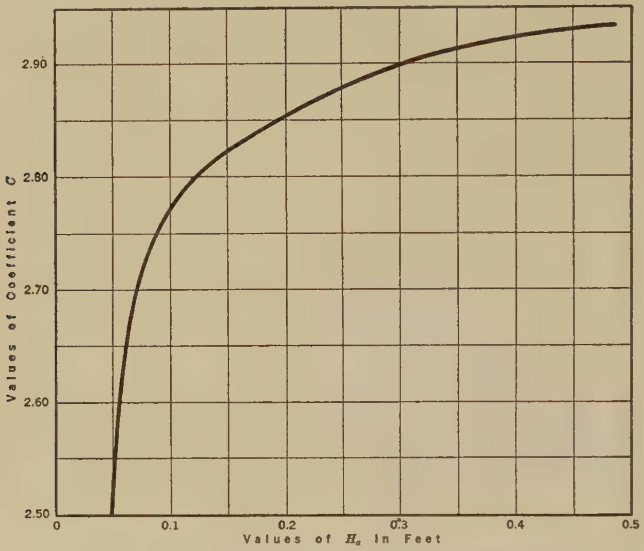

FIG. 39.—VARIATION OF WEIR COEFFICIENT, C, WITH TOTAL HEAD, H_a FROM EQUATION, $C = \frac{Q_1}{H_a^{\frac{3}{2}}}$

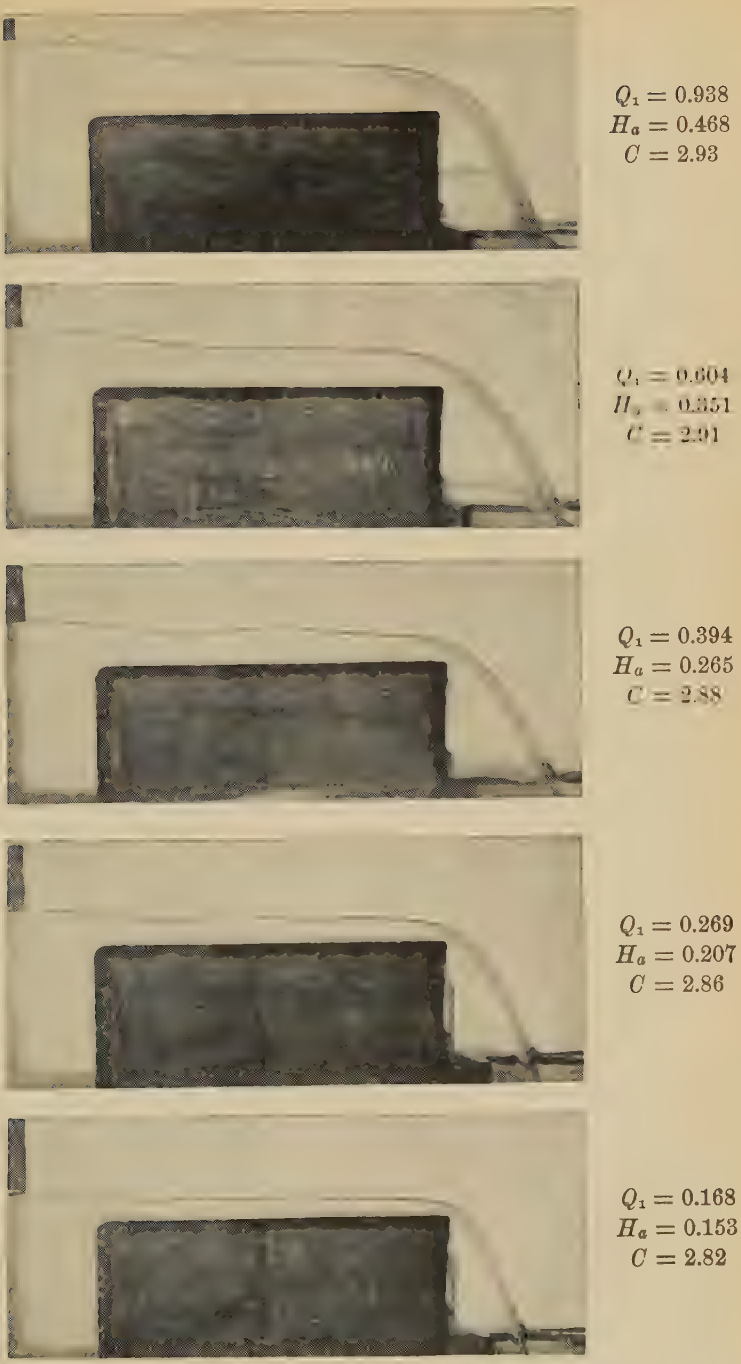
The tests of the three weirs (2 ft. broad and 4, 8, and 12 in. high, respectively) with level crest show that for heads up to 0.5 ft. and discharges up to 1 cu. ft. per sec., the weir coefficient increases with the head. (See Fig. 39.) The point of measurement of the head was 2.0 ft. up stream from the entrance to the weir. Practically the same curve has been obtained for each of the three heights of weir. Fig. 40 shows conditions of flow over the



$Q_1 = 0.938$
$H_a = 0.468$
$C = 2.93$

$Q_1 = 0.604$

$C = 2.82$

FIG. 40.—FLOW OF WATER OVER BROAD-CRESTED WEIR

weir 12 in. high. The crest was level, 2.0 ft. broad and 1.0 ft. high, in a flume 0.999 ft. wide. The entrance was rounded on a radius of 0.1 ft. The formation of waves at the lower heads is apparent.

While the writer was in Europe in 1930 as Freeman Scholar from the Society, he was on the alert particularly for investigations of broad-crested weirs, critical depth, hydraulic jump, and associated phenomena. He found very little work being done along these lines. At the Technical Institute of Zurich, a candidate for a doctor's degree under Professor Robert Dubs was making some tests of a weir about 6 ft. broad with a sloping entrance in a channel 1 m. wide, with a view to the measurement of irrigation water in Egypt. At the same Institute, another advanced student under Professor Meyer-Peter was studying the formation of surface rollers and the hydraulic jump in the discharge through submerged gates. At the University of Delft, tests were in progress under Mr. J. Thijsse to show the nature of the discharge to be expected over the partly completed dikes of the Zuyder Zee during flood tides. These dikes are really broad-crested weirs of a cross-section somewhat similar to that of the railroad embankments mentioned by Mr. Yarnell.

Aside from these investigations, the writer found no tests on this subject in progress in any of the thirty hydraulics laboratories visited. However, European hydraulicians are of course well acquainted with the problem. In fact, as Professor Bahkmeteff points out, the theory of the two stages of flow, and of flow at critical depth, was developed at nearly the same time by a number of investigators, working independently, in different countries.

With Discussion by Messrs. C. S. Mullen, H. L. Thackwell, B. P. Harrison, E. P. Arneson, and Gibb Gilchrist.

Synopsis

Highway location problems are treated very broadly in this paper. Basically, the subject has been divided into two parts. The first part, dealing with physical aspects, emphasizes the dangers attendant upon locating new highways so that they follow old routes. The advantages of aerial photography are mentioned, and aerial survey methods adopted by the Texas State Highway Department are described briefly.

In the second part, the paper describes the non-physical aspects of highway location, such as safety, economy, and utility of operation. This section is concerned with the influences of local and through traffic demands on the location problem. The paper also contains a brief comment on financing.

Introduction

When the highway location problem is solved, the highway problem itself is well on its way to solution. Early in 1929 one of the influential and best informed members of the Texas Legislature sent a questionnaire to the State Highway Department, requesting information on various phases of its program. One of the questions was as follows: "Give the average life of roads built of the various approved types of construction, such as reinforced concrete, concrete with an asphalt surface, macadam, gravel, etc." The answer given was that the life of any particular type of road depended, first, on its location and, second, on the width of its right of way, and that the type of surface was of secondary consideration. Of course, in this reply the writer had in mind the utility of a highway as applied to its use as an important trafficway. He had no reference to the stability of any particular type of surfacing, but wished to bring forcibly to the attention of those engaged in enacting highway legislation that the life of a highway should be considered as the length of time during which it would or could be used as an artery of traffic. He wanted, furthermore, to emphasize the fact that necessity and public opinion would demand that such a highway, either now or in the future, be located with a fair degree of economy.

[1] Presented at the Joint Meeting of the Highway and Construction Divisions, Dallas, Tex., April 25, 1929.

[2] State Highway Engr., Austin, Tex.

Physical Aspect of Highway Location

In laying out a State highway the engineer has been too prone to follow what has been generally and popularly termed the "line of least resistance." For example, he has followed the right of way of a railroad or interurban, or if there has been no such easy route, he has chosen to locate one along section lines or property lines without any particular regard for the terrain which he traverses or for the suitability of such location for possible future heavy traffic. This policy of the engineer may be partly justified by the explanation that a majority of the locations for highways has not been made by engineers. Too often they have been determined at mass meetings or conferences of citizens who were thoroughly eager and sincere in their determination of routings but who failed to calculate, or to have the economy of either road location or construction determined by experts. This is not stated as criticism because without such action by those interested in road improvement in the various States, the Nation would be much less advanced than it is to-day. Furthermore, the writer knows of very few cases in which the location or construction of any type of road or highway has not at least paid for its investment over the period in which it has been used. How much greater return, however, could have been obtained from the use of highways if, as time went on, the cost of traveling a much greater distance could have been saved; and with how much more safety the public could have reached its goal!

Almost every important railroad is rather closely paralleled by a State highway. This, of course, is largely due to the fact that the railroads have developed the population centers and the demand for highways has been along the same general line. However, with the location of State highways parallel to the railroads, the engineers have been too ready to accept the railroad location as being along the best ground. This is usually true for a steam road, but problems of highway location are considerably different from those confronting the railroad locating engineer, and much distance can be saved to highway travel in country where railroads have considerable trouble making 1% and 1.25% grades and have to make distance for gradient.

The writer was once in charge of a railroad location in which the limiting grade was 1.25 per cent. The final located route between two points measured 14.5 miles, and more than 75 miles of preliminary lines were run and much adjustment was necessary to obtain that. Between these same two points a State highway is now being planned, with a maximum 3% or 3.5% grade, and the total distance will be shortened to 11.5 miles. Instances of this kind are very common in the State of Texas.

Aerial Photography.—Any discussion of highway location by one familiar with the situation in Texas would be incomplete without a reference to the use of aerial photography. In reconnaissance the Texas Highway Department is using such service to a great extent and has found it very valuable. No other improvement in the field of reconnaissance or location has contributed so largely to the efficiency of engineering.

The usefulness of an aerial survey begins at the first inception of the work and continues until the last shovelful of dirt is in place. It puts in the hands of the engineer many of the details that are to be found on the ground and in addition it gives him a broad view of the field of operation that has never been available in any other way. He may make locations directly on aerial mosaics; he may study minutely the locations of drainage structures and other proposed improvements; he may calculate stream flow and plat drainage areas without the use of field operations; and throughout the progress of his work the aerial survey stands by as a constant check upon the more exact field calculations.

The Texas State Highway Department has secured some very excellent results by making a location on the ground after having laid it out on an aerial map. The aerial photographer furnishes an approximate scale of each map, and in most cases these determinations are found to be very accurate. The aerial maps are especially useful in crossing streams and determining routes through cities and towns. Where little information is available from previous surveys or maps it is always economical to have an aerial map made. Such maps on an approximate scale of 700 ft. to an inch cover a strip of terrain about 6 000 ft. wide for single-flight, or 9 000 to 10 000 ft. wide for double-flight, maps. The cost is from $14.00 to $17.50 per lin. mile for a single-flight and approximately twice these amounts for double-flight maps.

After the completion of reconnaissance either by aerial photography or by preliminary lines, the best plan is to locate the final line on the ground, making such shifts of tangent or curve as may better fit the terrain from the actual field measurements. Very little difficulty has been experienced in laying out locations from aerial reconnaissance after walking over the proposed line once or twice, noting any physical conditions which might affect the location and then taking them into account. After the line has been laid out on the ground to complete what might be termed the locating problem, the engineer has only to prepare his alignment and right-of-way map, showing thereon such land as may be necessary to enable field notes to be prepared and giving the name and abstract reference to each tract of land. These plats are usually made on a 400-ft. scale which has been found to be the most adaptable to the use to which the map will be put.

In general, with regard to the location of a State highway, it is of prime importance to select the most direct line between two objectives. The line should be so located as to provide a minimum of waterways and the easiest grades and curves possible for the terrain. An important consideration is to select a line that will give not less than a 500-ft. sight distance between the eye of the driver and the top of an approaching automobile. Easy curves are not objectionable in order to increase sight distance where they do not materially lengthen the route. Such locations should be made and grades prepared with the primary object in mind so that, regardless of the development of the country through which the highway might pass, any surfacing placed on the prepared grade would be only a stage of improvement, the ultimate life of which would depend upon traffic requirements of the highway. This was what the writer had in mind in answering the question by the Texas State legislator. In other words, a highway properly located with a grade line of sufficient flatness to meet the exacting demands of increased traffic, and with curves in easy stages, will have its ultimate life more permanently assured as years go by and its condition should be better at the end of fifty years than at the end of five. With these considerations in mind the locating engineer, in considering his route between objectives, should disregard "the line of least resistance" unless he is prepared to see the day come within his own lifetime—or better still, within a decade—when the route he lays out will be relegated to the status of a lateral or community road, or be entirely abandoned. When such time comes, very likely it will be forgotten that the original location was perhaps determined by considerations purely local, and the necessity for relocation or abandonment, may, without much fear of contradiction, be explained as the correction of a mistake in engineering.

The problem of locating a highway with respect to topography, drainage, grade line, sight distance, and all those phases which must be studied in their entirety, is one that must command the expert attention of the locating engineer and the construction engineer. Nevertheless, its difficulty of solution is secondary to that of the economy of location with regard to traffic, the distance that must be traveled, and safety.

Location with Respect to Safety, Economy, and Utility of Operation

The writer believes in the democratic principle that the voice of the majority should rule. He has never known it to fail, that where the people of any State or Nation were acquainted with all the facts with regard to any problem, they did not eventually (by their majority) vote to solve this problem in a way that the thinking people of such a community or commonwealth might determine that it should be solved. The people should have what they want, even if it costs more, that is, when they have decided with all facts before them.

The building of State highways is a public enterprise and the solution of the problems with regard to such a public enterprise should be entered into with the idea that it would be inadequate if it did not meet and satisfy the demands of the thinking public and if it were not in line with sound public policies.

Highway engineers are very often concerned with the problem of routes leading into cities and towns. This problem has been uppermost in the minds of the people for some time and public sentiment is now undergoing a rapid transformation in regard to highway location in population centers, large and small. In the State of Texas much prominence has been given to certain isolated cases of location where the State Highway Department has, for safety purposes, undertaken to re-route certain highways. Charges have been made that the officials and engineers of the State Department have in mind the laying out of a highway system that would isolate the cities and towns. In order to combat this erroneous impression the Highway Department has gathered some statistics and has made some calculations. The State now (1929) has a highway system of approximately 20 000 miles as measured along present routes. When this system has been economically located or relocated the mileage will be about 19 000 miles and not only will all the control points be reached, but this system will reach directly, without material loss of distance, 97% of all towns, the population of which exceeds 200. Included in this percentage are all towns that have a prospective main-line highway passing through their corporate limits or, in case of no corporation, within four blocks of the main business street.

Through Traffic.—The general argument for the route of a State highway to pass through the business district of a town or along its most important street is that business is brought to the town by reason of the traffic on that highway. There is no doubt that certain classes of business establishments do profit to a certain degree by transient trade, but it would seem that a town depending to any degree on such trade would lack the foundation necessary for stable and continuous growth; that is, an established and a certain rural trade territory. The highway or road problem for any community will not be solved until every village and town is either provided with a highway or with a durable connection to the highway. The farmer or community trader will then have access at all times, not only to the State highway but to the main business center of his trading point, and the residents of the community will have a means of leaving and entering. It seems contrary to sound economic judgment and good public policy to deflect the location of an important State highway, carrying 2 000, or perhaps 5 000, vehicles per day, 2 or 3 miles out of the general course in order to pass through the main business district of a community which would perhaps not originate more than 100 to 200 vehicles per day. The problem should require and demand the careful thought of the people of any State, and they should consider the relative advantages and disadvantages to the traveling public in districts and cities. It has been the policy of the Texas Highway Department to link the various towns with State highways and to provide for first-class construction along these link routes. In many cases, it has been possible without materially lengthening the line, to serve, directly, the vast majority of towns of more than 200 population and a great many villages of smaller population. However, in serving towns, it is the purpose to provide a direct line, without right angles if possible, and along a street of sufficient width to care for traffic. It is, or should be, the purpose of the engineer in selecting a route through a town to relieve instead of to create congestion. A paved highway connecting with an unimproved street in a city or town or a provision for such connection should satisfy all conditions.

Locating Roads for the Tourist.—It would be quite a different problem if a special frontage tax or assessment were paid by business men dealing in commodities for which there is an incidental demand from the traveling public. Neither the stability nor the growth of a community can depend upon the trade that will come from those who would ordinarily not stop at a place of business unless the highway happened to lead by the door. It would seem that the authorities in charge of the streets in a small town would prefer to reserve such streets for the citizenship of the community to use for parking their trucks or for stopping their produce wagons. In one Texas town, the main street, which was of considerable width, had been paved and largely paid for by the merchants of the street. A complaint was registered with the Mayor that the people who lived in the town found the street almost blocked with cotton wagons and other traders. The Mayor's reply was that the street was paved for that purpose and that they should adjust their shopping periods to the needs of the community at large, and not try to use the street at the busy period when they could just as well select another time. This is a somewhat radical viewpoint, but the thought is worthy of consideration. In another instance, a filling station operator complained to one of the Texas Highway Commissioners that the highway was being moved from in front of his business to a street two blocks away. The operator exclaimed: "That road has been where it is for fifty years, to my own knowledge," to which the Commissioner replied: "Do you not think it is about time that your neighbor had it for a while?"

One of the chief arguments in registering complaints against the change of location for safety or other reasons within or adjacent to the towns is to say that the State is not building the road for the local people who pay the taxes, but for the tourist. Considerable misinformation has been spread under the name of "tourist trade and traffic." Recently, a Central Texas newspaper contained an editorial stating: "Do not build the road for the tourist but let the taxpayer benefit by having the road." The next editorial a few days after the first said: "Let the traffic pay for the road and relieve the property owner." Within a few days a slogan was published in the same paper: "Make our city the tourist headquarters of the South." These varying comments appeared within a period of seven days.

Webster's dictionary defines a tourist as "one who travels from place to place for pleasure or culture." A citizen of Texas, for example, might leave his home on the morning of a certain day and travel as a tourist along a State highway through many cities and towns; and then, overnight, his status might be changed so that on his return home he would belong to whatever classification might be given him, depending on his rights as a traveler or the contributions he might make for the construction and maintenance of State highways. Such a traveler in Texas might, and very likely would, pay an *ad valorem* tax to build State highways or lateral roads in his home county. He would also, or rather should, pay an *ad valorem* tax on his automobile. He will pay a license fee distributed between the State and County for the maintenance of State highways and, finally, a gasoline tax. When such a traveler leaves his home county for pleasure or culture and travels across his own State, or any other, should he have no consideration given him in that his journey might be made as safe as possible and as direct? Consider, also, for example, a traveler from some other State who might enter the State of Texas and travel for pleasure or culture. In a material way this visitor is required to pay a gasoline tax and, if for no other reason, he is entitled to consideration. State highways should be bought and paid for by the traffic using them and any local funds used in construction should be refunded. Consequently the maximum consideration should be given the traveler in making locations. He should have the option of proceeding on his journey along the most practical route, and if he desires to visit the business districts of any of the towns along the highway a way should be provided for him in case the route does not lead directly through. No particular distinction except for statistical purposes should be made in the classification of traffic. The motorist is not a class and does not pay taxes with a class for the reason that the vast majority of the Nation's tax-payers in all lines use the Nation's highways.

The Influence of Financing on Location.—The day of the *ad valorem* tax for highway construction is passing. In 1929 the Texas Highway Department recommended to the State Legislature that provision be made for adjustment between the various counties and reimbursement of expenditures for State highways, and this issue failed of submission by a very small margin. There is no doubt that State highways should be built from sources of revenue other than property taxes, and this principle has already been put in effect by a number of progressive States. A study of the accomplishments of such States shows that they are well in the lead of others in the status of their road program. The method of financing State highways should and does have considerable bearing on the location, but even with a portion of the construction cost being paid from an *ad valorem* tax in a road district or in a county, no property owner should claim any special rights to the traffic along a certain road since he pays no special privilege for such traffic.

It is only fair that when a hard surfaced highway has once been constructed along a certain street in a town or into a larger town as far as the laws will permit, that such highway or road should be continued and maintained by some agency; but the owners of business houses along such a route have no right to say that the general traveling public cannot, with finances belonging to the general public, construct such additional highways or by-passes as will enable it to proceed with safety.

The writer agrees with a recent editorial entitled "Getting Away with Antiquated Ideas."[3] The author deplored the conservatism of many highway executives in clinging to conceptions of road building that were in vogue during the age of horse-drawn vehicles. To salvage the old roads is often not worth while because it is costly in terms of human life.

CONCLUSION

State highways should be located for present and anticipated traffic requirements so that—whether he be tourist (if there is such a classification), business man, or farmer—the user of the highway can proceed along his route and accomplish his purpose or his duty or receive his pleasure or culture with ease, directness, safety, and economy. Any plan or system of location which does not take these features into account is running contrary to sound public policy. There can be no denying the fact that such public policy, in laying out a great system of highways and lateral roads, must necessarily prescribe a practical directness for the mass of traffic. It must provide more conveniences for traffic originating locally or bound for local destinations. With the adoption of a plan whereby the revenue for State highways comes from State sources, the solution of this problem becomes easier and the "dog will begin to wag the tail" instead of the contrary, which has been the case in many highway locations.

---

[3] *Highway Engineer and Contractor,* Vol. 20, April, 1929, p. 28.

Highway engineers should take every opportunity to acquaint the public with facts regarding the economy of highway location and to lay before it for inspection the ledger entries on the debit and credit side regarding the operation of a State highway. They should always have an eye for the future and if it is not possible to lay out a plan for economical routing when first construction is obtained, the plan should be so broad as to anticipate future demands.

DISCUSSION

C. S. Mullen,[4] Esq. (by letter).—The author has covered his subject so thoroughly that a discussion is practically limited to an approval or disapproval of his statements.

Greater emphasis might be placed on the fundamental assertion that the life of a highway is not a function of surface, but of location. Thousands of examples all over the United States could be cited, where road surfaces entirely adequate to carry existing traffic for many years are being abandoned, because the location on which they were built is no longer safe or economical.

The use of aerial photography as an aid to highway location is comparatively new, but in many cases will prove very economical and at times invaluable.

The suggestion as to introduction of horizontal curves to secure increased sight distance is, in the writer's opinion, questionable. As the added sight distance is desirable for greater safety it is suggested that this safety feature could be better secured by widening the surface at summits, rather than by breaking up the alignment and introducing a curve which is a constant potential danger point.

Mr. Gilchrist's belief in the democratic principle that the majority should rule, is not a safe guide in highway location. It has been demonstrated a number of times that where this principle has been followed, serious mistakes have been made which later were condemned by that selfsame majority.

The question as to locating a highway so as to pass through all cities and small towns on its approximate route, is one of the most puzzling that confronts the highway engineer. It is believed that in such cases the question of traffic congestion should receive most serious consideration and the location made, if possible, to avoid this condition.

H. L. Thackwell,[5] Assoc. M. Am. Soc. C. E. (by letter).—The answer given to Mr. Gilchrist's questionnaire, that "the life of any particular type of road depends, first, on its location and, second, on the width of its right of way, and that the type of surface was of secondary consideration", is certainly true in part. There are other factors, however, that play an important rôle, namely, climate, attention to maintenance, drainage, etc. Highway maintenance funds should vary with the topography, traffic, and climate.

State highways in Texas, as located in 1930, certainly have been improved in alignment, and distances have been shortened by curve elimination. However, grades are still prominent by their frequent reversals. The rigid policy of exactly proportioning cut and fill, and not allowing waste fills or excessive borrows, is not in accord with the vision of to-morrow.

---

[4] Chf. Engr., Dept. of Highways, Richmond, Va.

[5] Cons. Engr., Jacksonville, Tex.

Many highways from 5 to 10 years old are being abandoned or their locations are being changed radically; such change of mind or policy would indicate that still further changes or eliminations may be expected in the near future on newer locations.

A city of several thousand people in Texas surely has an expectancy of life equal to 1 000 years. It is also reasonable to conclude, in spite of air travel, that wheeled traffic will still be in vogue 1 000 years hence. If these two assumptions are correct, the roadbed (earth foundation which has an exceedingly long life) should be designed and located so that there would be no likelihood of changes in grade or curvature for many decades in the future. Hard surfacing which may have an expected life of from 2 to 30 years (depending on the type, location, and traffic), may be changed in a few years without violating fundamentally economic laws. Roadbeds, with right of way and drainage structures, often cost 50% of the total in places where a standard concrete pavement is used; hence, a mile of roadbed costing $20 000, that has an ultimate life of 1 000 years, would capitalize without interest at $20 per mile per year. The concrete surface might also cost $20 000 ($800 per mile per year), and have a life of 25 years.

The roadbed is frequently altered or abandoned by change of policy, administration, or vision, while it still may retain 99% of its expected life, but not its economic utility. The surface, however, is never abandoned or changed, until its useful life has been largely exhausted.

It does not take great imagination to visualize railroads replacing steel and ties with concrete surfacing and using huge wheeled vans drawn by tractors or individually propelled cars. They may run on their own roadbed in the country districts and, traversing cities, run on city paving and unload the cargo and freight at warehouses wherever they may be situated.

State highways of the future will abandon the present system of numerous short reverse grades and deep drainage ditches, and will incorporate storm sewers, curb, and gutters, with widened pavement, somewhat similar to city pavements, thus taking care of the ever-increasing traffic. Such a highway will provide relief from congestion, will increase safety, and will utilize the acquired rights of way economically.

The writer is of the opinion that aerial highway location should be followed by plane-table topography, the latter being conspicuous by its absence in Texas highway surveys.

Formerly, the improved highway locations for King County, Washington, were always projected on topographic maps which were sufficiently accurate to make possible an economic paper location that would conform to any preconceived rule as to alignment and grade economies.

The dissimilarity between highway location and city street location is marked most strongly by the tendency for highway grades to be above the adjoining property so that free drainage may be adequately maintained. In city paving, on the contrary, the grades are lower than abutting property, and storm water falls over the curbs and is ejected through the storm sewers. This cardinal difference in tendency has caused many cases of objectionable grade transition on roads located through small cities, by highway engineers, and of paving construction carried out by city engineers at a later date.

In conclusion, it is the writer's commentary, but not criticism, that it would be better to have fewer reversed grades, fewer deep ditches, greater use made of storm sewers and gutters, and a gasoline tax so proportioned for maintenance that the hilly country with high precipitation would have more maintenance funds per mile of road than the flat dry country of equal traffic weight. No State aid for cities should be permitted and State highways should begin and end abruptly at city limits. Cities should be required by State law to keep up an economic paved roadway connecting the State highway through the city, that is financed by refund of a proportion of the gas tax to the municipality. State highways should be financed, owned, and operated by the State and Federal Governments and these groups should not expect aid from counties or local communities. The so-called co-operation of funds is largely responsible for frequent criticism by local communities against the removal of existing highways, and has naturally culminated in selfish interference, through politics, with economic engineering locations. The engineer's call of distress is well justified, but the cure will be at hand only when the financing policies have been changed.

The grand success of the Appian Way and its magnificent permanence are due more to the splendid Roman administration and policy than to the engineering of the highway itself. The original location is unchanged and the foundation still endures, while gravestones crumble and empires fall.

B. P. HARRISON,[6] M. AM. SOC. C. E. (by letter).—Too little emphasis is given in this paper to the part that safety should have in the location of highways.

Should not the engineer feel some responsibility for the lives lost due to a faulty location? The roads are crowded with poor drivers and the toll of human life is rapidly increasing. The tendency of the day is for increased speed. Some States have increased the speed limit, while others have even done away with the speed limit entirely. Every one agrees that the loss of life is far too great and that something should be done to lessen the mortality.

Is the engineer doing his part by insisting upon proper locations? In days gone by, with slow traffic, it was probably economical and proper that bridges should be built at right angles to the streams. The writer has seen many examples in which locations have been badly distorted in order to accomplish this purpose. Bridge engineers sometimes fight a location because it will require a bridge to be built crossing the stream on a skew. The time has come when the highway engineer must insist upon the proper location, whether it will require a bridge to be built on a tangent, a curve, or a skew. The hazard is too great to permit the old right-angle crossing with its dangerous curves at or near each end of the bridge. Generally speaking, engineers must build the bridge to fit the location and not make the location to fit a bridge site.

---

[6] Associate Highway Engr., U. S. Bureau of Public Roads, Washington, D. C.

Often there are restrictions, as to sight distance, or curvature that does not require super-elevation. If the sight distance required in a specific case is 500 ft., how seldom does the motorist have any more? The tendency is to do no more than is necessary "to get by". If it should be required that all curves of more than 6° be superelevated, the curves will be made 5° 58′, to avoid superelevating. Why should there be the tendency to do no more than is absolutely necessary to "get by", with any location and plan? Economy has played too great a part in past locations. The engineer responsible for highway locations should spend a little more money, make highways "fool" proof, cut out grade crossings, and thus save many lives. The locating engineer has a wonderful opportunity. Will he take advantage of it?

E. P. ARNESON,[7] M. AM. SOC. C. E. (by letter).—The author's views are refreshing and stimulating, dealing as they do with the human element in highway location. His conviction, that the people want the highways located for the interest of the many and not for the few, may well be taken by the locating engineers of America as a tenet of faith. All rules of highway location flow as corollaries from that proposition.

The author makes another sententious and challenging statement—that the life of a road is not so much dependent on the type of its surface as on its location. There is an implication here as to the importance of the time element, which the writer would like to discuss.

Referring to the original interest to be served—that of the many as opposed to the few—one knows that this interest may change with the passing of the years. Therefore, the influence of the time element should always be weighed when one is about to fix the position of a proposed highway. The need for the road may be greatly lessened, or indeed it may virtually disappear, in a number of years, by reason of changes in the habits of the people served. The point is, as the author states, that not only does the road wear out, but its very location may have a limited life.

Because of the influence of the time element one may be justified in giving a road an impermanent location, if the ascertained facts warrant. The writer remembers a case in point, where two highways were to be located on general routes which converged on a city with an angle of about 45 degrees. The Northeast Highway, being the more important, was run on a line as nearly direct as the topography permitted. For the East Highway there was the choice of an independent and direct location into the city, or of a combined location by joining the Northeast Highway six miles outside the city. In the latter alternative about $360 000 in first cost could be saved at the expense of some lost distance for the East Highway traffic.

The solution of this problem resulted about as follows: A reasonable estimate of the future traffic on both highways indicated that the joint track would be safe from congestion for twenty years. Moreover, the comparison of the costs and benefits of the independent route for the East Highway indicated that it would take about twenty years for the benefits to pay for the extra investment of $360 000 and its interest. The decision was to combine the two highways, reasoning that it was unwise to build the more direct and independent location of the East Highway, when it would apparently take as long as twenty years to pay for itself, provided the future developed as predicted by the engineer. Nevertheless, the time may come when the East Highway can properly be given an independent and direct entry to the city. Then the road, as theretofore located, will be one more route cast into the limbo of impermanent locations. Permanency of location is a relative matter.

[7] Civ. Engr., San Antonio, Tex.

Gibb Gilchrist,[8] M. Am. Soc. C. E. (by letter).—That serious mistakes have been made by following the principle of the majority rule is the opinion expressed by Mr. Mullen, who also states that these have later been condemned by the selfsame majority. This theory would be entirely correct if an engineer should build a structure of inferior and inadequate design, such as an important river bridge which might fail under increased loads, but in the case of highway location the engineer's duty should be to acquaint the governing body—whether it be the board of directors or the entire electorate—with all the facts and arguments for proper location, so that a principle of location may be established along which he may exercise the best technical knowledge for the most economical construction. He will find in a great majority of cases that, when the facts are presented by an engineer impartially and correctly, the decision as to policy will be along the proper line.

Mr. Harrison believes that too little emphasis is given to safety and he discusses the tendency of engineers to build a right-angle crossing of a stream with too much curvature at each end. Just as much criticism may be given to a plan in which alignment only is considered, and the bridge is constructed on too much of a skew. Latitude in this case should be given each way as easy curvature is not particularly objectionable and a compromise can easily be found.

The writer cannot agree with Mr. Harrison that the tendency is to do no more than is necessary "to get by." It is believed that engineers are giving more and more attention to location in a common-sense way and that radicalism in one direction is perhaps as bad as carelessness or vacillation in another. He cannot agree, either, with Mr. Harrison that more money should be spent to make highways "fool-proof"; this is an impossibility as far as location or construction is concerned. The only way to make highways "fool-proof" is to keep the "fools" off the highways, and the people riding in automobiles with "fools" as drivers will simply have to take their chances. Every consideration, of course, should be given for the safety of highways along reasonable lines for the protection of the traveling public.

Public sentiment has changed wonderfully on highway location, and it is still changing. It had evidently taken a step backward in the not too distant past, if evidence[9] given by Mr. James Dean, Land Agent and Civil Engineer, before a Committee on Highways of the House of Commons, on April 1, 1819, can be given credence. This might have been written in 1932:

[8] State Highway Engr., Austin, Tex.

[9] "Road Making," by McAdam, p. 183.

"The first and most obvious improvement is to shorten distances; but even that must be governed by circumstances often of a local nature; a sound foundation, and the contiguity of good stone or gravel to a road, should not be overlooked in choosing a new line, or departing from an old one."

Reference was made in the original paper to a principle of democracy. Two letters written by President Thomas Jefferson under date of August 6, 1808, indicate that problems have not changed greatly in the meantime. They also show that the attitude of those in authority was not much different 125 years ago.

Writing to Kerr, Moore, and Williams, Commissioners of the "Western Road," Jefferson called attention[10] to a petition by the citizens of the Town of Washington (then in Pennsylvania) for a relocation of a through highway so that it would pass through their town. The argument was advanced that such a detour would be only a mile longer, that it would pass through better ground, and would cost less. While the principle purpose of the road was a communication directly westward, President Jefferson decided that if minor deflections would benefit particular places and accommodate travelers better, these circumstances should be considered. The letter ends by charging the Commissioners with the duty of reporting material facts and their own opinions, for the President's consideration.

On the same day President Jefferson wrote[11] to the Secretary of the Treasury, Albert Gallatin, and explained some of the location problems behind the letter to the Commissioners. It developed that this was a move made after a first concession had been granted to another town; a third petition was being prepared at still another town.

"I should have listened to these solicitations with more patience," wrote Jefferson, "had it not been for the unworthy motives presented to influence me by some of those interested. Sometimes an opposition by force was held up, sometimes electioneering effects, as if I were to barter away, on such motives, a public trust committed to me for a different object."

While many States are still using county aid obtained from the *ad valorem* tax for the construction of State highways, the tendency is not only for the construction funds to be obtained from transportation, but also for transportation to bear the assumption or refund of county funds spent on highway construction. For this and other reasons highway location should be determined according to the needs of the traveling public and the safety and convenience with which a traveler, or a group of transportation units, may reach their destinations with the minimum of travel and the maximum of safety, decisions being at all times governed by common sense for which a suitable substitute has never been found.

HIGHWAY LOCATION: PRACTICAL CONSIDERATIONS[1]

By A. R. Losh,[2] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. H. K. Bishop, J. C. Carpenter, H. J. Spelman, H. S. Kerr, H. W. Giffin, and A. R. Losh

Synopsis

The purpose of this paper is to present some of the major problems of highway location. There are administrative as well as physical limitations which determine in a large measure the work of the engineer on location. It is fundamental that the ultimate purpose of the road be kept in view and the location made to accomplish that end. Highway location does not include merely lines, grade, and construction costs, but traffic as related to towns and cities, other highways, and the general needs of the public. Too much location "for present needs" has been followed in the past with resulting loss, under relocation, to the public and to the individual citizen along the highway as well. Insufficient right of way for the protection of the highway is a serious handicap to its future usefulness.

Introduction

It is recognized that the detail problems of location depend on the peculiar conditions of the individual project. It is equally true that there are general problems on roads of the same class, but these may be decidedly different for roads dissimilar in their uses. Thus, different governing conditions apply in the location of roads for sectional and interstate traffic than for local roads serving small agricultural communities. Roads located primarily for parkways, pleasure drives, and for recreational purposes where scenic considerations are of major importance, will naturally impose conditions differing from those of the other classes. There is, however, one fundamental principle which should be the controlling feature in any road location. Briefly, this is that the resulting location should be adequate for present and prospective future needs of the highway. Present needs are readily determined; future needs require the exercise of judgment and foresight.

---

[1] Presented at the Joint Meeting of the Highway and Construction Divisions, Dallas, Tex., April 25, 1929.

[2] Mgr., Asphalt and Road Oil Div., Anderson-Prichard Corp., Oklahoma City, Okla.

The reconstruction and improvement of roadway surfaces and structures can be readily justified from prolonged usage or for needed increased facilities in the same way that the rebuilding and remodeling of homes, office buildings, mills, and other structures, but the relocation of a large portion or all of the road does not present a similar case. This change of location involves a substantial loss of the right of way, roadbed, and structures, as well as the expense of their reproduction on the new line. It is difficult to find suitable explanation or justification for the building, by the present generation, of many of its main highways three times and on three different locations.

It is not to be understood that the mistakes in location in the past rest solely upon the highway engineer; this is not the case. Many of the earlier improved roads were not located; they merely followed land lines or existing rights of way of older roads. The engineer was given little or no opportunity to develop a suitable location. Road funds were provided by local governmental units and the roads were placed so as to be acceptable to the governing boards or commissions. Most of the present lines of travel were originally only local roads, and the subsequent traffic development was not anticipated. This condition no longer exists except for the local roads. The main highways are financed by the road user at large, by the State, and by the Federal Government. The engineer should approach the location problem with the future uses of the road in mind and should endeavor to provide a location which will be suitable for this purpose. This will include—in addition to alignment, grades, stream crossings, and similar engineering work—provision for future development of the highway and its protection from encroachment by industries and other utilities. Briefly, the mere located line without adequate right of way and roadside protection will not be sufficient.

It will be the writer's purpose to discuss the major problems of locating State and Federal Aid highways. The engineer has received very little assistance on highway location from engineering textbooks. The subject is discussed only briefly if at all, and then usually on the assumption that the existing road will be followed with only minor changes in alignment. The location of highways purely as transportation lines is not the usual practice. This is not a condition readily attainable, nor is it strictly desirable on public highways. The service of the project in the highway plan as a whole is the consideration which should be followed.

DESIGNING FOR PRESENT OR FUTURE CONDITIONS

There are still some who would consider present highway building as primarily of local importance and for the immediate local needs, it being proposed at some future time to build a system of through highways on more direct lines. Such a line of reasoning has been applied to a considerable extent in the past with the following results:

(*a*) The location of important through highways has been materially affected by purely local considerations.

(*b*) Frequently, local and through traffic were combined where a separation would be preferable.

(*c*) When reconstruction for the through traffic is undertaken it is exceedingly difficult to make adequate relocation.

(*d*) When the indirect line is used a number of years subsequent development results in increased property values which may be seriously impaired by substantial changes of location.

(*e*) Right-of-way changes resulting from relocations are usually more expensive than if made under the original construction, due to increased property values and damages to improvements.

(*f*) The value of the old road in terms of right of way, roadbed, surfacing, and structures, is a loss unless the road can be used advantageously for local purposes. Even then, it must be considered that 1 mile of main highway costs as much as several miles of serviceable local roads and there is a loss in changing a main road to a local one.

(*g*) The roadbed structure consolidated and compacted by years of use is lost for reconstruction purposes.

It is this line of reasoning which would make the work of the engineer follow the development of the country rather than to lead and aid materially in that development. It is "the line of least resistance", of temporary expediency, and of future changes with attendant losses. The aim of the engineer should be to provide a location which will remain as a major line of highway transportation and which is so planned as to meet the requirements of the future. A location of this character approaches the "permanent road feature" as nearly as is humanly possible.

RESTRICTIONS ON LOCATION

On all highway projects there are administrative controls or restrictions which determine at least the general location of the project, or the route of which it is a part. Thus, the termini of the project are predetermined and the intermediate location may or may not be fixed. These restrictions will occur under the following classifications:

1.—Major control points of the Federal Aid System determined by the Secretary of Agriculture and the State Highway Departments and subject to modification by joint action.

2.—State highways and control points designated by State Highway Commissions under legislative authority.

3.—Control points for State highways fixed by legislation.

4.—County or road district bond issues used for a part of the construction cost may require a definite location to be followed.

Under Conditions 1 and 2 there are opportunities for a general engineering study before the controls are specified and also for a revision of controls based on further engineering investigations. Condition 3 may or may not be based on engineering investigation, or it may permit some departure from the established route at the discretion of the State Highway Commission. Condition 4 presents the greatest difficulty because frequently, where local funds are contributed, the detailed location is fixed primarily to serve local wishes. The writer has known of cases in which the increased cost of these features placed by local influences was greater than the local funds provided. For example, in Jefferson County, Oklahoma, county funds were provided to aid in the construction of U. S. Highway 81 on a location determined by the county officials. This location involved three more railroad intersections, one additional bridge, and some increase in distance over a location selected by the State Highway Commission and the United States Bureau of Public Roads.

This system of financing has been responsible for most of the unsatisfactory locations in the Southwest during the fifteen years since 1914. Where it is necessary to continue this system of financing in fairness to all parties concerned, the location should be determined in advance of the local arrangements for financing.

Even under Conditions 1, 2, and 3, there is too great a tendency to follow existing lines of improvement with relatively unimportant control points established; under Condition 4 this tendency often reaches the point of affecting the detail of location. Regardless of how the conditions are imposed they may in effect restrict the work of the locating engineer to mere details of design. Administratively, controls are necessary and should be general in character and limited to the following conditions:

(*a*) A town or city on or near the general line of the route between adjacent control points of the route.

(*b*) A town or city of sufficient importance to be a terminal point for the traffic passing between the adjacent controls.

(*c*) A junction point, preferably near a town or city, of several highways for the distribution of traffic.

(*d*) Topographical features based on engineering investigations.

Within the limitations established as controls the engineer should determine, as far as practicable, upon an economic location, considering at their relative weights both through and local traffic. This selection will be the line which will provide the long-run least cost, including construction, maintenance, and traffic operations. The shortest line will usually be the economic location for the reason that practically all items of cost except earthwork and structures vary directly with the length of the line. In a country of broken topography the cost of earthwork and structures may be much less on the longer line, but the other items of construction, and of maintenance and operation, will usually determine the location. Local traffic can generally be served more cheaply by lateral spurs from the main line than by attempting to give direct service.

One of the usual problems before the engineer is to determine whether or not to swing the main line from its direct course in order to give highway service to an intermediate point, such as a small town or community. Theoretically, the problem can be solved by estimating the cost of construction, maintenance, and operation for each of the two possible layouts; that is, the cost of the main line direct with a lateral spur and cost of the main line on indirect location through the intermediate point.

A similar problem is that of combining two or three highways for some distance out from the city in order to reduce construction mileage. While economically desirable, frequently this involves the questionable practice of encouraging traffic congestion at junctions and terminals.

Studies of State highways show a substantial volume of traffic outside the purely local class. Thus, the California studies of 1922 show the average length of truck hauling to be 31 miles and that of passenger buses, 41 miles. The Pennsylvania studies show that 43.8% of the State highway traffic travels 50 miles or more, and for the Ohio study this figure is 30.3 per cent. Similar data are not available for the State highways of the Southwest, but it is believed that there is a larger percentage of long-distance movement.

Traffic of this character is benefited more by the possible economic operation over the whole line than by the detail location through small communities with which they may have little or no contact. This provides the basis for considering the needs of local and through traffic separately. It is recognized that grades, character of road surface, alignment, traffic hazards, and conditions causing loss of momentum, use of brakes, and extra wear on the machine are all factors affecting adversely the cost of traffic operation, but the data are not available in a form to be readily used.

Effects of Topography and Grades

In working out the detail location further economies can be made by taking advantage of topographic conditions, soils, available local material, or railroad facilities for importing materials. Approximately 4 000 tons of materials are required per mile of 18-ft. concrete pavement. An increased dead haul of 1 mile will increase the cost of the road about $1 000 per mile. In addition, there will also be the cost of moving construction equipment on and off the job as well as the cost of hauling structural materials. The use of long radius curves reduces the total length of line and the amount of surface widening. For a change in direction of 90°, a curve of 1 000-ft. radius gives a line 214 ft. shorter than a 500-ft. radius. To widen the curve of 500 ft. radius would require about 938 sq. yd. of additional pavement.

Topographical conditions affect the details of location and, in some instances, are major controlling factors. All soils which are unsuitable for subgrades, such as shifting blow sands and rock classifications, are to be avoided if practicable. Overflow sections require high embankments with costly structures, and, for this reason, valley locations are frequently undesirable. Stream crossings must be selected with the view of reasonable permanency of the banks, suitable foundations, and required span length, and they must be within the general location. Grades and curves adjacent to bridges should be reduced to the minimum. It is desirable to have a tangent of at least 150 ft. and a light or flat grade at each end of a major structure. These conditions permit the driver to adjust his machine into the bridge alignment. In the past, grades have probably received more consideration than other features. Considering the motor vehicles now in use some sacrifice of grade can be made to improve alignment. Short grades as steep as 8% can be climbed readily by modern motor vehicles, but continuous grades of more than 6% are objectionable. Tangent profile grades are not particularly advantageous, due to the headlight glare, and do not justify increased expense. A rolling profile fitting the topography is less objectionable for night driving.

Grade separations at railroad intersections are desirable, but not always possible financially. When grade crossings are adopted the line should be located so that future separation can be developed, and in all cases approach curves and grades should not restrict sight distance.

Restricted areas in and near cities are frequently obstructions to direct highway location. This includes parks, golf courses, institutional reservations, cemeteries, railroad yards, and air ports. Generally, it is impracticable to pass through these areas and the location must be carried around them. The location should give access to railroads and air ports, but should be sufficiently removed to permit full operation of all facilities without congestion. A location directly adjacent to the railroad may be congested by trucks loading and unloading at the station and also by industrial spur tracks being constructed across the highway. Location along the railroad is usually adopted because good alignment is obtainable in this way and because the right of way is not difficult to secure. It has the additional disadvantage of permitting development on only one side of the highway whereas if removed ¼ mile or more from the railroad, property on both sides of the highway would develop.

One of the major problems of the engineer is to provide suitable locations into, through, and around towns and cities. It is necessary to provide suitable connections into the street system of the city. It is highly desirable also to have a direct through connection, even if it may be congested by city traffic, in order to take care of through traffic making a temporary stop in the city. A belt line, or by-pass location, is equally desirable for the through traffic to avoid the city congestion in reaching its destination and to permit the sorting or segregation of traffic for different locations.

The desirable condition for the urban approach would be connections which would permit the distribution of traffic to:

(*a*) The retail section.
(*b*) The wholesale and industrial sections.
(*c*) Railroads and air ports.
(*d*) The several residential sections; and
(*e*) To other highways by direct connections, outside the city proper.

Many town and city officials believe that the highway should be considered as a continuation of "Main Street" out into the country and that it should be carried through the principal thoroughfares of the city. This is especially true of cities of less than 10 000 population and the smaller the municipality the more insistent it is as a rule that the highway pass through the main streets. The larger cities have their local traffic problems and as a rule are glad to secure any relief possible by routing through traffic over outlying streets or through the suburbs. In a great many cities, however, highways are taken directly through retail sections where the streets are congested with electric street cars, motor vehicles, and pedestrians. There are numerous street intersections, sharp curves, grade crossings, congestion due to parking, and other hazards of city traffic. The through traffic is delayed and local traffic congestion is increased with possibilities of accidents multiplied. Too many towns and cities are placing restrictions on through traffic by means of speed ordinances, stop signs, signals, and other regulations. These measures in most cases are necessary for the local traffic, but the through traffic can operate better without them and outside the city. Table 1 gives information on several highways through cities of the Southwest.

The development of proper approaches to cities with arterial routes for traffic to and from the city and belt lines for traffic distribution requires the co-operation of State, county, and municipal authorities. It also requires a careful traffic study and analysis, upon which to base present and future plans for improvements. The Plan of Highway Improvement in the Cleveland Regional Area is an outstanding example of this character of work. As a result of this survey the City of Cleveland and its contiguous territory have developed a plan of major road and street improvements for ten years ahead and may proceed with individual projects, knowing their final position in the broader plan.

* Other routes give less curvature, but more traffic congestion.

Increase in most of the speed limits now in force (1929) appear inevitable. The engineer should anticipate this with provisions in his location to meet the conditions. Greater sight distance on horizontal and vertical curves is beneficial; 600 ft. is not excessive. Where this cannot be obtained extra width of surfacing is desirable. In the level and rolling country of the Southwest, engineers are providing horizontal curves of 4° and less. This makes extra width unnecessary, very little superelevation is required, and line length is reduced. The older practice of placing changes in alignment at the top of hills has been discontinued. It is considered a hazard to traffic. Other conditions being equal, curves should be placed where they may be seen readily by the approaching driver.

RIGHT-OF-WAY FEATURES

To a great extent engineers have allowed right-of-way considerations to influence location. This is especially true in regions where the section-line road system prevails. It is seldom that on rural highways more than 80 ft. of width is secured, which amounts to approximately 9½ acres per mile. Considering the cost of State highways at about $30 000 per mile there could be a justified expense of $3 000 per acre for a proportional reduction in length of construction. This does not take into consideration any savings in maintenance and operation costs.

The width of right of way needed depends on the future requirements of the road and also the means for its protection from encroachment and exploitation. Few States have adequate laws regarding right-of-way acquisition and roadside protection. A Texas statute permits the State to obtain 100 ft. for a State highway, which ordinarily is ample. Oklahoma may obtain an easement for any width "for highway purposes." There is nothing, however, to prevent the abutting property owners from building garages, service stations, and other roadside establishments on the property line, and utilizing a part of the highway for the transaction of their business.

Until such time as adequate legislation is enacted placing roadside development under the supervision of highway authorities, the engineer should use such means as are available to protect and preserve the highway for its complete utilization. To this end the writer offers five suggestions:

(1) Acquire sufficient right of way for future development of the highway.

(2) Obtain extra widths at all road intersections and other strategic points where it is likely that roadside enterprises would be established.

(3) In making acquisitions it will usually be possible to retain in the right of way the narrow strips, gores, and other small parcels of land cut off from the original tract. These parcels may be utilized for highway purposes in the future or for roadside planting and beautification. In any event they are not available as sites for billboards and roadside establishments.

(4) Through areas of natural beauty either obtain in fee or protect with long-term leases, several hundred feet extra width on each side of the right of way.

(5) The interest of civic organizations and public-spirited citizens should be encouraged and their aid secured to obtain the desired ends.

PUBLIC CONSIDERATIONS

It is apparent to every one that, aside from the commercial features of highways, there are social and political considerations which cannot and should not be disregarded. Roads are for public usage and must be located, constructed, and maintained with that end in view. Whether for business or for pleasure the public travels to definite points of interest and attraction. Schools, churches, and Courts are the mainstays of the Commonwealth. The public must have access to these institutions by highways. Rural mail and express deliveries, transportation of farm products, and rural community life, while usually served directly by local roads, are affected by their connection with the main highways. There are patriotic shrines in every section of the country which should be made accessible from the highways. National and State parks and forest preserves are visited annually by thousands of citizens and, with improvements in the roads, these properties will be used by many more for recreational purposes.

Every governmental unit should be connected finally with the country at large. The writer has always believed that the larger unit of government has this obligation to its constituent parts: The Federal to the State, the State to the county, and the county to its towns and communities.

These considerations of schools, churches, Courts, and other conditions vitally affecting the citizenship of the Nation cannot be weighed in terms of economics or engineering, but must be taken under the "General Welfare" clause of the fundamental law.

DISCUSSION

H. K. Bishop,[3] M. Am. Soc. C. E. (by letter).—The primary use of a modern highway, generally speaking, is to provide means for vehicular transportation of the various classes of travel and commercial haulage from one common center to another, either local, State, or National. They should be established over the most direct route possible with the least gradient. The most direct route may be defined as a road with alignment free from curves that have dangerously short sight-distances based on the importance of the road and the speed limit involved; and the least gradient should be such that it will not retard materially the reasonable speed of present-day vehicles.

The most direct route and least gradient, however, may be dispensed with advantageously, to some extent, in certain areas of heavy snowfall for reasons of economy in snow control. These factors may be ignored also in cases of scenic development, when locating forest and park roads or other lanes of traffic promoted solely for pleasant landscape effect, recreation, or educational travel.

For the winter of 1929-30 the States in the heavy snowfall area of the country reported that about 185 000 miles of main rural roads were kept clear of snow at an approximate cost of $8 250 000, and statistics show that more than 779 000 private automobiles entered, and more than 2 270 000 people visited the National parks during the 1930 season. Also, more than 28 760 000 people visited the various National forests by automobile during 1929.

The cost of clearing roads of snow in areas presenting certain topographical features can be greatly reduced by appropriate study of the proposed locations, and consideration should be given to the many patrons of the great out-of-door sections by creating alignment for the roads built, that will unfold, to the best advantage, the scenic wonders of the region visited.

Location to Prevent Snow Drifting.—Removal of deep snow is likely to create considerable expense in regions subject to heavy snowfall, and anything that can be accomplished to prevent drifting is of great value, not only from the viewpoint of economy, but also for the convenience of winter traffic. Snow drifting is often prevented or greatly reduced by proper road location. For this reason a number of highway departments give the snow problem careful consideration in planning their new or relocated roads, and, consequently, they experience fewer blockades on highways recently constructed than on the older ones. For drift prevention, proper location is often of primary importance and is influenced by efforts to keep the roadbed away from northern slopes and to eliminate various other conditions that tend to cause drifting.

The locating engineer for roads of this nature should be familiar not only with the territory in which he is engaged in connection with ordinary features, but he also should have a knowledge of snowfall and prevailing wind conditions. In some instances, the sacrifice of alignment and grade, to a reasonable extent, may be necessary to secure drift-free roads. In open areas the highway should follow ridges where possible or should be placed on slopes against the prevailing winter winds. Long shallow cuts should be avoided, but where this is impracticable the location and construction should be such that they will not cause drifting.

---

[3] Chf., Div. of Constr., U. S. Bureau of Public Roads, Washington, D. C.

In low flat country snow drifting has been lessened and often eliminated over a location where the new grade can be elevated 2 or 3 ft. above the surrounding land and with the construction of 1 on 4 slopes. In instances of this kind it would also be better to widen the cuts on either side to the boundary lines of the road. In mountainous or sparsely settled areas where the winter traffic is not sufficient to justify the expense of keeping the roads open during the entire winter, proper exposure is highly essential in order that the snow may melt and free the road for traffic as early in the spring as possible.

In States with heavy snowfall a winter reconnaissance should be made, or at least an inspection, during the snow season and prior to the completion of the plans in order that all snowfall, wind, and drifting conditions may be given careful consideration and data submitted for the use of the locating engineer in the final determination of his alignment. A number of these and other methods have been followed by various States and, in some instances, have caused the roads to remain fairly free of drifts through the winter months.

Tourist Parkways.—In the location of roads proposed to carry ordinary traffic, examination of the country through which it is to pass, with reference to the topographical features encountered, is necessary. Furthermore, consideration must be given to the nature and extent of traffic. On the other hand, for sight-seeing roads, other questions may arise regarding the proposed lines relative to greater comfort and convenience of travel and also regarding the pleasure and knowledge to be derived from use of the roads proposed. Often esthetic and historical features are present that suggest modifications of alignment that would not appear as good engineering practice in choosing locations for common roads.

In locating State and county roads, existing traveled ways are often utilized with necessary changes here and there to improve the alignment and grades; but for park and forest roads it is at times desirable to avoid all traveled thoroughfares, both in regard to following their alignment and in crossing them. Recreational roads are built principally for sight-seeing traffic and should be located with the convenience of the traveler in mind regardless of reasonable extra expense. Where intersections of existing roads are unavoidable, under or over-passes should be provided with ramps constructed where necessary for feeders to the parkway.

For ordinary roads the most suitable locations are those that reduce the yearly expense for transportation to the minimum, reduce the annual maintenance cost for the roadbed, and keep the original cost of construction as low as possible consistent with good engineering practice. These elementary problems are also applicable to tourist roads in greater or less extent, especially relative to the cost of construction. This first cost depends largely upon adjustment of the grade to the existing surface in order that minimum quantities may be involved in excavation and embankment and the location determined to avoid in the largest degree both major and minor drainage structures. For all types of roads great care must be exercised in selecting locations away from unstable foundations, such as swamps and soft ground, where construction is expensive and drainage difficult.

In locating tourist roads existing historical sites must be skirted to provide interest for the traveling public, but they must not be mutilated in any way by proximity or intersection. While wooded routes are generally desirable, large or rare trees must be spared and saved from the axe. In building parkways deep cuts are apt to cause scars in the natural landscape and, therefore, are not allowed. In places where embankments are essential, instead of balancing quantities in the usual manner, a reasonable cut is made with the remaining material provided by borrow from pits out of sight of the traveling public. When rock cuts and fills are unavoidable their new surfaces are re-covered with top soil for vegetation growth. Consequently, in locating roads of this character, the availability of suitable loam to mask the scars inflicted must be considered.

Forest and park roads usually traverse one or the other of these playgrounds, form a parkway between them, or act as lanes connecting historical points. Their routes vary in topography from flat and rolling country at tidewater levels to rough and rugged mountainous regions 10 000 ft. and more above sea level. Such proposed roads, however, usually extend through scenic country primarily for recreational purposes. From their nature they follow wooded and wild territory where location is difficult. At times, in fact, the degrees of roughness encountered are such that tunneling is considered more economical and desirable. For these classes of roads, as well as for most others, study of the proposed alignment should begin with the reconnaissance and should continue until the improvement is advertised or construction actually started.

For wooded sections or regions with irregular configuration, the benefit of aerial photography can not be over-estimated. This is especially true considering the fact that a reconnaissance should embrace a territory and should not merely follow a line. From these photographs a strip of land for location can be approximated between control points. In a general way the proposed location can be narrowed thus within reasonable limits. With this accomplished, topographical maps in one form or another are very useful. Drawn to a scale of 1 : 62 000 such maps are available for most sections of the country. While these are helpful in determining a line, maps covering the same territory greatly enlarged are procurable from the various Federal agencies at least at reasonable cost.

With maps covering the territory selected from the aerial photographs enlarged to about 400 ft. per in., the best and most economical alignment can be determined with surprising accuracy. Another method followed by the Government is to use maps for approximate alignment data compiled from so-called strip, topography surveys. The work is performed by the U. S. Geological Survey at a cost per square mile depending upon the scale desired. These strip, topography maps are prepared in about the same manner and carry data similar to those found on the ordinary U. S. Geological Survey maps, but the area is confined to the strip selected—probably ⅛ or ¼ mile wide—with the salient points located, if possible, with greater care.

With Geological Survey maps at hand, especially those enlarged, or others plotted from strip, photography surveys with accurate contours, a trained and competent location engineer will note the direction of flow of streams; the positions of thick or light wooded sections; the height and formation of the various slopes; the position of ridges that may be followed; and the location and elevation of the various passes through which it might be possible to carry the line; and from them he will adopt the most suitable alignment.

Scenic routes generally are proposed for country composed of numerous valleys enclosed by ridges of varying heights, all branching in like direction with the main watercourse of the territory. With a careful study of these principal features from the map used, the location may be determined with a fair degree of accuracy, leaving only the minor details to be settled for final location and for staking out the center line.

J. C. CARPENTER,[4] M. AM. SOC. C. E. (by letter).—The paper by Mr. Losh brings out the fact that highway location in the past has followed the path of least resistance. This is obvious to any one who studies the existing system. Until a broader policy is adopted by the officials in control of this important feature of engineering the same mistakes will be made as are now evident in past practice.

The first State highways were located adjacent to the larger centers of population and the location was not a matter of serious thought, the object being to improve the "old road". With the passage of the Federal Aid Road Act, in 1916, the States were required to map out a system of highways, on which Federal Aid could be expended. The systems thus laid out were not limited to mileage, and while an attempt was made to provide a system of transportation that would properly serve the State, the result was not at all satisfactory. The projects built on this system were more or less development roads and some of them are now being eliminated as parts of the system. Short sections, radiating in all directions from the centers of population, were the rule, rather than the exception, under the procedure in vogue at that period of the highway development program.

The "Federal Highway Act" of 1921 added some desirable features which were introduced with the intention of developing a system of properly located, connected routes. A new system of primary and secondary highways was adopted, and the mileage was limited to 7% of the total public highway mileage of the State. This system was approved by routes with official control points tied in to a description. The procedure in approving projects requires that the routing between official control points be determined and approved before any part of the route is improved. This was undoubtedly a step forward and has served to locate the improvements on a system of main highways, "interstate in character". There have been numerous instances, however, of poor locations due to the necessity of tying in the old work that was completed under the first system. The plan also results in "center-to-center" locations which lead the traffic to the congested parts of the larger centers of population.

---

[4] Fort Worth, Tex.

Under the foregoing procedure the highways of the United States have been developed in such a way that it is possible to travel to all sections on some type of improved road. Traffic trends are becoming stabilized. It is an opportune time to "take stock" and do some real planning that will serve to provide some permanent locations. With the present systems as a basis, a revised system of highways can be laid out in such a manner as better to serve local and through traffic for the entire country. It is important that such a system be developed at an early date. Based on present and probable traffic trends, on the development of the industrial and agricultural sections of the country, the growth of cities, and the controlling topographic features, a careful study should be made in each State and a major system laid out and filed for use on new work. It will be necessary carefully to consider entirely new locations, extending across the State, in some instances. The principles discussed in the paper should be applied in developing this ideal system, as, for instance, the development of locations through cities, locations at suitable distances from railroads, etc. While it will be impossible to change from the present system to such an ideal system at once, the data should be compiled and the system developed and placed on file with the expectation of utilizing it as funds become available. With such a plan in reserve, a State Highway Department is prepared to justify a change from the present routing and any short section constructed on the major plan eventually will become a part of the larger plan. Under the present policy, large outlays of money are required to reconstruct old projects on narrow rights of way with undesirable alignment, and traffic congestion is increased rather than diminished. With the same funds a new highway can often be built on good alignment, with adequate width of right of way for future development and with much better planned surfacing, leaving the old road to serve local traffic with a much smaller annual maintenance cost for the two routes. The new location develops and serves an additional local community and, in addition, provides ample room, at low ground rental, for commercial activities necessary for highway traffic, such as garages and hotels, without interfering with established stores and other services, essential to the community, on the old road.

In determining the location through small centers it is sometimes advisable to route short sections of the highway on an undesirable location, as a temporary measure. The location should be so developed outside the village that, when traffic increases to a point such that the local congestion becomes unbearable, the road can be projected past the town on a direct location, leaving a detour through the village. All highway departments are more or less dependent on local sentiment for their popularity. They cannot carry out a large program, even where purely State funds are available, unless they have the active support of the people. Opposition of a small community may be serious. In the early development of the highway system for any locality, due to the small amount of through traffic, there is no very serious operation expense involved in routing the highway along a longer line to carry it through the center of trade for the unit under consideration. If the line is on a through highway the foreign traffic will increase in a short time, to such an extent that the same interests that were insistent upon the "Main Street" location will be clamoring to have this outside traffic taken off their city streets to save maintenance expense and relieve the traffic congestion. Local people will then "discover" the short direct line outside the city and, as has sometimes happened, they may provide the funds to build the by-pass. If the traffic does not develop in a measure that will induce this action, the road is not of enough importance to be classed as a through highway. Local traffic will still be the portion to be accommodated and the line should follow the main street.

H. J. SPELMAN,[5] M. AM. SOC. C. E. (by letter).—Unquestionably, too many of the roads built during the life of the present generation have become obsolete too early; long before the expiration of the "reasonable life" anticipated by the engineer who located and designed them. In the future, highway engineers must locate more boldly than ever, lest the next generation find locations of the present day as obsolete as those built in 1915 or 1920 have become in 1931.

In 1919, and prior to that time, the average motor vehicle traveled at a speed of 20 to 25 miles per hour. The average motor vehicle now travels at a speed of from 40 to 50 miles per hour. Who knows but that the average speed of a generation from now, on many roads, may not be from 60 to 75 miles per hour, with 100 and 125-mile speeds at least as common as the 65 and 70-mile speeds at present? It is the increases in speeds that have caused the older road locations to become obsolete, because these higher speeds require gentler curvatures, longer sight distances, and greater widths of paving, roadway, and right of way.

In making present-day locations, highway engineers should not only locate with a view to traffic conditions as they are to-day, but should endeavor to anticipate those of the future. The future will undoubtedly bring higher speeds which will create a need for still wider sections and gentler curvatures.

As Mr. Losh has stated, property values increase very rapidly adjacent to a road after it is improved, and, hence, re-location and widening of a road once built, are particularly expensive. This again stresses the need for location and width of right of way adequate for the future. It is very much a question if any highway department to-day is obtaining rights of way of adequate width for the future on very many of the roads they are building.

In many cases a road has been located under low standards of alignment, and with narrow section and right of way, on the theory that such a road was a secondary or tertiary road that would never carry much traffic. With the improvement of the road, traffic flowed to it, and it really became a primary road from a traffic standpoint. Consequently, it soon become inadequate and required reconstruction. In order to avoid such occurrences the only remedy would appear to be a study of the traffic needs of the entire community or district, and a comprehensive road plan for such community or district, in the same way that city planning is now being done in many of the larger urban centers.

---

[5] Washington, D. C.

This paper seems particularly valuable in that it is an excellent summary of just what the highway engineer-executive must consider in making highway locations. It is valuable, too, in pointing out the mistakes of location in the past; and it is to be hoped that a study of these mistakes will enable the avoidance of similar ones in future locations.

H. S. KERR,[6] M. AM. SOC. C. E. (by letter).—The major problems of highway location as presented in Mr. Losh's paper have been particularly well handled. The writer is generally in accord with the views therein set forth and can consistently approve the conclusions reached.

The prime consideration in highway location, with reference to topographic conditions, is, of course, to find the man who is a competent locator. In all the State highway departments the country over there are an extremely limited number of men gifted with that "sixth sense" which is the peculiar distinction of the high-class locator, and when such men are found, their worth is beyond price. In the old days of active railroad expansion these "sixth sense" locators were always in great demand, even if in some instances they might be decidedly below the average in handling engineering work aside from locating. The policy of the State of Utah is to confine difficult locations to the few men in the State Highway organization who have this qualification, and to apply railway methods. No better method has been evolved than an adherence to the long established railway practice of projecting the location in difficult sections, based on a carefully determined preliminary line, established after thorough consideration has been given to all alternate routes possible. Aerial photography is a help in finding the satisfactory location, and it is to be regretted that this method was not available several years before the problems (at any rate, as affecting interstate highways in Utah) were practically solved. Even though aerial photography came into vogue after the difficult locations in Utah were made, the final results are eminently satisfactory. The writer knows of no revisions that merit consideration in the case of any highway locations in this State during the eight years, 1924 to 1931, inclusive.

While agreeing that short sections of road with grades as steep as 8% are, in some instances, allowable, there are only a few such cases in Utah, although it is a mountainous State, where such gradient applies. In these cases a future reduction to 6%, in most cases without re-alignment, is reasonably practicable when traffic increase justifies the change.

In Utah the counties and the Road Commission have the power to protect the right of way from encroachments and prohibit advertising signs thereon, and there is necessity for constantly combatting the tendency, noted in the paper, of infringing upon the public right in this respect. A number of earlier projects, including some introduced subsequent to the enactment of the Federal Aid Act, have a right-of-way width of 66 ft. which it is proposed to increase, where feasible, to 100 ft., the general standard. Even wider rights of way are now being considered for roads across the public land areas.

---

[6] Chf. Engr., State Road Comm., Salt Lake City, Utah.

With reference to the conflicting interests between local and through traffic, the conditions cited are those that have formerly obtained in Utah, and, in many instances, it would not have been practicable to have attempted to work out an ideal location, particularly between 1915 and 1925, during which period local requirements were largely controlling factors in location. However, now that the towns and cities have generally been taken care of, to the maximum extent possible, between control points, consideration may properly be given to the best location for accommodating through traffic, utilizing to this end, portions of existing secondary highways, in by-passing congested areas and in reducing mileage. This would not have been practicable between 1915 and 1925 because the need of good roads was then so urgent in connecting centers of population. There are only a few cases in Utah, however, where such revisions are necessary on this account, or because construction standards are so much higher now (1931); this latter consideration is due to the fact that the first requirements in Utah were for roads in the valley sections where construction costs were relatively light and grading and structure costs per mile were not such as to cause public opinion to interfere with suitable location. In later years highway improvements have been extended from the more populous districts, to and through the mountain and desert sections, to the State borders. In so doing it has been possible to finance projects which average, in some instances, far in excess of $30 000 per mile, an accomplishment which would not have been feasible some years earlier. Now, however, it can be readily effected on account of the more recent trend of public opinion with reference to highway costs. The result has been that location involving heavy work during several years past has been entirely satisfactory.

With reference to location the following factors should be given due consideration, namely, annual interest, maintenance, and operation costs. Only the first item can be computed accurately, the remaining two, at best, can be but closely approximated, the result depending upon the ability and judgment of the locator in properly considering all items appertaining to each and every project.

Railroad grade crossings have been and are being eliminated by the Utah State Highway Department as rapidly as possible, the majority by relocation rather than by structures. In regard to co-operative railroad costs, the practice in Utah has been, unless conditions justified a variation, to divide the costs of structures on a "50-50" basis, and to arrange for the most satisfactory highway alignment, resulting generally in skew crossings. The most recent grade separation divided the costs equally for the overhead structure and the approach fills. Elimination of grade crossings by revision, in the case of low-cost construction, is handled on a "50-50" basis also, but where heavy work is involved, a contribution on the part of the railroad benefited, is arranged on the basis of $9 000 per double-track, main-line crossing and $6 000 for a single-track crossing. The construction or the vacating of railroad crossings is, in Utah, subject to the approval of the Public Utilities Commission. However, with respect to grade crossings on State highways, the

Commission requests that the Highway Department present, in advance of hearing, the details and stipulations tentatively agreed upon by that Department and the utility concerned.

Improvements are under way in the State on U. S. Highway No. 50. From a connection with U. S. Highway No. 91 this route extends across the mountains and the desert a distance of 223 miles, on the original route, to the Colorado line. The problems of location are, in the main, purely of an engineering character; they are entirely so from Green River eastward to the State line, a distance of 85 miles. The original route included twenty-eight railroad grade crossings, numerous right-angle turns, steep gradients, and sharp curves. Elevations varied from 4 080 to 7 450 ft. In the re-location survey of this highway it was possible to obtain results eminently satisfactory from an engineering standpoint, there being only a few restrictions applying that prevented an ideal location. The re-alignment effects a saving on the total distance of 14 miles. The major portion is now (1931) completed or under construction. All double-track crossings will have been eliminated by the programmed construction. A few single-track and relatively unimportant crossings will be temporarily continued although the plans call for the ultimate elimination of these crossings also. Little value is attached to the old highway between Price and Colorado, 155 miles, which lacked even numerous necessary bridges. The new 223-mile line, when entirely completed, will have less than one-half the total degrees of curvature of the trans-continental railway which it approximately parallels. Minimum surfacing requirements call for 18-ft. gravel surfacing of 6-in. depth, in two courses, 100% of which must pass a 1-in. screen, round opening. From this, types range to 12 miles of completed concrete pavement.

The total cost, including 1931 construction, is estimated at $3 047 548, with an estimate of $838 000 additional, to complete, or an average cost of $18 800 per mile. Considerably less than this average develops on the desert section of Eastern Utah, while on the mountain section, costs, in 1930, on some projects ran as high as $60 000 per mile for grading and structures only. Of the gravel mileage about one-half will be oil-treated within a short time and some miscellaneous paving will be done, which costs are not included in the foregoing figures.

H. W. GIFFIN,[7] ASSOC. M. AM. SOC. C. E. (by letter).—Highway location is not altogether an engineering problem. The construction of highways is dependent on public support and the locating engineer or highway planner must constantly keep in mind that his handiwork must be approved by the present generation, irrespective of how future generations may regard it. Perhaps in the future the highways of to-day will be judged as the highways of a former day are now regarded. The principal reason for highway construction to-day is the love of the human race for swift, smooth motion without effort. Probably no highway bond issue was ever floated because of a desire to increase the economy of transportation. The policies of the highway planner in determining location are the result of his estimate of public approval and it is useless to try to get too far ahead of that. This means some waste as the years go by and locations become obsolete with changing conditions and the greater demand for locations approaching more closely to the ideal.

---

[7] Field Engr., State Highway Dept., Trenton, N. J.

The author states that "curves should be placed where they may be seen readily by the approaching driver". It would be well to go further and say that every condition of the highway, whether it is a change of direction, an intersection, a railroad crossing, or anything that requires the driver's attention, should be placed, or otherwise brought to his notice, so as to give him time to take appropriate action. It is suggested that some advance designation, such as a number denoting the sharpness of the curve be used on signs which now denote curves and their direction. Although some motorists would not know what a stated degree of curve meant, they would soon learn to associate the numbers with the relative sharpness of the curves. To-day, the same sign that frequently is used to warn the motorist of a sharp curve is also used for flat ones.

Because of the adoption of some degree of curve as a maximum, locating surveyors do not always feel that every effort should be made to secure flatter curves. Long flat curves mean additional work for the survey party, but such curves should be as flat as 30′, cost permitting. Where necessary to have a curve near a summit it should be located if possible so as to extend for some distance on both sides. Where vertical curves are coincident with horizontal curves on summits, pleasing alignment is attained. It is not easy to define the conditions which produce an alignment that displeases the eye, but it is suggested that the location that contains, within one view, three tangents and two curves, or two complete changes of direction, whether horizontal or vertical, is not pleasing.

The sight distance desired along the highway is governed by the prevailing speed of the traffic at the particular location. Highways laid out for fast traffic (that is, those which are wide and reasonably straight) in the country should have sight distances of 800 to 1 000 ft. if obtainable at reasonable cost. City conditions do not require more than 300 ft. Where difficulty is experienced in obtaining satisfactory sight distances the roadway, under some circumstances, may be separated into one-way roads, thus permitting the required sight distance to be cut in half.

Because of the relative high cost per unit of length in comparison with the remainder of the highway, bridges have exerted a great influence on location. Despite this high cost, the location engineer should remember that the ordinary bridge is only a part of a highway, and is often unnoticed by the motorist unless the alignment impresses it upon his mind. An otherwise satisfactory alignment is sometimes spoiled because the requirement of securing a less costly bridge is exaggerated.

The segregation of through and local traffic is desirable and advantageous to both classes, but it is seldom reasonable or economical until each reaches sufficient volume to justify separate roadways. The construction of the by-pass is the common method of accomplishing this purpose. This may be termed second-stage planning and has not been as readily understood and approved by the public as the first stage, which may be defined as the extension of the main street of one town to that of another.

Near metropolitan centers the subject of intersections is an important, and often neglected, phase of highway location. The capacity of a highway is limited by its intersections and, obviously, the combined capacity of two intersecting highways is limited to that of the larger unless some special provision is made to increase the intersection capacity. Where new highways are planned, that cross a network of other important highways, it is sometimes necessary for the locating engineer to study first the available locations for the type of intersection suitable to the requirements.

It is not necessary to go far back in one's memory to prevailing speeds of 25 to 30 miles per hour. Prevailing speeds to-day (1931) are at least 20 miles per hour faster. Must the highway planner anticipate speeds of 70 miles per hour as the ordinary condition 10 or 15 years hence?

While it seems wise in laying out new highways to obtain sufficient right of way for widening within a few years, too much planning for the future should not be attempted. How many could have appreciated to-day's highway problems ten or fifteen years ago? Any attempt, other than widening, to plan for to-day's highways fifteen years ago would probably have been unappreciated at that time and would probably prove unsatisfactory now.

Mr. Losh's excellent paper has focused attention on some important problems of highway location.

A. R. Losh,[8] Assoc. M. Am. Soc. C. E. (by letter).—The writer appreciates the favorable comments his paper has received from members of the Society who have had extensive experience in National and State highway programs. The information and suggestions contributed have added materially to the discussion.

The importance of conditions which will reduce or eliminate the difficulties of snow drifting was stressed by Mr. Bishop. This is worthy of careful attention not only from the viewpoint of reducing the cost of snow removal, but, as Mr. Bishop states, to keep the roads open to the public. The cost of snow removal during the winter of 1929-30 as given by Mr. Bishop was $8 250 000 for 185 000 miles of road, or an average of $44.50 per mile. Considering the severe conditions of that season this is not high. The cost of snow removal on Oklahoma highways for the same season was an average of $30.00 per mile. The loss to the State in gasoline taxes alone was more than three times the cost of snow removal, due to the fact that extreme winds created drifts along the roads three times after they had been broken open. The real loss to the traveling public is, of course, unknown. In the plains country fine dry snow carried by a winter gale will drift into every cut and depression. Until the snow has settled and partly packed, it is difficult to keep an east and west road open. Freedom from snow hazard is an important location consideration in places subject to heavy snowfall.

---

[8] Mgr., Asphalt and Road Oil Div., Anderson-Prichard Corp., Oklahoma City, Okla.

Referring to tourist roads, parkways, scenic highways, and places of historic or recreational interest, Mr. Bishop points out the necessity of departing from the engineering phases of grades and alignment in location studies and giving due weight to those features which determine the general nature of the road. Conditions such as these are unusual in highway location, but their importance has been properly stressed by Mr. Bishop.

The advancement of highway location standards resulting from the Federal Aid acts is well brought out by Mr. Carpenter. He also makes the point that public sentiment too often must be given consideration on detail location. Of particular value is his suggestion that a major location plan be worked out for future improvement, and that this be utilized on individual sections as the opportunity arises. His solution of the "main street" location for the small city is a practical one frequently used to advantage.

The improvement of the motor vehicle and the higher permissible speeds of receent years have brought about the necessity of better location, as stated by Mr. Spelman. Unless, as he suggests, highway engineers locate more boldly and with a freer hand than in the past, 1931 locations will be obsolete a few years hence.

Mr. Kerr's discussion referring to the work of the Utah State Highway Department brings out a number of general conditions to be met in highway location. First is the necessity of solving the political and economic problems as was done in the earlier locations of that State when the towns and cities were provided with service along somewhat local lines. Having met this local pressing need the Department could work with a freer hand in developing the transcontinental routes. The trend of public opinion was for the cross State routes once the immediate needs of the populous sections had been met. This later work permitted the exercise of engineering skill to the fullest extent. Fortunately, the more expensive construction came at a time when the location was possible on an engineering basis.

Public support is a necessity in any highway program. This statement by Mr. Giffin is borne out in Mr. Carpenter's discussion, and also by Mr. Kerr. While it is highly desirable to locate for the future, present problems must be met. The public can be led to a certain extent, but the leader must not get too far ahead of the procession. The writer agrees fully with Mr. Giffin in that every condition on the highway which requires special action on the part of the operator should be brought to his attention in ample time for him to control the vehicle; and, as he further states, speed is the important factor to consider. A curve of 50-ft. radius was no hazard for vehicles moving at 8 miles per hour; but a 500-ft. radius is a serious condition for speeds greater than 35 miles per hour. In answer to Mr. Giffin's query, the writer feels that anticipated speeds of 70 miles per hour are not improbable ten years hence. Traffic is moving at nearly this speed in the open country now (1932), and at too great a hazard from intersecting highways at grade, narrow structures, embankments of insufficient width, and other conditions which the engineer must eliminate in the future.

STRESSES IN GRAVITY DAMS BY PRINCIPLE OF LEAST WORK[1]

By B. F. Jakobsen,[2] Esq.

With Discussion by Messrs. William Cain, William Gore, L. J. Mensch, Lars R. Jorgensen, C. A. P. Turner, Donald P. Barnes, Anthony Hoadley, Fred W. Ely, M. H. Gerry, Jr., Fredrik Vogt, Eugene Kalman, Fernand Campus, A. Floris, Robert E. Glover, P. Wilhelm Werner, and B. F. Jakobsen.

Synopsis

In order to determine the stresses in gravity dams, it has been customary to assume a linear stress distribution on horizontal planes. An examination of English tests on model dams shows a non-linear stress distribution. A theoretical investigation, in which the Principle of Least Work was substituted for the usual assumption of a linear stress distribution, leads to a stress curve similar to that found in the English tests.

The bending stresses, that is, the vertical normal stresses due to the water load, found by the usual method, are equal at the up-stream and down-stream faces, while the proposed theory gives a considerably higher bending stress at the up-stream face and a correspondingly lower stress at the down-stream face.

The maximum stress is found to be less than by the usual method, but this is of no particular advantage, since the compressive stress in the up-stream face with reservoir full should exceed a definite minimum, and this will generally be the determining factor in the design.

The writer believes that the stress distribution based on the Principle of Least Work will more nearly approach the true load stresses than the results obtained by the usual method.

I.—Introduction

The section of the straight gravity dam to be considered is triangular with a vertical up-stream face. It is assumed, that the concrete is homogeneous and isotropic in every respect, that is, that each unit of volume weighs exactly as much as any other; that its temperature, moisture content, and general conditions do not vary from point to point; and that the modulus of elasticity is the same for compression as for tension and is the same at all points of the dam. It is also assumed that there is no uplift and no residual stress. The stresses to be considered are those due to the load imposed by the weight of the structure itself and by the horizontal thrust of the water acting on the up-stream face. It is further assumed, that the deformations are elastic and infinitesimal, so that the shape of the structure is not altered when the load is applied. These are the usual assumptions made when dealing with engineering structures.

---

[1] Published in September, 1930, *Proceedings*.

[2] Cons. Engr., Los Angeles, Calif.

Evidently none of these assumptions is rigorously true. Some of them, as for example, those regarding uplift and residual stress, may be so far wrong that for purposes of engineering design they must be separately considered in order to obtain the actual stresses. Föppl has shown,[3] that the load stresses are independent of the residual stresses, when the usual assumptions are made. Regarding plastic deformations (time effect), the tests made by R. E. Davis, M. Am. Soc. C. E., indicate[4] that these increase linearly with the stress and therefore are not likely to influence the stress distribution. They may be taken into account by assuming a lower modulus of elasticity.

II.—Usual Theory—Stresses

Referring to Fig. 1, let:

n_y and n_x = vertical and horizontal normal stresses at any point;
t = shear or tangential stress in the same point;
w = weight of concrete, in pounds per cubic foot;
g = weight of 1 cu. ft. of water, in pounds;
M = moment, in foot-pounds, about a point on the Y-axis, y ft. below the crest;
W = weight, in pounds, of a 1-ft. thick slice of dam, y ft. high;
b = base width, in feet, y ft. below the crest;
ϕ = angle at crest between up-stream and down-stream faces; and,
$k = \tan \phi = \frac{b}{y}$.

Then,

$$W = 0.5\, w\, b\, y = 0.5\, w\, k\, y^2 \qquad (1)$$

and,

$$M = 0.5\, k\, y^2 \frac{b}{3} + \frac{g}{6} y^3 = (g + w\, k^2) \frac{y^3}{6} \qquad (2)$$

Referring to Fig. 2, take tension as positive and the sign for shear such that on the plane on which the positive direction of a normal stress is in the positive direction of the axis to which it is parallel, the positive direction of shear will also be in the positive direction of the axis to which it is parallel; thus, the horizontal shear in a gravity dam will have the negative sign.

It is assumed that there are no stresses acting at right angles to the section, that is, normal to the plane of the page in Fig. 1. The only stresses which will be considered are n_y, n_x, and t. This implies, that the vertical limiting planes of the section are free to deform in accordance with these stresses. (See Appendix III.)

---

[3] "Drang und Zwang," Vol. 2, Article 91 (1920 Edition).

[4] *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, Table 28, p. 213. When plotted, these tests give a straight line between deformation and stress.

The statical conditions require that,

$$\int_0^b n_y \, d\, x = -\, W = -\, 0.5\, w\, k\, y^2 \dots\dots\dots\dots\dots\dots (3)$$

$$\int_0^b n_y \, x\, d\, x = -\, M = -\, (g + w\, k^2)\, \frac{y^3}{6} \dots\dots\dots\dots\dots (4)$$

and, also, that,

$$\int_0^b t\, d\, x = -\, S = -\, 0.5\, g\, y^2 \dots\dots\dots\dots\dots\dots (5)$$

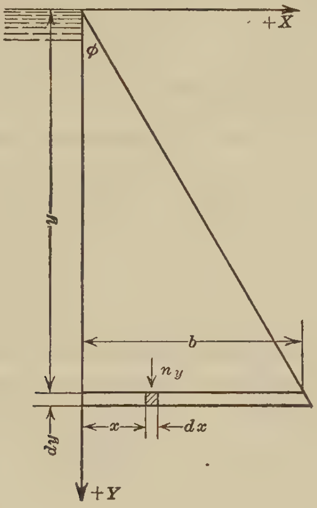

Fig. 1

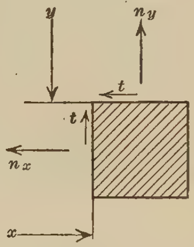

Fig. 2

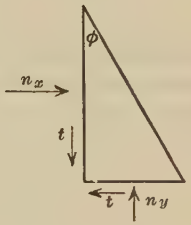

Fig. 3

Equation (5) is not an independent condition, since for transverse loading, $S = \frac{d\, M}{d\, y}$, which checks, inasmuch as the influence of w on the bending moment must be excluded. The bending produced by vertical forces gives rise to horizontal shear stresses, which, however, must total zero across the entire section. The equilibrium equations for any small particle, $d\, y$, $d\, x$, $d\, z$, in a point (y, x), are:

$$\frac{d\, n_y}{d\, y} + \frac{d\, t}{d\, x} + w = 0 \dots\dots\dots\dots\dots\dots (6)$$

$$\frac{d\, n_x}{d\, x} + \frac{d\, t}{d\, y} = 0 \dots\dots\dots\dots\dots\dots (7)$$

in which, $\frac{d\, n_y}{d\, y}$, etc., are the partial differential coefficients, usually written $\frac{\partial\, n_y}{\partial\, y}$. The boundary conditions are, at the up-stream face, $t = 0$ and $n_x = -\, g\, y$. At the down-stream face (Fig. 3), it must be,

$$t = n_y \tan \phi \dots\dots\dots\dots\dots\dots (8)$$

and,

so that,

$$\left.\begin{aligned} n_x &= t \tan \phi = n_y \tan^2 \phi \\ n_y\, n_x &= t^2 \end{aligned}\right\} \qquad (9)$$

Equations (8) and (9) follow from the fact that the forces acting on the small triangle must be in equilibrium. The weight of the triangle is not involved, since this is infinitely small compared to the forces.

These conditions, that is, Equations (3) to (7), inclusive, and the stress relations at the up-stream and down-stream faces, do not suffice to determine the stress distribution. An additional assumption must be made; and this is, in the classical theory, that the vertical stress is linear across a horizontal joint, that is,

$$n_y = A\, y + B\, x \qquad (10)$$

in which, A and B are constants, which may be determined from Equations (3) and (4). There results,

$$A = -w + \frac{g}{k^2} \qquad (11)$$

and,

$$B = \frac{w}{k} - 2\,\frac{g}{k^3} \qquad (12)$$

Introducing these values for the constants into Equation (10) gives n_y; and the two remaining stresses are found from Equations (6) and (7). There results, in units of pounds per square foot,

$$\left.\begin{aligned} n_y &= \left(-w + \frac{g}{k^2}\right) y + \left(\frac{w}{k} - 2\,\frac{g}{k^3}\right) x \\ t &= -\frac{g}{k^2}\, x \text{ and } n_x = -g\, y \end{aligned}\right\} \qquad (13)$$

These are the usual linear equations found when the classical assumption, that is, Equation (10), is made. In textbooks the vertical stress is generally given only for the up-stream and down-stream faces, that is, for $x = 0$ and $x = b$, these being the two most important values.[5] For the purpose in hand, the stresses are expressed as functions of the co-ordinates, y and x.

III.—Usual Theory—Deformations

The usual assumption, that n_y is a linear function of x, is equivalent to stating that horizontal planes remain plane, provided the modulus of elasticity is constant and that the shear deformation is neglected. Fredrik Vogt, Assoc. M. Am. Soc. C. E., has shown,[6] that the bending moment produces an **S**-shaped curving of the foundation; therefore, the classical assumption is incorrect, at least for sections near the foundation. The tests made at the Stevenson Creek Test Dam show a remarkably close agreement between the actual displacements of the foundation and those computed from Dr. Vogt's formulas.[7]

---

[5] See "Notes on Arched Gravity Dams," *Transactions*, Am. Soc. C. E., Vol. 92 (1928), Equation (14), p. 771. Note that for a straight dam, $R_u = \infty$.

[7] *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 127, and Fig. 82.

That the usual assumption was probably incorrect near the foundation has been accepted for many years by authorities on dam design.[8]

IV.—Stress Distribution by the Principle of Least Work

This principle was first applied to engineering structures by Castigliano in his work[9] published in 1879. It was introduced into American technical literature by the late William Cain, M. Am. Soc. C. E., in a paper entitled "Determination of the Stresses in Elastic Systems by the Method of Least Work"[10] and it was applied by him to obtain a correct and elegant solution of the problem of stresses in arches of dams in his well-known paper, "The Circular Arch under Normal Loads."[11]

The writer has shown[12] that the arch stresses found from the tests on the Stevenson Creek Dam agree remarkably well with the Cain formulas, when the deformations and displacements of the abutments are included in the calculations in the manner suggested by Dr. Vogt. (See Article III.) These tests are, therefore, an experimental verification of the Principle of Least Work as applied to the stresses in an arch dam.

In lieu of the classical assumption, that n_y is a linear function of x, assume that the stress distribution is such as will make the internal work the least possible.[13] It is clear that this assumption is less restrictive than the classical assumption and includes the latter as a specific case. If, for example, the shear stress, t, and the horizontal normal stress, n_x, are assumed as negligible, the principle of least work requires that the stress, n_y, must be linear.

The internal work is,[14]

$$L = \frac{1}{2\,G} \int\int\int \left[\frac{n_y^{\,2} + n_x^{\,2}}{2} - \frac{(n_y + n_x)^2}{2\,(m + 1)} + t^2\right] dy\,dx\,dz \ldots\ldots (14)$$

in which, G is the shear modulus and $\frac{1}{m}$ is Poisson's ratio.

The shear modulus is defined by,

$$G = \frac{m\,E}{2\,(m + 1)}$$

in which, E is Young's modulus of elasticity. Equation (14) implies that the modulus of elasticity is constant and the same for tension as for compression, which is believed to be true for ordinary working stresses.[15]

Instead of the simple Equation (10) for n_y, the condition that Equation (14) must be a minimum is now introduced. This is a problem in variational calculus, but instead of treating it as such, which would be very complicated, a method of approximation may be resorted to, by assuming n_y as a function of y and x. This method, due to Ritz,[16] transforms a problem in variational calculus into a simple problem of differentiation. The procedure is as follows: The stress, n_y, is assumed with more constants than are needed to satisfy Equations (3) and (4); the equilibrium equations, (6) and (7), serve to determine n_x and t as functions of y and x and of the constants in the equation for n_y. The condition that Equation (14) must be a minimum then serves to determine the free constants in the equation for n_y. Assume,

---

[8] Professor Cain calls attention to this in the opening sentence of his paper, "Stresses in Masonry Dams," *Transactions*, Am. Soc. C. E., Vol. LXIV (1909), p. 208; and Professor Résal in his paper, "Formes et Dimensions des grands barrages en maçonnerie" in *Annales* des Ponts et Chaussées, II, 1919, deals at some length with this subject.

$$n_y = A\,y + B\,x + C\,\frac{x^2}{y} + F\,\frac{x^3}{y^2} \quad \ldots\ldots\ldots\ldots\ldots (15)$$

in which, A, B, C, and F are four constants, any two of which, for example, A and B, may be expressed as functions of C and F by means of Equations (3) and (4), by carrying out the simple integrations indicated. There results,

$$A = -\,w + \frac{g}{k^2} + C\,\frac{k^2}{6} + F\,\frac{k^3}{5} \quad \ldots\ldots\ldots\ldots\ldots (16)$$

and,

$$B = \frac{w}{k} - 2\,\frac{g}{k^3} - C\,k - 0.9\,F\,k^2 \quad \ldots\ldots\ldots\ldots\ldots (17)$$

The two independent constants, C and F, must now be determined so that the internal work is a minimum, or,

$$\frac{d\,L}{d\,C} = 0; \text{ and } \frac{d\,L}{d\,F} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)^{17}$$

It will simplify the calculations to differentiate under the integral sign, instead of first integrating and then differentiating. There results,

$$\frac{1}{2\,G}\int_0^1 d\,z \int_0^H d\,y \int_0^b d\,x \left[\frac{m}{m+1}\left(n_y\,\frac{d\,n_y}{d\,C} + n_x\,\frac{d\,n_x}{d\,C}\right) - \frac{1}{m+1}\left(n_y\,\frac{d\,n_x}{d\,C} + n_x\,\frac{d\,n_y}{d\,C}\right) + 2\,t\,\frac{d\,t}{d\,C}\right] = 0 \quad \ldots\ldots\ldots (19)$$

in which, H is the total height of the section considered.

Likewise,

$$\frac{1}{2\,G}\int_0^1 d\,z \int_0^H d\,y \int_0^b d\,x \left[\frac{m}{m+1}\left(n_y\,\frac{d\,n_y}{d\,F} + n_x\,\frac{d\,n_x}{d\,F}\right) - \frac{1}{m+1}\left(n_y\,\frac{d\,n_x}{d\,F} + n_x\,\frac{d\,n_y}{d\,F}\right) + 2\,t\,\frac{d\,t}{d\,F}\right] = 0 \quad \ldots\ldots\ldots (20)$$

It is now necessary to express t and n_x as functions of the co-ordinates, y and x, and of the constants, A, B, C, and F. Differentiating Equation (15) toward y and introducing the result into Equation (6),

$$A - C\,\frac{x^2}{y^2} - 2\,F\,\frac{x^3}{y^3} + \frac{d\,t}{d\,x} + w = 0$$

---

[16] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 325. The writer used this method to determine the stresses in the buttress of a multiple-arch dam.

[17] $\frac{d\,L}{d\,C}$ and $\frac{d\,L}{d\,F}$ indicate the partial differential coefficients usually written $\frac{\delta\,L}{\delta\,C}$ and $\frac{\delta\,L}{\delta\,F}$. In this paper, d has been used for δ as there is no danger of misunderstanding.

Integrating and bearing in mind that, for $x = 0$ (that is, at the up-stream face), $t = 0$,

$$t = -A\,x + \frac{C}{3}\,\frac{x^3}{y^2} + \frac{F}{2}\,\frac{x^4}{y^3} - w\,x \ldots\ldots\ldots\ldots (21)$$

Differentiating Equation (21) toward y and introducing this into Equation (7),

$$\frac{d\,n_x}{d\,x} = -\left(-\frac{2}{3}\,C\,\frac{x^3}{y^3} - \frac{3}{2}\,F\,\frac{x^4}{y^4}\right)$$

Integrating toward x, remembering that the constant of integration, $f(y)$, is a function of y, but not of x, and that for $x = 0$, $n_x = -g\,y$, or $f(y) = -g\,y$, there results,

$$n_x = \frac{C}{6}\,\frac{x^4}{y^3} + 0.3\,F\,\frac{x^5}{y^4} - g\,y \ldots\ldots\ldots\ldots (22)$$

The equations for t and n_x must also satisfy Equations (8) and (9) at the down-stream face; that is, for $x = b = k\,y$, $t = k\,n_y$, and $n_x = k\,t$.

By introducing the values of n_y, t, and n_x, from Equations (15), (21), and (22), into Equations (8) and (9), and eliminating the two constants, A and B, by means of Equations (16) and (17), the desired check is obtained. Equations (15), (21), and (22) for the stresses, n_y, t, and n_x, therefore, satisfy the statical requirements (Equations (3) and (4)), the equilibrium equations, (6) and (7), the boundary conditions at the up-stream face (that is, $t = 0$ and $n_x = -g\,y$), and also the boundary conditions at the down-stream face (Equations (8) and (9)). This means that Equations (15), (21), and (22) represent a possible stress distribution, no matter what arbitrary finite values, including zero, are assigned to the two constants, C and F.

The differentials required for Equations (19) and (20) may now be formed, bearing in mind that the constants, A and B, are functions of C and F as given by Equations (16) and (17), so that,

$$\frac{d\,A}{d\,C} = \frac{k^2}{6};\ \frac{d\,B}{d\,C} = -k;\ \frac{d\,A}{d\,F} = \frac{k^3}{5};\ \frac{d\,B}{d\,F} = -0.9\,k^2$$

Then,

$$\frac{d\,n_y}{d\,C} = \frac{k^2}{6}\,y - k\,x + \frac{x^2}{y}$$

$$\frac{d\,n_x}{d\,C} = \frac{x^4}{6\,y^3}$$

$$\frac{d\,t}{d\,C} = -k^2\,\frac{x}{6} + \frac{x^3}{3\,y^2} \ldots\ldots\ldots\ldots (23)$$

Likewise,

$$\frac{d\,n_y}{d\,F} = \frac{k^3}{5}\,y - 0.9\,k^2\,x + \frac{x^3}{y^2}$$

$$\frac{d\,n_x}{d\,F} = 0.3\,\frac{x^5}{y^4}$$

$$\frac{d\,t}{d\,F} = -\frac{k^3}{5}\,x + 0.5\,\frac{x^4}{y^3} \ldots\ldots\ldots\ldots (24)$$

Substituting these values in Equations (19) and (20), integrating from $x = 0$ to $x = b = k\,y$, and arranging, the final Equations (25) and (26) are obtained. The calculations are somewhat extensive, but involve nothing but multiplications and integrations of simple algebraic expressions. Equation (25) has been divided by k^5 and Equation (26) by k^6. The final results are,

$$\begin{aligned}\frac{1}{2\,G}\int_0^1 d\,z\int_0^H y^3\,d\,y\,\Bigg[&\frac{m}{m+1}\left(\frac{C}{180}+\frac{F}{120}\,k+\frac{C}{324}\,k^4\right.\\&\left.+\frac{F}{200}\,k^5-\frac{g}{30}\right)-\frac{1}{m+1}\left(\frac{A}{30}+\frac{B}{36}\,k+\frac{8}{315}\,C\,k^2\right.\\&\left.+\frac{F}{42}\,k^3\right)-\frac{A}{45}+\frac{C}{105}\,k^2+\frac{F}{72}\,k^3-\frac{w}{45}\Bigg]=0 \ldots\ldots\ldots\ldots (25)\end{aligned}$$

$$\begin{aligned}\frac{1}{2\,G}\int_0^1 d\,z\int_0^H y^3\,d\,y\,\Bigg[&\frac{m}{m+1}\left(\frac{C}{120}+\frac{9}{700}\,F\,k+\frac{C}{200}\,k^4\right.\\&\left.+\frac{9\,k^5}{1\,100}\,F-\frac{g}{20}\right)-\frac{1}{m+1}\left(\frac{A}{20}+\frac{3}{70}\,B\,k+\frac{C}{25}\,k^2\right.\\&\left.+\frac{4}{105}\,F\,k^3\right)-\frac{A}{30}+\frac{3}{200}\,C\,k^2+\frac{F}{45}\,k^3-\frac{w}{30}\Bigg]=0 \ldots\ldots\ldots\ldots (26)\end{aligned}$$

These two equations, combined with Equations (16) and (17), suffice to determine the four constants, A, B, C, and F. It is apparent that the values of the constants are independent of the height, H, of the dam, since in Equations (25) and (26) the expressions in the square brackets must be zero.

An examination of these equations shows, that if the shear stress, t, and the horizontal stress, n_x, are both equal to zero, Equations (25) and (26) reduce to,

$$\frac{C}{180}+\frac{F}{120}\,k=0;\ \text{and}\ \frac{C}{120}+\frac{9}{700}\,F\,k=0$$

Both these equations cannot be correct, except when $C = F = 0$. Then A and B take on the values given in Equations (11) and (12) and all the stresses are linear.

V.—Stress Distribution—Numerical Example

In order to investigate the stress distribution found by the Principle of Least Work and to compare it with the usual theory, assume that $k = \tan\phi = \frac{b}{y} = 0.645$, $g = 62.5$, and $m = 8$. Let the weight of the concrete be chosen so that the stress in the up-stream face is zero for reservoir full, when the ordinary theory is used. This requires that the coefficient for y in Equation (10) must be zero, or from Equation (11), that $w = \frac{g}{k^2}$, or $w = 150.23$ lb. per cu. ft.[18]

When these values are introduced into Equations (16) and (17), there results,

$$A = 0.069337\ C + 0.05367\ F \ldots\ldots\ldots\ldots\ldots\ldots (16a)$$

$$B = -\,232.92 - 0.645\ C - 0.37442\ F \ldots\ldots\ldots\ldots (17a)$$

---

[18] All computations have actually been carried out several decimal places beyond the recorded results.

From Equations (25) and (26), when multiplied by 1 000,

$$8.2013\,C + 8.2909\,F - 25.926\,A - 1.9907\,B = 5\,190.3 \ldots\ldots (25a)$$

and,

$$12.568\,C + 13.011\,F - 38.889\,A - 3.0714\,B = 7\,785.5 \ldots\ldots\ldots (26a)$$

The solution of these four equations gives the values of the constants, when the stresses are expressed in pounds per square foot. Dividing these values by 144, there results, $A' = 0.3765$; $B' = -5.777$; $C' = 9.50$; and $F' = -5.263$. The stresses are in pounds per square inch,

$$\left.\begin{aligned} n_y &= 0.3765\,y - 5.777\,x + 9.504\,\frac{x^2}{y} - 5.263\,\frac{x^3}{y^2} \\ t &= -1.420\,x + 3.168\,\frac{x^3}{y^2} - 2.632\,\frac{x^4}{y^3} \\ n_x &= -0.4340\,y + 1.584\,\frac{x^4}{y^3} - 1.579\,\frac{x^5}{y^4} \end{aligned}\right\} \ldots\ldots\ldots (27)$$

TABLE 1.—STRESSES IN NO-UPLIFT SECTION ($k = 0.645$), 100 FEET BELOW CREST ($y = 100$), WHEN RESERVOIR IS FULL.

(Stresses, in pounds per square inch.)

x.	n_y.	t.	n_x.
0	+37.650	0.000	−43.403
3	+21.161	....	....
6	+ 5.274	....	....
10	−11.140	−13.908	−43.389
20	−44.082	−26.238	−43.200
30	−64.332	−36.172	−42.503
40	−75.048	−43.254	−40.962
50	−79.389	−47.839	−38.438
60	−80.512	−50.868	−35.201
64.5	−80.809	−52.119	−33.616

For a horizontal section, 100 ft. below the crest ($y = 100$ ft.), and with reservoir full, the stresses are as given in Table 1. At the down-stream face, $n_y\,n_x = t^2$; this acts as a check on the calculations.

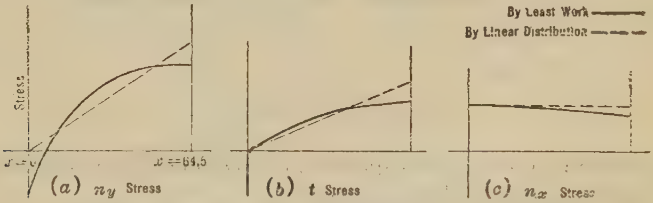

FIG. 4.—COMPARATIVE STRESS DISTRIBUTIONS. UP-STREAM FACE TO THE LEFT.

The stresses are plotted to scale in Fig. 4. On the assumption of a linear stress distribution, Equations (11) and (12) give, when divided by 144, $A'' = 0$ and $B'' = -1.6175$ and the stresses are by Equation (13), $n_y = -1.6175\,x$; $t = -1.0433\,x$; and $n_x = -0.43403\,y$. These stresses are also plotted in Fig. 4, for $y = 100$ ft. For the down-stream face, $x = 64.5$ ft., and, $n_y = -104.33$; $t = -67.291$; and $n_x = -43.403$.

A comparison of the vertical normal stresses shows, that according to the new stress distribution, there is considerable tension in the up-stream face and the angle between the n_y-stress and the horizontal decreases as x increases, while the usual method gives zero stress at the up-stream face and a constant angle. Furthermore, the tension in the up-stream face increases directly with y.

VI.—Calculation of Internal Work—Numerical Example

As a check on the calculations, from Equation (3),

$$\int_0^b n_y \, d\,x = A\,y\,b + B\,\frac{b^2}{2} + \frac{C}{3}\,\frac{b^3}{y} + \frac{F}{4}\,\frac{b^4}{y^2} \quad \ldots\ldots\ldots(28)$$

in which, $b = 64.5$ and $y = 100$. This gives 484 791 lb., while $0.5\,w\,k\,y^2$ gives 484 497 lb., an error of about 6 in 10 000. Equations (4) and (5) were likewise found to check closely. The stresses at the down-stream face are related, as shown by Equations (8) and (9). Since $n_y = -80.809$, t should be -52.122, and n_x should be -33.619, whereas in Table 1, $t = -52.119$ and $n_x = -33.616$. Also, from Table 1, $n_y\,n_x = 2\,716$ and $t^2 = 2\,716$. That these figures check, proves merely that the calculations are correct as far as Equations (16) and (17) and Equations (6) and (7) are concerned; it proves nothing with respect to the correct values of the two free constants, C and F.

When the stresses are expressed in pounds per square inch, the internal work, in foot-pounds, is, from Equation (14),

$$L = \frac{144}{2\,G}\int_0^1 d\,z \int_0^H d\,y \int_0^b d\,x \left[\frac{n_y^{\,2} + n_x^{\,2}}{2} - \frac{(n_y + n_x)^2}{18} + t^2\right] \ldots(29)$$

In order to obtain the internal work, Simpson's rule was used. The internal work due to n_y^2 is,

$$L_y = \frac{1}{4\,G}\sum\left[\frac{1\,440}{3}\,(h_0 + 4h_1 + 2h_2 + \ldots\ldots + h_6) + 144\,\frac{4.5}{2}\,(h_6 + h_{6.45})\right]\ldots(30)$$

h_0, h_1, h_2, etc., represent the ordinates, n_y^2, for $x = 0$, 10, 20, etc., as given in Table 2. The same formula applies to n_x^2. The internal work due to $(n_y + n_x)^2$ is, omitting the integral toward z and y, as before,

$$L_{y+x} = \frac{1}{36\,G}\sum\left[\frac{1\,440}{3}\,(h_0 + 4\,h_1 + 2\,h_2 + \ldots\ldots + h_6) + 144\,\frac{4.5}{2}\,(h_6 + h_{6.45})\right]\ldots\ldots\ldots\ldots\ldots\ldots\ldots(31)$$

The internal energy due to t^2 is expressed, as was that due to n_y^2, only, instead of $4\,G$ in the denominator, there is now $2\,G$.

The internal work, when the usual assumption is maintained, was found by integration. It was $n_y = -1.6175\,x$; $n_x = -0.43403\,y$; and $t = -1.0433\,x$, so that,

$$L' = \frac{144}{2\,G}\int_0^1 d\,z \int_0^H d\,y \int_0^b d\,x \left[\frac{1.6175^2}{2}\,x^2 + \frac{0.043403^2}{2}\,y^2 - \frac{(1.6175\,x + 0.43403\,y)^2}{18} + 1.0433^2\,x^2\right]\ldots\ldots\ldots\ldots(32)$$

TABLE 2.—VALUES OF STRESSES FOR CALCULATION OF INTERNAL WORK.
(Stresses, in pounds per square inch.)

x.	n_y.	n_y^2.	n_x.	n_x^2.	t.	t^2.	$(n_y + n_x)$.	$(n_y + n_x)^2$.

(n_y^2)	8 424 000	8 891 000
(n_x^2)	4 374 000	3 902 000
$(n_y + n_x)^2$	−2 590 000	−2 489 000
t^2	7 010 000	6 349 000
Total energy	17 218 000	16 653 000

There was some doubt in the writer's mind regarding the accuracy of the term depending upon $(n_y)^2$ because this becomes zero between $x = 0$ and $x = 10$. Applying Simpson's rule to the first three values of n_y, that is, for $x = 0$, 10, and 20, the internal work is,

$$\frac{1}{4\,G}\,144\,\frac{10}{3}\,(h_0 + 4\,h_1 + h_2) = \frac{462\,800}{G}$$

If the n_y curve is assumed as straight, the energy represented by the first three values is,

$$\frac{1}{4\,G}\,1\,440\left(\frac{1\,417.5 + 1\,943.0}{2} + 124.1\right) = \frac{604\,900}{G}$$

There is a difference of $\frac{142\,100}{G}$, equivalent to about 40% of the difference between the total energy of the usual and the proposed theory. The correct value, therefore, was determined by integration for $y = 100$,

$$\frac{144}{4\,G}\int_0^b d\,x\left(0.3765\,y - 5.777\,x + 9.504\,\frac{x^2}{y} - 5.263\,\frac{x^3}{y^2}\right)^2 \quad \ldots.(33)$$

This gives 8 875 000, which is 16 000, or 0.18%, less than is found by Simpson's rule. The internal work by the new theory is, therefore, slightly less than that given in Table 3. It is interesting to note that if t and n_x are neglected (see

Table 3) the usual theory gives the smaller value for the internal work. The terms inside the square bracket in Equations (14) and (29) then reduce to $\frac{m}{2\,(m+1)}\,n_y^{\,2} = \frac{4}{9}\,n_y^{\,2}$.

VII.—RESERVOIR EMPTY ($g = 0$)

When, in Equations (16), (17), (25), and (26), g is put equal to zero, there results, in pounds per square inch, after dividing by 144,

$$\left.\begin{aligned} n_y &= -1.0579\,y + 1.8251\,x - 0.6558\,\frac{x^2}{y} + 0.5752\,\frac{x^3}{y^2} \\ \text{and,}\qquad t &= +\,0.0146\,x - 0.2186\,\frac{x^3}{y^2} + 0.2876\,\frac{x^4}{y^3} \end{aligned}\right\}\ldots\ldots(34)$$

TABLE 4.—STRESSES IN NO-UPLIFT SECTION ($k = 0.645$), 100 FEET BELOW CREST ($y = 100$), WHEN RESERVOIR IS EMPTY.
(Stresses, in pounds per square inch.)

x.	n_y.	t.
0	−105.79	0.0000
10	− 88.137	+0.127
20	− 71.450	+0.163
30	− 55.385	+0.0807
40	− 39.596	−0.0788
50	− 23.738	−0.2050
60	− 7.466	−0.1182
64.5	+ 0.0837	+0.0536
55		+0.8203

For $y = 100$ and $b = 64.5$ the values are given in Table 4 and the shear stress is plotted in Fig. 5. The value of n_y checks Equation (3) and t checks Equation (5); the total horizontal shear is zero. The n_y stress distribution is practically a straight line, the same as that found by the usual method. This was to be expected, because the shear stresses are small. There is a slight tension at the toe, while the usual method gives $n_y = 0$ at the toe. Equations (11) and (12) give for $y = 100$ ft., $A = -w$ and $B = \frac{w}{k}$, so that, $n_y = -w\,y + \frac{w}{k}\,x$, which, for $x = 0$ and $x = 64.5$, gives $n_y = -104.327$ and $n_y = 0$. The shear is zero throughout as is also n_x.

VIII.—BENDING STRESSES ($g = 62.5$ AND $w = 0$).

With the usual assumption, the stresses for a full reservoir may be obtained by superimposing the stresses produced by the water on those obtained when the reservoir is empty. The stresses for $g = 0$ and $w = 150.23$ have been determined in Article VII. If, now, $w = 0$ and $g = 62.5$ are introduced into the equations determining the constants, A, B, C, and F, there is obtained, when the stresses are expressed in pounds per square inch,

$$n_y' = 1.4344\,y - 7.6016\,x + 10.159\,\frac{x^2}{y} - 5.8380\,\frac{x^3}{y^2}\ldots\ldots(35)$$

When this is added to the stress found for $g = 0$ in Article VII, there results,

$$n_y'' = 0.3765\,y - 5.7765\,x + 9.503\,\frac{x^2}{y} - 5.263\,\frac{x^3}{y^2}\;\ldots\ldots\ldots(36)$$

This is identical with the stress found directly in Article V (see Equation (27)). Since E is assumed constant, the two results should be equal. The fact that the two results check is merely evidence of correct numerical calculations.

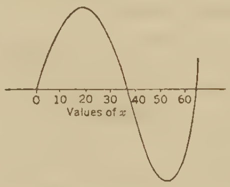

FIG. 5.—VARIATION IN SHEAR STRESS, $g = 0$

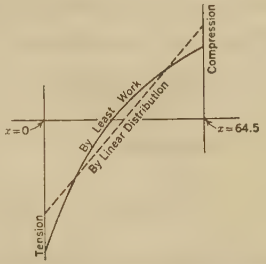

FIG. 6.—VARIATION IN BENDING STRESS, $w = 0$.

It may be noted that the bending stress found by the usual method is uniform and gives the same value at the up-stream face as at the down-stream face. In this manner the bending stresses for a triangular section are the same as for a rectangular one. This does not seem plausible, and the resulting principal stresses are not alike. By the usual method, the bending stress is, for $y = 100$,

$$n_y' = \frac{62.5}{0.41602}\,\frac{100}{144} = 104.33 \text{ lb. per sq. in.}$$

This may also be obtained by the usual formula,[19]

$$n_y' = \frac{M}{I}\,y = 6\,\frac{M}{b^2} = \frac{1\,000\,000 \times 0.43403}{4\,160} = 104.33$$

TABLE 5.—BENDING STRESSES IN NO-UPLIFT SECTION ($k = 0.645$), 100 FEET BELOW CREST ($y = 100$); RESERVOIR FULL AND WEIGHT OF DAM NEGLECTED.

(Stresses, in pounds per square inch.)

x.	n_y.	x.	n_y.
0	+143.41	40	− 35.45
10	76.99	50	− 55.65
20	27.37	60	− 73.04
30	− 8.94	64.5	− 80.88

The bending stress found by the Principle of Least Work is listed in Table 5 and both curves are shown in Fig. 6. The distribution of the bending stress could readily be tested, since it does not involve w.

---

[19] "Notes on Arched Gravity Dams," *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 766.

IX.—The Section of Maurice Lévy

Lévy laid down the rule that when the normal vertical stresses are calculated by the usual method, the compression in the up-stream face with reservoir full should be qual to, or greater than, the hydrostatic pressure of the water.[20] Assume $g = 62.5$ and $k = 0.844$, then from Equation (13), for $x = 0$,

$$n_y = -62.5\ y = \left(-w + \frac{62.5}{0.844^2}\right) y$$

or, $w = 150.24$ lb. per cu. ft. Carrying out the calculations for the constants, as before, there results, in pounds per square inch,

$$\left.\begin{aligned} n_y &= -0.0351\,y - 3.7381\,x + 6.6507\,\frac{x^2}{y} - 3.2487\,\frac{x^3}{y^2} \\ t &= -1.0083\,x + 2.2169\,\frac{x^3}{y^2} - 1.6243\,\frac{x^4}{y^3} \\ n_x &= -0.43403\,y + 1.1085\,\frac{x^4}{y^3} - 0.9746\,\frac{x^5}{y^4} \end{aligned}\right\} \ldots\ldots.(37)$$

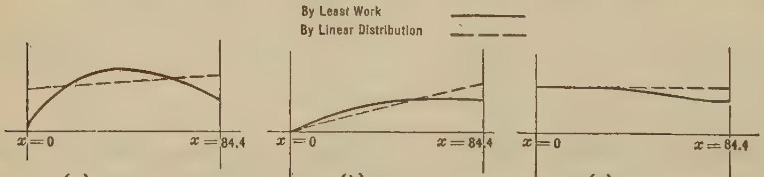
These stresses are shown in Table 6 for $y = 100$ and are plotted in Fig. 7; they were checked by planimeter to see that they conform to Equations (3) and (5).

TABLE 6.—Stresses in Full Uplift Section ($k = 0.844$), 100 Feet Below Crest ($y = 100$); Reservoir Full.

(Stresses, in pounds per square inch.)

x.	n_y.	t.	n_x.
0	— 3.507	0.000	—43.403
10	—34.562	— 9.877	—43.393
20	—54.265	—18.652	—43.257
30	—64.566	—25.578	—42.850
40	—67.412	—30.301	—41.563
50	—64.754	—32.854	—39.521
60	—58.540	—33.662	—36.616
70	—50.721	—33.539	—33.169
80	—43.244	—33.688	—29.937
84.4	—40.546	—34.237	—28.896

When the usual theory is employed, the stresses at the up-stream face, for $y = 100$ ft., are $n_y = -43.403$ and $t = 0$, and at the down-stream face, $n_y = -60.930$ and $t = -51.425$. The proposed theory gives compression



(a) n_y Stress (b) t Stress (c) n_y Stress

Fig. 7.—Comparative Stress Distribution for Full Uplift Section.

---

[20] "Quelques considérations sur la construction des grands barrages," *Comptes Rendus*, Vol. 121 (1895).

in the up-stream face, which is materially smaller than that found by the usual theory.

X.—Maximum Stress

The two principal stresses* are,

$$\left.\begin{aligned} s_1 &= \frac{n_y + n_x}{2} - \frac{1}{2}\sqrt{(n_y - n_x)^2 + 4\,t^2} \\ s_2 &= \frac{n_y + n_x}{2} + \frac{1}{2}\sqrt{(n_y - n_x)^2 + 4\,t^2} \end{aligned}\right\} \ldots\ldots\ldots\ldots (38)^{21}$$

The maximum stress occurring in a horizontal cross-section is the greatest value of the principal stress. With the usual assumption, all three stresses increase with x and reach their greatest value for $x = b$, so that the maximum stress occurs at the down-stream face and is, $s_{\text{max.}} = \frac{n_y}{\cos^2 \phi}$. An inspection of Table 1 shows that the same is at least approximately true for the section there investigated. Table 6 shows that it does not hold for the Maurice Lévy section. The principal stresses for this section are given in Table 7. The maximum stress is 87.4, while on the usual assumption it is $\frac{60.93}{0.584} = 104.33$ lb. per sq. in. As a check, $n_y + n_x$ should equal $s_1 + s_2$.

TABLE 7.—Principal Stresses in Full-Uplift Section ($k = 0.844$), 100 Feet Below Crest ($y = 100$); Reservoir Full.

(Stresses, in pounds per square inch.)

x.	s_1.	s_2.
0	—43.4	— 3.5
10	—49.8	—28.2
20	—68.2	—29.3
30	—81.5	—25.9
40	—87.4	—21.6
50	—87.3	—16.9
60	—83.0	—12.2
70	—76.6	— 7.3
80	—70.9	— 2.2
84.4	—69.4	0.0

At the up-stream face, s_1 is horizontal and at the down-stream face, s_1 is parallel to the face of the dam. The angle between the vertical and s_1 should be,

$$\tan(2\,\phi) = \frac{2\,t}{n_y - n_x} \ldots\ldots\ldots\ldots\ldots\ldots (39)$$

This gives $\phi = 40°\ 10'$, for $x = 84.4$ ft., which checks $\tan \phi = k = 0.844$, as it should.

In engineering literature too much emphasis has been placed on the necessity of limiting the maximum stress and too little on the importance of not

---

[21] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 294. A more comprehensive explanation is given by Professor Cain in his paper, "Stresses in Masonry Dams," *Transactions*, Am. Soc. C. E., Vol. LXIV (1909), Appendix, p. 220. In Fig. 5 of that paper, the direction of the greatest principal stress is shown for a number of points of a horizontal section.

designing with too low a value of the least principal stress at the up-stream face, or rather that stress which is parallel to the up-stream face and which is generally the least principal stress. The writer has called attention to this before,[22] but it needs to be insisted upon, quite irrespective of whether or not the proposed stress distribution is the correct one. The stress in the up-stream face with reservoir full, is obtained by subtracting one stress from another, and the result will always be subject to considerable uncertainty, especially when the residual stresses are also considered, as they should be. Professor Cain has also called attention to this point.[23]

The writer has never heard of the failure of a triangular-shaped, gravity dam due to excessive maximum stress, but a number have failed because they were designed with too little compression in the up-stream face, which, by uplift or other action, resulted in tension.[24]

XI.—THE INFLUENCE OF POISSON'S RATIO, $\frac{1}{m}$

There is considerable variation between the values of m for concrete given by various investigators, and it is admittedly most difficult to obtain reliable values. It may also be that m varies, as does the modulus of elasticity, with the water-cement ratio, the aggregates, the age of the concrete, and the length of time during which the load is applied.

Consider again the section, $k = 0.645$, for which the stresses were determined in Article V on the assumption that $m = 8$, and calculate the constants, A, B, C, and F, on the assumptions that $m = \infty$ and $m = 2$. The latter value is applicable to rubber; the English tests, to which a more detailed reference will be given, were made on rubber having a value of m approximately equal to 2. In each case, the calculations are exactly the same as before, and the results are given in Tables 8 and 9.

TABLE 8.—VALUE OF CONSTANTS FOR VARIOUS VALUES OF m.
($k = 0.645$; $g = 62.5$; and $w = 150.2$.)

	$m = 8$.	$m = \infty$.	$m = 2$.
$A' =$	0.3765	0.3832	0.3581
$B' =$	−5.7768	−5.8061	−5.7047
$C' =$	9.5037	9.3941	9.8553
$F' =$	−5.2633	−4.9958	−6.0611

There is no great difference between the three sets, the tension is smallest for $m = 2$. When $m = \infty$, C and F are independent of w, the weight of the concrete, and the constant, B, does not enter into Equations (25) and (26). The value of w determines the slope, B, and also affects the value of A, which is the stress at the up-stream face.

XII.—DISCUSSION OF THE ENGLISH TESTS

Some tests on gravity dam models were made by Mr. L. W. Atcherly and Professor Karl Pearson in 1904.[25] These models were built up of thin strips of wood, arranged horizontally in one set of tests and vertically in another. It was claimed that these tests indicated the presence of considerable tension across vertical planes near the down-stream toe. In order to throw additional light on this important subject, some additional tests were made.[26]

One set of tests was made with a model of plasticine, a kind of modeling clay. An inspection shows that the results near the up-stream face are too erratic to permit of any conclusions being drawn. The curving of the n_y-stress seems established and also the unlikelihood of tension near the toe. The model was constructed so that the resultant fell in the down-stream middle-third point when the reservoir was full. Another set of tests was made on rubber models. The weight of the dam was increased by attaching weights acting vertically downward, and the water loading was imitated by weights acting horizontally. It is not quite clear what the corresponding water load was, but it seems to have been intended that the resultant should fall at the down-stream middle-third point.

These tests have been generally taken to demonstrate the correctness of the ordinary assumption of linear stress, although, as stated in the conclusions,[27] tensile stresses were observed in every case at the up-stream heel, that is, where the concrete meets the foundation. Moreover, all the tests show the curving of the n_y-stress curves, as found by the Principle of Least Work. Fig. 8 (which is Fig. 11 in the original paper) shows the strains as measured, and Fig. 9 (which is Fig. 19 in the original paper) shows plainly the curving of the n_y-stress for the nearly triangular section, C. It shows no tension, except at the heel. The curves at Elevations 3-3 and 4-4 show the curving in the opposite direction to those at Elevations 5-5 and 6-6.

More details than those given are necessary to estimate the reliability of the results. The tests are not wholly satisfactory on account of the possibility

of considerable local strains, where the weights are attached, and the uncertainty as to the elastic behavior of the rubber, the time effect, etc. There is need of carefully made tests on models, which would represent a high gravity dam. The foundation should be sufficiently deep, and the method of attaching the dam to it might present a problem.

XIII.—General Remarks

For some years the writer has doubted the correctness of the assumption of a linear stress distribution and has suggested that some caution might be justified.[28] He has called attention to the fact that horizontal sections are not normal sections, as the theory of bending requires, and that the assumption of a linear stress distribution on horizontal sections is not a conservative assumption when dealing with multiple-arch dams.[29] This question was also discussed by Professor Cain[30] and had been discussed by Résal in his paper to which reference has already been given. The writer found, as did Résal, that for gravity dams the usual horizontal sections gave practically the same result as normal sections, when the usual assumption of linear stress distribution was made.[31]

The writer has used the Principle of Virtual Velocities to determine the stress distribution in thick arches of dams[32] and Professor Cain showed that the same result was obtainable by the Principle of Least Work.[33] After Dr. Vogt's work in connection with the deformation of the foundations[34] had become known to the writer, he made an attempt to determine the stress distribution at the abutments of the Pacoima Dam by the Principle of Least Work. Due to the fact that the abutments were not radial, it was evident, that the usual formulas were not exact. Meantime, further studies had convinced him, that the assumption of linear stress distribution in gravity dams was probably incorrect, entirely aside from the effect of internal stresses. It was believed,[35] that if the assumption was in error, this would be likely to be aggravated in very high dams. The result of the investigation set forth in this paper seems to justify this apprehension.

If the proposed theory had given values for the stresses, which were less conservative than those found by the usual theory, the new theory should be disregarded until it could be firmly established by carefully made tests. As it is, the new theory gives stresses which are less advantageous, and dams designed by the usual method may not be safe when tested by the proposed theory. It will also be recognized, that the Principle of Least Work is more fundamental than the arbitrary assumption that n_y is linear. Tests only can determine which theory is the correct one.

[35] Rept. by the writer to the Colorado River Comm. of Arizona, sent to the Colorado River Board of Engrs. (care, U. S. Reclamation Service), November, 1928.

The proposed solution is only an approximation, limited by the equation assumed for n_y, which has two free constants. If a more complicated equation is assumed for n_y, one having more free constants, a greater degree of approximation should be attained. This would involve much more work.

By putting $F = 0$ in Equation (15), a solution is obtained with only one free constant. There results, $A' = 0.296$; $B' = -4.37$; and $C' = 4.27$; and, for $y = 100$ ft., the corresponding values of n_y are shown in Table 10. These values agree quite closely with those found in Table 1, indicating that the true stress distribution is probably not far from that obtained when using two free constants. (See, remarks relative to Equation (36) in Article VIII.)

TABLE 10.—One Free Constant Only.
($y = 100$; $k = 0.645$; and $m = 8$.)

x.	n_y.	n_y from Table 1.
0	+29.6 (tension)	+37.7
10	− 9.87	−11.1
20	−40.8	−44.1
30	−63.2	−64.3

50	−82.4	−79.4
60	−79.2	−80.5
64.5	−75.0	−80.8

The writer has made an attempt to apply the theory to arched gravity dams. The mathematical complications were found to be considerable, although only one free constant was used in the expression for n_y. Equations (3) and (4) become more complicated in that W contains both y^2 and y^3 and M contains y^3 and y^4. Also, the equilibrium equations, (6) and (7), are more complicated. The solution found thus far agrees with the formulas presented in this paper when the radius becomes infinitely large, but it involves calculations with infinite series, which greatly augment the labor. This difficulty may be inherent in the problem, but it may also be that an expression can be selected for n_y which will avoid these difficulties. If the theory proves valid by tests on gravity dams the question arises as to how the stress distribution in multiple-arch dams is affected, when the principle is substituted for the assumption of linear stress across normal sections.

A few historical remarks may be of interest. In 1747, Maupertuis, President of the Berlin Academy under Frederick the Great, enunciated a principle, which he called "le principe de la moindre quantité d'action.[36] His paper was in three parts, the first being, "an examination of the proofs of the existence of God", which according to the second part must be sought in the general laws of motion. He declared the principle to be one which eminently accorded with the wisdom of the Creator and applied it to the equilibrium conditions of the lever and to the motion of light. Maupertuis was not a skilled mathematician and his exposition was confused and obscure.[37]

---

[36] "The Principle of Least Action," by Philip E. Jourdain, The Open Court Pub. Co., Chicago, Ill.

[37] "The Science of Mechanics," by Dr. Ernst Mach, late Professor at the University of Vienna, Open Court Pub. Co. (1919), pp. 364 and 454.

Mach suggests[37] that the principle would soon have been forgotten, had not Euler taken up the suggestion, magnanimously leaving Maupertuis the glory of the invention, and converted it into something serviceable. The theological point of view was retained by Euler who declared that since the universe is the handiwork of an All-Wise Maker, nothing can be met with in which some maximal or minimal property is not displayed. These were the studies which culminated in Euler's work in the calculus of variations and with the isoperimetrical problems; and the equation for the solution of these is still known as Euler's equation.[38]

That Nature performs in such a manner as to involve the least expenditure of energy, is an assumption which appeals strongly to the intuition; but, whether or not it applies in a specific case, or how it is to be interpreted, only actual tests can determine. For, as Mach says, it cannot be proved by mathematics that Nature must be exactly what it is.

ACKNOWLEDGMENT

The first draft of this paper was submitted for criticism to Professor Cain and to Dr. Vogt, to whom the writer's sincere thanks are due for calling attention to some errors of calculation and encouraging the writer to continue his studies of this subject.

APPENDIX I

From the tests on the plasticine model (having a base of 26 in.), referred to in Article XII, Sir John W. Ottley and Mr. A. W. Brightmore derived a stress distribution[39] which at the heel is zero (the same as found by the linear stress distribution) and at the toe is about 80% of the linear stress. Calling the stress at the toe for linear distribution, 100%, the stress distribution is as given in Table 11 and as plotted in Fig. 10.

TABLE 11.—STRESS DISTRIBUTION FOUND FROM TESTS ON PLASTICINE MODEL, IN TERMS OF PERCENTAGE OF STRESS AT TOE.

[38] "Advanced Calculus," William F. Osgood, Macmillan Co. (1925), Chapter XVII.

[39] *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII (Session 1907–08), Pt. II, Lond., 1908, Fig. 4, Pl. 3.

The question now arises whether Equation (15) can represent a curve similar to Fig. 10, so that in case this is the correct stress distribution, the constants could be determined so as to give a curve similar to Fig. 10.

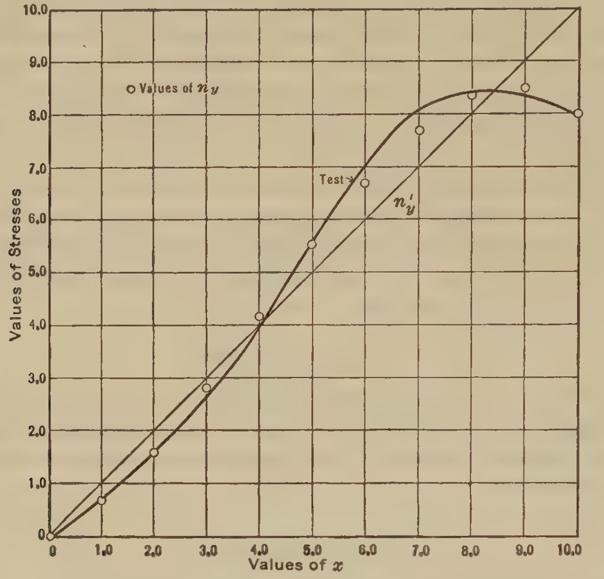

FIG. 10.—COMPARISON OF TEST AND EQUATION (15a), FOR $F = -0.02$.

Let $n_y' = a\,x$ be the linear stress distribution. From Equation (15), since y is a constant, $n_y = A + B\,x + C\,x^2 + F\,x^3$. Since, for $x = 0$, n_y is zero, it follows that $A = 0$.

From Equations (3) and (4),

$$\int_0^b n_y\,d\,x = \frac{B}{2}\,b^2 + \frac{C}{3}\,b^3 + \frac{F}{4}\,b^4 = \int_0^b n_y'\,d\,x = \frac{a}{2}\,b^2$$

and,

$$\int_0^b n_y\,x\,d\,x = \frac{B}{3}\,b^3 + \frac{C}{4}\,b^4 + \frac{F}{5}\,b^5 = \int_0^b n_y'\,x\,d\,x = \frac{a}{3}\,b^3$$

For the down-stream toe, $b = 10$ (Fig. 10), there results, $C = -12\,F$ and $B = 30\,F + a$; so that for $a = 1$, $n_y' = x$, and,

$$n_y = (30\,x - 12\,x^2 + x^3)\,F + x \ldots\ldots\ldots\ldots\ldots (15a)$$

For $x = 0$, $n_y = n_y' = 0$. If $F = 0$, then $C = 0$ and $n_y = n_y' = x$. If $F \neq 0$, the points in which n_y and n'_y are equal are found from, $30 - 12\,x + x^2 = 0$, or $x = 3.55$ and 8.45, no matter what F is. If F is less than zero, the resulting curve is similar to the one found in the English tests. If F is greater than zero, the curve is reversed with respect to the straight line, n_y', that is, the part nearest to the up-stream face lies above n_y', etc.

In Equation (15a), for n_y, F could be determined by the method of least squares, so as to fit the test curve in the best possible manner, but a quite close fit is obtained by assuming that $F = -0.02$, as may be seen by comparing

Tables 11 and 12, and from Fig. 10, in which the small circles are values of n_y determined from Equation (15*a*), when $A = 0$ and $F = -0.02$.

TABLE 12.—VALUES OF n_y FOR $A = 0$ AND $F = -0.02$.

x.	n_y.	x.	n_y.

40	4.16	100	8.00
50	5.50		

APPENDIX II

An Airy's stress function, F, may be determined to satisfy the linear stresses given by Equations (13). This stress function is defined by:

$$n_y = \frac{d^2\,F}{d\,x^2};\ n_x = \frac{d^2\,F}{d\,y^2};\ t = -\frac{d^2\,F}{d\,x\,d\,y} - w\,x \ldots\ldots\ldots\ldots (40)$$

in which, n_y, n_x, and t are given by Equation (13). This gives,

$$F = \left(-w + \frac{g}{k^2}\right)\frac{y\,x^2}{2} + \left(\frac{w}{k} - 2\,\frac{g}{k^3}\right)\frac{x^3}{6} - g\,\frac{y^3}{6} \ldots\ldots\ldots (41)$$

Equation (41) satisfies Equations (13) and, therefore, satisfies the equilibrium equations, (6) and (7), the statical conditions, Equations (3) and (4), and the boundary conditions, which lead to Equations (13) for the stresses. According to Föppl, the compatibility equations, which guarantee the geometrical continuity of the structure, are satisfied when:[40]

$$\frac{d^4\,F}{d\,x^4} + 2\,\frac{d^4\,F}{d\,x^2\,d\,y^2} + \frac{d^4\,F}{d\,y^4} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

Equation (41) satisfies this condition. Of course, a function, F, may also be determined from Equation (27), and Equation (42) may be written,

$$\frac{d^2\,(n_y + n_x)}{d\,y^2} + \frac{d^2\,(n_y + n_x)}{d\,x^2} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (43)$$

Equation (27) does not satisfy Equation (43); and, according to Föppl, it should not.[41]

APPENDIX III

The plane stress distribution considered in this investigation, assumes that $n_z = t_{zy} = t_{zx} = 0$ (Fig. 11). The quantity, n_z, is the normal stress acting parallel to the Z-axis and t_{zy} and t_{zx} are the shear stresses acting in the X-Y

---

[40] "Drang und Zwang," Vol. I, p. 248 (1924 Edition).

[41] *Loc. cit.*, Article 13, p. 97.

plane. When $n_z = 0$, the displacement, u_z, in the direction of the Z-axis, is determined by:

$$\frac{d\,u_z}{d\,z} = \frac{1}{2\,(m+1)\,G}\,(n_y + n_x) \dots\dots\dots\dots\dots\dots (44)$$

Since $n_y + n_x \neq 0$ (Table 2), it follows that the plane limiting surface, ABC, in the X-Y plane of Fig. 11, is transformed into a warped surface by the load stresses, n_y, n_x, and t. Consequently, t_{zy} and t_{zx} are zero only in the boundary surfaces, such as ABC and in the middle plane (on account of symmetry); and n_z, in general at least, is zero only in the boundary surfaces, ABC and $A'B'C'$, of Fig. 11. A plane stress condition, therefore, in general, must lead to contradictions, if both the equilibrium and compatibility equations are used.[42] None the less Föppl advances the idea that if the exact stress function is not known and if F_a is an approximate function, containing free constants, these may be determined from:

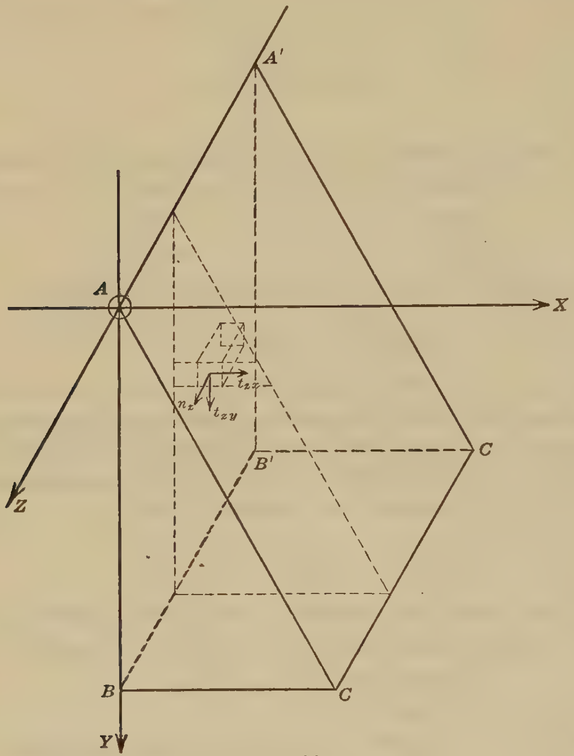

FIG. 11.

$$\int \left(\frac{d^4\,F_a}{d\,y^4} + 2\,\frac{d^4\,F_a}{d\,y^2\,d\,x^2} + \frac{d^4\,F_a}{d\,x^4} \right)^2 d\,A = \text{Minimum} \dots\dots (45)$$

in which, dA is an element of area and the constants in F_a are to be determined by the method of least squares.[43] This solution, according to Föppl, has the same right to be considered a valid approximation as the result obtained by the Principle of Least Work. Equation (45), however, must lead to Equation (41), which is equivalent to Equations (13), and represents a linear stress distribution, which does not agree with the result obtained by the Principle of Least Work.

---

[42] Teknisk Elasticitetslaere," by A. Ostenfeld, Article 20, p. 105 (1916 Edition); see, also, Föppl, "Drang und Zwang," Vol. I (1924), p. 129.

It is clear that Equation (14) for the internal work is inaccurate, in that it assumes $n_z = t_{zy} = t_{zx} = 0$, for the entire volume under consideration. If $n_z = \frac{1}{m}(n_y + n_x)$, that is, if n_z is just sufficient to prevent displacements in the direction of the Z-axis, then t_{zy} and t_{zx} are both zero, and while there is no displacement in the direction of n_z, this latter, since it varies with the load stresses, influences the displacements in the direction of n_y and n_x. In general, nothing definite is known about the value of n_z in gravity dams. It is affected by shrinkage, temperature changes, etc., and no doubt varies from point to point and from time to time.

When $m = \infty$ it may be assumed, without error, that $n_z = t_{zy} = t_{zx} = 0$; all the compatibility equations are satisfied, and Equation (14) is exact. It has been shown in Article XI that there is no great difference between the stresses obtained for $m = 8$ and for $m = \infty$ and the assumption that $m = \infty$ leads to considerable simplification of the calculations. It is admitted that the assumption, $n_z = t_{zy} = t_{zx} = 0$, is not exact, except when $m = \infty$, but it is believed that this inaccuracy will not materially influence the stress distribution obtained by the Principle of Least Work, while the use of the compatibility equations in connection with the equilibrium equations may lead to contradictions due to the incorrect assumption.

The present investigation does not take account of the irregularities introduced by the foundation, where the section is suddenly changed. Whether or not the stress distribution furnished by the Principle of Least Work applies at the foundation more nearly than the ordinary assumption, only tests can decide. The ordinary assumption is incorrect at the foundation, since as Dr. Vogt has shown, the foundation does not remain plane when the stresses are linear. This is also shown by the English tests (Article XII), which also indicate that the stress distribution obtained by the Principle of Least Work may at least approximate the actual stress distribution at the foundation.

---

[43] "Drang und Zwang," Vol. I, p. 336 (1924 Edition).

DISCUSSION

WILLIAM CAIN,[44] M. AM. SOC. C. E. (by letter).—In designing straight gravity dams it has been customary to limit the position of the resultant of the water pressure and the weight of the dam to the middle third of any horizontal section. This rule held whether the uplift due to water penetrating the sections was considered, or otherwise. Furthermore, for the given resultant, the vertical unit stresses on a horizontal plane were supposed to be computed as if the vertical section of the dam was rectangular, on the hypothesis that plane sections remained plane sections after stress. This led to the so-called "trapezoid law" of variation of stress, or a uniformly increasing stress from the water face to the down-stream face. It followed that, if the resultant cut the corresponding horizontal section at one-third its width from the outer toe, the unit stress at the inner toe was zero and the stress increased uniformly from the inner to the outer toe where it was a maximum. There was consequently no tension exerted anywhere on the horizontal section.

It has long been the belief of some engineers that such conclusions or hypotheses were untenable; but it remained for Mr. Jakobsen to prove it theoretically[45] and for English engineers by experiments on plasticene and India-rubber models of dams[46] to establish it experimentally. In the case of the plasticene model dam, water was applied to the face of the model through a thin rectangular India-rubber bag made to fit the frame. The results were only qualitative, but were sufficient to indicate the variation of stress on horizontal sections and to realize the fear that tension might be exerted at the inner toe and that cracks might be formed at the water face even when the resultant cut the base at one-third its width from the outer toe.

In the case of the India-rubber model, water was not applied, but its exact equivalent was substituted in the form of weights, acting through strings over pulleys, the strings being given directions at right angles to the water surface where they were attached to small plates bearing, through thin rubber pads, directly on the model. It was found necessary virtually to increase the density of the rubber by attaching other weights to small pins passed through holes in the rubber cut through centers of gravity of certain imaginary sections. Such weights were adjusted to correspond with the volume of rubber they were made to represent. It was not found that the small holes appreciably affected the physical constants of the rubber. Wooden wedges were placed at the upper and lower ends of the large foundation portion of the dam to give it full support. The entire apparatus was most ingenious, as was likewise the method of measuring strains.

The unit stresses at numerous points in the dam and foundation were determined from the displacements by usual formulas and are represented by the ellipses of stress shown in Fig. 12. The principal stresses, or those acting normally to their planes, are represented in amount and direction by the semi-axes of the ellipse. These are observed to act parallel to the inclined down-stream face near that face, but at the up-stream face where the dam is subjected to water pressure the direction of the principal stress is nearly normal to that face to counteract the large normal pressure of the water. The variation of stress along horizontal planes above the foundation is of especial interest in relation to the author's main problem, and such variations for the vertical pressure on horizontal planes, the horizontal pressure on vertical planes, and the shear on horizontal planes have all been computed and diagrams made to show the variation.

[44] Prof. Emeritus, Univ. of North Carolina, Chapel Hill, N. C. Professor Cain died December 7, 1930.

[45] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 276.

[46] Excerpt, *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session 1907–08, Pt. II.

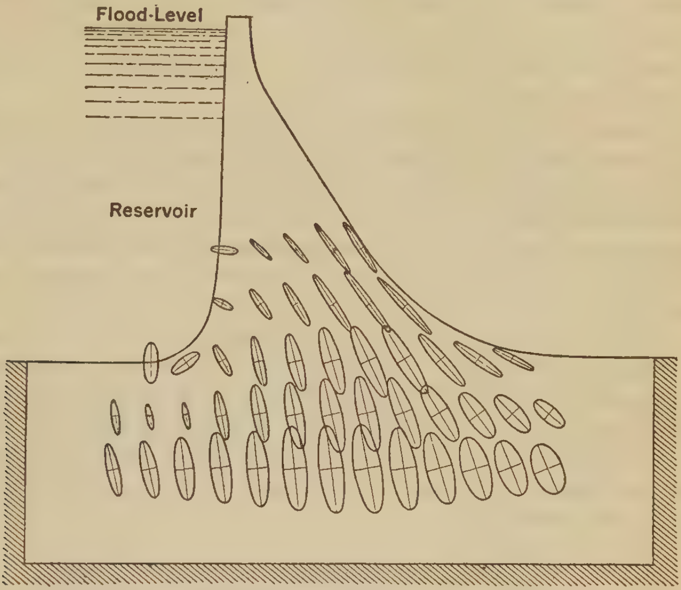

Fig. 12.—Ellipses of Stress, Ends of Foundation Supported.

The author has endeavored to find this stress distribution theoretically by the method of least work and he has succeeded remarkably well in effecting it. To this end, after writing certain fundamental relations, he assumes that the vertical unit stress on a horizontal plane at (x, y) is given by an expression of the form of Equation (15),

$$n_y = A\,y + B\,x + C\,\frac{x^2}{y} + F\,\frac{x^3}{y^2}$$

in which, A, B, C, and F, are constants; and in which, by antecedent equations, A and B can be expressed as functions of C and F, as given by Equations (16) and (17). The elastic internal work, L, is expressed by Equation (14), as given by Föppl, which equation is likewise given in another form, easily reduced to this, by Molitor.[47]

---

[47] "Kinetic Theory of Structures," p. 37.

It will be convenient now to refer to Castigliano's "Systèmes Elastiques"[48] for a fundamental principle (given in Chapter 1, Article 11, for an articulated system of bars, and in Chapter 2, Article 4, for a solid body), that if the elastic work of deformation is expressed as a function of the exterior forces (including the reactions as exterior forces), then its partial derivative with respect to any one of these forces will give the relative displacement of its point of application in the direction of the force. Similarly, it is proved (in Chapter 1, Article 12, for articulated structures and in Chapter 2, Article 5, for solids), that the derivative of the elastic work of deformation of the structure or body with respect to the moment at a certain section expresses the rotation of this section.[49]

It is assumed, in developing these relations, that a linear relation exists between a force and its corresponding displacement, and, consequently, that the elastic work of deformation (or the potential energy) can be represented as a homogeneous function of the second order of the external forces, and that the forces are independent of each other. The author's Equation (14) affords an illustration. In fact, it is a very exceptional structure where the relations noted do not hold.[50]

The "method of least work" is easily deduced by aid of these two principles. Thus, consider an arch "fixed at the ends", by which is meant that there is no displacement at the abutment sections and no rotation there, so that the sections remain plane after stress; then, if at the left abutment (say), the tangential component of the reaction is P_1, the radial or shearing component is S_1 and the moment is M_1; and if L = elastic work of the entire arch, then, by the principles just given,

$$\frac{d\,L}{d\,P_1} = \text{displacement of } P_1 = 0$$

$$\frac{d\,L}{d\,S_1} = \text{displacement of } S_1 = 0$$

and,

$$\frac{d\,L}{d\,M_1} = \text{rotation of abutment section} = 0$$

These partial derivatives being equal to zero express the fact that the elastic forces after deformation are such as to render the elastic work a minimum. Thus is proved for this case (and similarly for other structures) the "Method of Least Work".

Castigliano's treatment of the change of the unknown quantities[51] is very informing. It proves that, if the work of deformation can be expressed in terms of an equal number of new unknowns, the latter can be found directly by placing the partial derivative of the elastic work with respect to each of them equal to zero.[52] This treatment suggests the following, referring to Mr. Jakobsen's main problem. Note that from Equations (16) and (17), it is seen that A and B are functions of C and F. For convenience, the values of n_y, n_x, and t, are grouped together. Thus, in Equation (15),

---

[48] An English translation, with the title, "Elastic Stresses in Structures," is pub. by Scott Greenwood and Son, 8 Broadway, Ludgate, E. C. 4, London, England.

[49] All the fundamental principles of Castigliano's theory are given by the writer, by aid of the theory of "virtual velocities," in "Determination of the Stresses in Elastic Systems by the Method of Least Work," *Transactions*, Am. Soc. C. E., Vol. XXIV (April, 1891), p. 265.

[50] This subject is very clearly put in Timoshenko and Lessells' "Applied Elasticity," pp. 117–126.

[51] "Systèmes Elastiques," Chapter 10, Article 2.

$$n_y = A\,y + B\,x + C\,\frac{x^2}{y} + F\,\frac{x^3}{y^2}$$

In Equation (22),

$$n_x = \frac{C}{6}\,\frac{x^4}{y^3} + \frac{3}{10}\,F\,\frac{x^5}{y^4} - g\,y.$$

and in Equation (21),

$$t = -A\,x + \frac{C}{3}\,\frac{x^3}{y^2} + \frac{F}{2}\,\frac{x^4}{y^3} - w\,x$$

The partial derivatives as to C are:

$$\frac{d\,n_y}{d\,C} = \frac{x^2}{y};\ \frac{d\,n_x}{d\,C} = \frac{x^4}{6\,y_3};\ \frac{d\,t}{d\,C} = \frac{x^3}{3\,y^2}$$

If L is the total work of deformation for a 1-ft. length of dam, as given by the author's Equation (14), then L is a direct function of n_y, n_x, t; and as these are functions of C and F, by the known formula of the differential calculus (the derivatives with respect to C, being partial derivatives),

$$\frac{d\,L}{d\,C} = \frac{d\,L}{d\,n_y}\,\frac{d\,n_y}{d\,C} + \frac{d\,L}{d\,n_x}\,\frac{d\,n_x}{d\,C} + \frac{d\,L}{d\,t}\,\frac{d\,t}{d\,C} = \frac{d\,L}{d\,n_y}\,\frac{x^2}{y^2} + \frac{d\,L}{d\,n_x}\,\frac{x^4}{6\,y^3} + \frac{d\,L}{d\,t}\,\frac{x^3}{3\,y^2}$$

Now by Castigliano's theorems stated on the derivatives of work for any point (x, y) of a horizontal section of the dam,

$$\frac{d\,L}{d\,n_y} = \text{vertical displacement}$$

$$\frac{d\,L}{d\,n_x} = \text{horizontal displacement}$$

and,

$$\frac{d\,L}{d\,t} = \text{displacement due to shear}$$

If at the base, each of these displacements is zero, the equation reduces to,

$$\frac{d\,L}{d\,C} = 0$$

Similarly, it can be found that,

$$\frac{d\,L}{d\,F} = 0$$

These two equations show that the internal work is a minimum, as stated by the author. This demonstration assumes the base of the dam unyielding.

---

[52] This treatment of the change of unknown quantities is likewise given in full in the paper cited, *Transactions*, Am. Soc. C. E., Vol. XXIV (April, 1891), p. 292.

Fredrik Vogt, Assoc. M. Am. Soc. C. E., in a very interesting discussion[52] regards the base, whether the foundation of the dam or the abutment of an arch, as yielding for a certain small distance, below which it is absolutely unyielding and plane sections remain plane.[52a] If this hypothesis is adopted, it is perhaps only necessary to assume approximately the base of the dam removed to a parallel position, presumed to be unyielding, for which the supposed plane section remains plane and the method of least work is seen to apply to the revised position or to a slightly increased size of dam. On this supposition the original foundation will no longer remain plane, but will become a slightly warped surface.

Recurring now to the original problem, where the base of the dam (or foundation) is supposed to be unyielding, the writer is glad to testify to the complete scientific accuracy of the author's analysis, of which he has checked Equations (1) to (25), inclusive. For the stress distribution, for the numerical illustration of Article V, the values of A', B', C', F', are readily found, and the formulas for the stresses at (x, y) are given by Equation (27), and their numerical values at the base, $y = 100$ ft., are recorded in Table 1.

The author has noted the important fact that the constants, A, B, C, F, are independent of the height, H, of the dam, "since in Equations (25) and (26) the expressions in the square brackets must be zero." It is thus only necessary in Equation (27) to substitute for (x, y), their numerical values to compute the stresses at any point (x, y) in the dam. This dam is designed so that the stress in the up-stream face is zero when the usual theory of (linear) stress distribution is used, straight lines limiting the unit stresses as shown in Fig. 4. Likewise, Fig. 4 gives the stress distribution as determined by the method of least work and it is seen that by this method there is appreciable tension at the up-stream face, and, further, that the angle between the curve of the n_y stress and the horizontal decreases as x increases. The important fact is the occurrence of tension at the up-stream face; and it is evident that the only way to avoid it is to increase the base or the value of $k = \frac{b}{y}$. This would alter slightly Equations (16a), (17a), (25a), and (26a), and lead to new values of A, B, C, F, and new formulas for n_y, t, n_x.

In place of assuming k and computing w, assume $w = 145$ (say), for the weight of 1 cu. ft. of concrete and compute, $k^2 = \frac{g}{w} = \frac{62.5}{145} = 0.431$; whence $k = \frac{b}{y} = 0.656$; or for $y = 100$ ft., $b = 65.6$ ft., thus giving the base for reservoir full for stress zero at the up-stream face when the usual linear stress distribution is assumed. Now b must be increased to avoid tension at $x = 0$ when the method of least work is used. As a first trial, suppose b increased by 5 ft., so that $b = 70.6$, whence for the same $w = 145$, $k = 0.706$, and the new values of A and B in terms of C and F are derived from Equations (16) and (17).

[52a] *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 554.

The solution proceeds by the use of Equations (25) and (26) exactly as the author indicates, so that eventually the formulas for n_y, t, n_x, can be written. If n_y at $x = 0$ should turn out to be either zero or a small negative value (compression), the solution may suffice. Otherwise, another small change in b will have to be assumed, and a new formula for n_y must be derived and tested as before. It should not require more than three trials before a satisfactory formula for n_y can be written.

As all the formulas refer to a triangular dam, they are approximate near the top when the usual additions to the section are made there; but for a high dam, they are sufficiently accurate for the lower sections. They furnish practical formulas for distribution of stress for most straight dams.

Hitherto, uplift (from water penetrating the base) has been neglected. If the uplift at the heel is assumed as the greatest possible (= 62.5 y lb. per sq. ft.), and as decreasing linearly to zero at the toe, then the total uplift is,

$$\tfrac{1}{2}\, 62.5\, y\, b = \tfrac{1}{2}\, 62.5\, k\, y^2$$

which is equivalent to the weight of a triangular mass of water acting upward on the base.

For 1 ft. in length of the triangular dam, its weight less the uplift is $\frac{1}{2}\, k\, y^2\, (w - 62.5)$.

It can now be easily verified that, for the triangular dam considered, all the general Equations (1) to (26) are valid when uplift is considered, by simply replacing w by $w' = (w - 62.5)$, which simplification is entirely due to the assumption of a triangular dam.

In Article VII, Mr. Jakobsen has derived the results for reservoir empty (when, of course, there is no uplift to consider) by the method of least work, and finds a small amount of tension at the toe. This would probably disappear when the base is slightly increased as previously suggested.

Partly as a check, the author has computed the internal work by the usual and the proposed theories and has subsequently computed the bending stresses for the same cases, and illustrated the results in Fig. 6. To render the solution more complete, the principal stresses have been computed and the influence of Poisson's ratio examined.

The labor involved in developing all the formulas and computing numerical results has been very great, and the author deserves the thanks of the profession for his excellent and convincing paper. The English experiments first proved the ordinary "inner-third rule" inadequate, and now Mr. Jakobsen confirms it by a close theoretical analysis. It will not suffice that the resultant of the water pressure and the weight of the dam should be required to cut the base simply at one-third its width from the outer toe; it must be at a greater distance from this toe. In other words, to avoid tension at the heel, the resultant should be confined to narrower limits than the middle third. It is a difficult problem to find such narrower limits, but, at least, it has been shown that the method of least work can materially aid in establishing them.

William Gore,[53] M. Am. Soc. C. E. (by letter).—Since the English tests of nearly a quarter of a century ago were published the general problem of the stresses in gravity dams has not received much attention. At that time this problem appeared to have been solved, but Mr. Jakobsen now raises it again from a new angle. The English tests indicated that, except at or near the foundations of a dam, the classical assumption of the trapezium or straight-line law, although not correct, was not so far wrong as to cause any anxiety concerning the safety of dams designed in accordance therewith, and all subsequent designs have followed these assumptions.

This situation has been a source of gratification to Mr. J. S. Wilson and the writer, who conducted most of the English tests. These tests had a direct bearing on the design of the first raising of the Assuan Dam, and their accuracy is a matter of considerable moment in discussing the author's paper. Mr. Jakobsen draws special attention to this, but he states that "the tests are not wholly satisfactory on account of the possibility of considerable local strains where the weights are attached, and the uncertainty as to the elastic behavior of the rubber, the time effect, etc." All tests, of course, are subject to possible inaccuracies such as those indicated by the author. They are also subject to inaccuracies due to the fact that the general assumptions and arrangements of the experimenters may not have been in agreement with the practical case they are intended to represent; but in the case of the English tests every effort was made to keep such inaccuracies as small as possible.

The work on gravity dams extended over a period of about four years and involved a considerable amount of labor, most of which was not seen in the published results. Everything possible was done to make the results classical. The exaggerated virtual weights of 6 000 lb. per cu. ft. for the masonry, and 2 500 lb. per cu. ft. for the water, were adopted in order that the strains produced could be large enough to be measured with reasonable accuracy while maintaining the same relative densities of concrete to water. The dam sections unloaded were distorted in form and it was only when fully loaded that the correct profiles were secured.

In Fig. 13, the broken lines show the model section and the principal lines in the unstrained position and the full lines show the model section and principal lines when fully strained with both "gravity" and "water weights". Test samples, cut from the same slabs as the sections, similarly treated and prepared, were subjected to various loadings under the same conditions as the sections, and were found to give an approximately straight-line relation between stress and strain within the limits of the tests. Owing to the time effect of stress upon rubber the models and similarly treated rubber sample tests were loaded for 24 hours, then rested for 48 hours, and the cycle repeated again and again until a permanent régime had been established. The measurement photographs of the loaded sections were taken after the loads had been applied 24 hours, and the unloaded sections, 48 hours after the loads had been taken off. Some time after loading, the pads conveying the water pressures were gently rolled sidewise to allow the soft rubber under them to creep to freedom. The models and fixed camera were in a room in which none beside the experimenters was allowed to enter, and great care was taken that the precise distance relationship between the camera and object was undisturbed.

---

[53] Cons. Civ. Engr. (Gore, Nasmith & Storrie), Toronto, Ont., Canada.

The later measurements were made upon large photographic negatives, especially prepared on plate glass, from 1½ to 2 times the actual size, by means of especially designed micrometer gauges. The gauge lines on the glass were opaque; they were projected by a lens in a vertical optical bench on the negatives and adjusted with a low-power microscope so that the black images of the gauge lines of the micrometer were caused to register upon the transparent lines or circles on the negatives. Length measurements to 0.001 in. were measured accurately and lengths of 0.0001 in. could be estimated in most cases. Angles of shear were read in the same manner accurately to tangents of 0.002.[54] All principal measurements were taken along lines midway between the load points, and the effects of the concentration of the loads are hardly discernible as the published measurements show. This is supported by theoretical considerations. In interpreting the stresses from the strains the calibration of every through line was adopted.

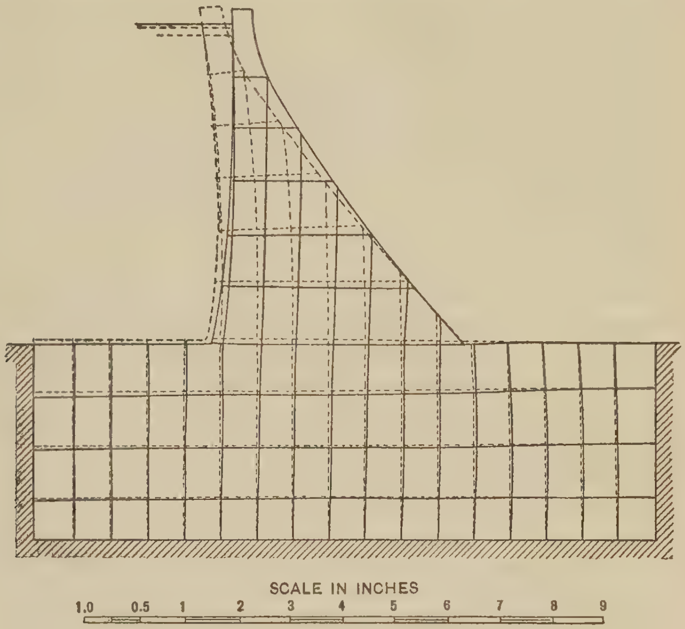

FIG. 13.—ENGLISH TESTS: MODEL SECTION CORRESPONDING TO FIG. 9.

It is possible that the elastic constants of a material such as rubber, even of the very best quality such as that adopted, do vary from point to point to some extent, but observations made during the English tests did not show these variations to be of great importance. The two sections (Figs. 8 and 9) constructed at different times compare very favorably; but in any practical case—

---

[54] *Engineering,* May 22, 1908.

whether by this or any other method—it is desirable that two or more models exactly alike be used and the results averaged. The results of the English tests have a high degree of accuracy and may reasonably be compared with the author's equations for n_y, n_x, and t.

At the time the English tests were made, it was held that a correct mathematical solution was not possible owing to the unknown and possibly arbitrary conditions at the base of the dam. The French engineer, Maurice Lévy, had attempted the solution by means of differential equations, but these did not take into account the base conditions. For a triangular dam, Lévy's solution was in accordance with the classical assumption, but in the case of a vertical wall the stresses showed considerable departures from straight lines; tensions were not indicated in either case. The first of the English tests were with a triangular dam of minimum section with a small base resting upon steel balls and free to travel horizontally.[55] It was only prevented from doing so by the application along the base of a system of forces equal and opposite to the water pressure and representing the shearing forces. These could be varied in any manner so long as static equilibrium was maintained.

When the applied distribution of shear at the base corresponded with the classical assumption no tensions were observed in the dam, although the line of resistance was theoretically following the down-stream boundary of the middle third. The curves of shear on horizontal lines at all levels were similar; they were nearly a straight line slightly turned up at the up-stream end and down at the down-stream end. The curves for n_y were similar. When a test was made with the classical shear distribution reversed, the effect of the change on the distribution of stress in the section was not considerable for more than 40% up from the base of the section, but the changes below the 40% level were extensive. Local tensions were observed at the up-stream heel. These tests established the type of stress curves in triangular dams not too near the base, and all subsequent tests of whatever source appear to confirm it.

The sections, Figs. 8 and 9, were developed later to deal in a natural and practical way with the lower part of the dam and the bed-rock foundations in the vicinity, including a considerable portion under the reservoir. For this purpose it was assumed that the rock and masonry were homogeneous and isotropic, and that they had the same elastic constants. The measuring photographic negatives did not include the higher parts of the sections although these were treated at a later date and disclosed n_y-curves similar to Line 3-3, Fig. 9. These tests did not indicate tensions in the upper parts of the dam, and Mr. Wilson and the writer were led to the conclusion that the tensions at the up-stream heel observed were due to the influence of the restricted connection to the great mass of the rock under the bed of the reservoir and the water pressures upon it. The tensions observed were quite local. These general results, although of considerable importance in dam design, except above the 40% level, appear to be beyond the problem dealt with by Mr. Jakobsen, which relates to a simple triangular section in contact with a rigid base at infinity.

---

[55] *Engineering*, August 4, 1905.

In interpreting his results, Mr. Jakobsen has introduced in addition to the conditions of static equilibrium, the requirement that the internal work done by the applied water and the masonry loadings shall be a minimum and this condition replaces the assumption of straight-line stress. The work has involved considerable analysis and is a very valuable contribution to this most important problem. Professor Cain has checked the author's work, and it may be regarded as accurate within the assumptions adopted.

An examination of the method, in conjunction with the English tests, indicates that the results should apply to the upper parts of a dam, not too near the rectangular top. The results, however, appear more nearly to fit the base conditions only as shown by the English tests, but the dropping of the n_y-curve at the up-stream heel is not nearly so local. This result is to be expected owing to the restrictions at the bases which, although local in the models, appear to be carried up the entire structure in Mr. Jakobsen's calculations. Thus, it must be admitted that there are serious differences between the author's analysis and the English tests, and as Mr. Jakobsen's method is an exceedingly attractive one, it would be interesting to find the cause of the differences—whether they are fundamental or due to some elusive further necessary consideration, or to over-restriction. His close association with the models leads the writer to the presumption that the conditions (both internal and external) applied to them do not nearly correspond with those assumed by the author in his calculations and, therefore, the results must be different.

The most noticeable feature of Mr. Jakobsen's treatment is his assumption of a rigid base and possibly an equivalent at higher levels. In all probability this is the cause of the excessive tension indicated and would be very serious indeed, if true, in actual gravity dams. In all the model sections, lines originally horizontal and straight move and tip down stream and also sag, and the change is such as to relieve the possible tension and to reduce maxima of either kind. Fig. 13 shows the strain picture of the English tests traced from photographs corresponding to the author's Fig. 9. The application of a straightedge to the horizontal lines will show the sag mentioned, and it will be noticed that considerable external work must have been done by the section, which somehow must come into any calculation of least work under the model conditions. Thus, the old conclusion is reached, namely, that when the conditions at the base are unknown both as to stress, strain, and work, no calculation is satisfactory, and the assumption of a rigid base or horizontal plane is not much nearer satisfaction than the classical assumption of the straight-line law and may lead to greater errors.

In any actual dam the supports go down into the body of the earth and extraordinary large displacements, including settlements, are only prevented by the unstrained banks at the ends of the dam. Except in very narrow gorges, where gravity sections are now seldom or ever adopted, the elastic bases may be more free than is provided in the models.

The author's reference to Maupertuis is interesting. The application of the principle of least work in this case so far seems to lead in the opposite direction to that indicated by Maupertuis. Its application to gravity dams leads not to a beneficient providential situation, but to destructive tensions in structures unable to resist them. It causes them to fail, releasing great bodies of water and spreading death and destruction over extensive territories. In this case, however, it is more providential to know the truth and then meet it than to carry on without the knowledge.

It seems in all probability that the principle of least work does actually apply to this most interesting problem and that the author has secured a solution for one over-restricted case; but the actual application of it in full to the general problem is beset with difficulties which may prove insuperable. It might be that the author could re-state his problem by assuming the strains at the base of the structure to be proportional to the stresses determined by his present results regarded as a first approximation, and then re-calculate the amount of least work, and so on, successively, until a permanent form had been established. Of course, any assumption that straight lines in the dam before loading remain straight lines after loading is not permissible. Fig. 14 shows some further results from the English tests on the model in Fig. 9; it relates only to the base line, 6-6. It should be noted that the departures from the straight line of the n_y-curves for reservoir empty and reservoir full are approximately reversed.

FIG. 14.—STRESSES AT BASE OF MODEL DAM: ENGLISH TESTS, LINE 6–6 OF SAME MODEL AS FIG. 9.

L. J. MENSCH,[56] M. AM. SOC. C. E. (by letter).—The title of this paper is a misnomer. The author confounds the Theory of Least Work of "Elasticity" with the metaphysical conception of the philosophers of the Eighteenth Century. Castigliano's theory is only a kind of shorthand notation of the general laws of an elastic body in equilibrium, and the equation of work on which it is based is practically identical with the equations expressing the principle of virtual work, the principle of potential energy, Maxwell's equation, or the many other methods which have been given names in the Nineteenth Century for the solution of elastic problems. This fact was emphasized by the writer on a previous occasion.[57] At that time the writer pointed out that tests to destruction do not agree with the result of the mathematical theory of elasticity, often not within 50%, because the latter is based on the assumption that Hooke's law holds and neglects the inelastic actions and internal frictions. The formula for the work of strain, as given by Equation (14), is of a highly speculative nature, and really satisfactory results (within 25 to 50% of tests to destruction) have been obtained only where stresses are low, or where they are of preponderant influence in one direction.

---

[56] Gen. Contr., Chicago, Ill.

Consider, for example, the case of a column under concentric axial load. The work performed by the load equals load times shortening of the column and this must be equal to the sum of the work performed by all interior particles, which are assumed to be uniformly loaded and strained, during their shortenings. The modulus of elasticity in compression is derived from this point of view; but according to the mathematical theory of elasticity there are a great many other stresses in such a simple structure. All textbooks in common use show that shearing stresses are acting in such a column in sections inclined to the axis and that these shearing stresses, disregarding internal friction, are a maximum for an inclination of 45°, when they are equal to one-half the axial stresses. The simple method of computing the internal work is incorrect, and the actual work of the axial stresses is only a part of the entire internal work. No way has been found, since the inception of the mathematical theory of elasticity, to verify experimentally the assumed distribution of work performed on each particle in the various directions of strain. For a proper solution it will probably be necessary to wait until the ultimate constitution of matter has been determined.

The novelty introduced by the author is a non-linear stress distribution in a horizontal section of a dam, the distribution following a curve of the fourth order, given by Equation (15). He has not tried to show that this distribution of stresses will really produce the least amount of work compatible with the loading conditions; he has only calculated the coefficients of this particular curve to satisfy the hypothetical Equation (14). Other writers have assumed a parabolic stress distribution; and the writer has tried a cubic parabola[58] to which he was led by comparing the results of tests to destruction on a large number of eccentrically loaded columns.

The writer finds it strange that the author uses the stresses in a horizontal section, which is inclined to the neutral axis of the dam, in such a delicate operation as the solution of Equation (14). From experiments with wedge-shaped beams of cast iron and reinforced concrete the writer knows that the line of failure follows somewhat the line, *AO'B*, in Fig. 15, which for convenience of calculation may be replaced by the dotted line, *A' B'*. An investigation of this section by Mr. Jakobsen with a stress distribution similar to Equation (15) would have shown the point of zero stress a great deal farther down stream than for a horizontal section, namely, at N instead of n in Fig. 15.

---

[57] "On a New Principle in the Theory of Structures," by the late George F. Swain, Past-President, and Hon. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 654.

[58] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1667; also, Vol. 93 (1929), p. 1250.

The author finds tension at the up-stream face and does not mention that such tension cannot exist in the joints of a non-monolithic structure. Sometimes it is permitted to assume tension in the design of brick masonry, but this is done for the following reason: When brick smokestacks were first

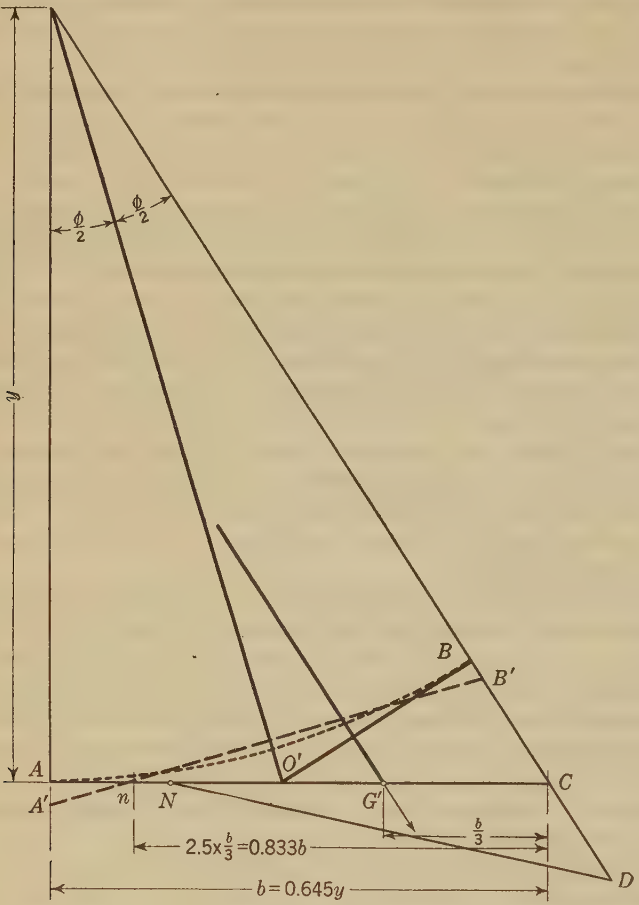

FIG. 15.

designed on scientific principles the calculations required an undue thickness of wall to prevent tension, which compared unfavorably with the work of ordinary masonry contractors who had built satisfactory stacks for a long time. In order not to be in contradiction with good practice, the custom of allowing tension in the statical calculation was developed, although the originators of this practice knew that such tensions are only imaginary. The straight-line theory was at fault.

The author has endeavored to correct the errors of the straight-line theory, but still persists in the error of assuming imaginary tensions. Tension in a joint indicates the opening of a crack which will have a width at the face of about 0.01 in. when the joints are about 10 ft. apart vertically. What will happen to the dam when the intruding water exerts a pressure in the joint? The great dams constructed by the New York Board of Water Supply have just such a section, and a discovery such as that claimed by the author might cause many sleepless nights to the engineers in charge. While the writer is quite convinced that such water pressure is exerted in the joints of many dams, he quite admires the judgment of the New York engineers who adopted this profile. It is entirely safe although it has been criticized lately by a number of engineers. Water pressure in joints opened up by the deformation of properly constructed dams is not dangerous because the joint just above it also exerts a downward pressure which is only slightly less than the one below it and the difference of pressure does not produce a great change in the stresses. The writer has shown[58] that a stress distribution according to a cubic parabola leads to reliable and easily computed results.

Fig. 16 shows the properties of such a parabola and G denotes the center of gravity of all stresses. In a horizontal section such as that chosen by the author, the point, G', in Fig. 16, must be at the intersection of the resultant of all forces with the line, $A\,C$, of Fig. 15. The distance of the point of zero stress from the down-stream face will be $2.5 \times \frac{b}{3} = 0.833\ b$, provided it is at all permitted to assume such a stress distribution in a horizontal section. Since the vertical load at G' in Fig. 15 is $\frac{1}{2}\ w\ y\ b$, the maximum vertical stress, in pounds per square foot, is, $\dfrac{\frac{1}{2}\ w\ y\ b}{\frac{3}{4} \times (0.833\ b)} = 0.8\ w\ y$. By a very laborious calculation the author obtains $0.775\ w\ y$; the straight-line theory gives $w\ y$ as maximum vertical stress. An investigation of the section, $AO'B$ (Fig. 15), shows that the stresses parallel to the down-stream face are about $1.17\ w\ y$, in which, y is the depth below the top at Point B; but the point of zero stress is now at N. The failure of the Bouzey Dam, in France, in 1895 shows a line of failure following the line, AND, in Fig. 15. The writer conceives this failure as follows: After tension, in a section, $AO'B$, developed to a point, N, the shear in the line, $N\,D$, became greater than the leached-out mortar of the masonry could stand and the dam sheared off. The shear is a maximum along a line inclined nearly 45° with the principal stress parallel with the down-stream face, and thus the line, $N\,D$, was located. Hence, shear failures are very dangerous to masonry dams as commonly built, or to concrete dams with improper horizontal and vertical joints. These shearing stresses are probably the dangerous ones in high dams of non-uplift section. For dams 700 ft. high they might reach values of 500 lb. per sq. in.

When a dam is sheared off at its foundation, or at higher elevations, it will have to move quite a distance before it topples over; consequently, an arched gravity dam must be safer than a straight dam. Most engineers deny the help given to a gravity dam by arch action, because the deflection of the dam as a cantilever is too small to allow of arch action. If, however, through some error, dangerous shearing stresses should develop, the movement will be large enough to close vertical cracks and open expansion joints, and arch action will prevent complete failure. The danger to a dam without an uplift section is in the foundation. When uplift can be exerted at the base of the dam, that is much greater than the pressure in the joints above it, due to the rock being weakened by the intruding water, as in the St. Francis Dam, or by fissures in the rock below the dam, then failure is likely to occur sooner or later, and for such doubtful foundation conditions a much larger section of dam must be adopted or resort must be had to deep anchorage into the rock near the up-stream face.

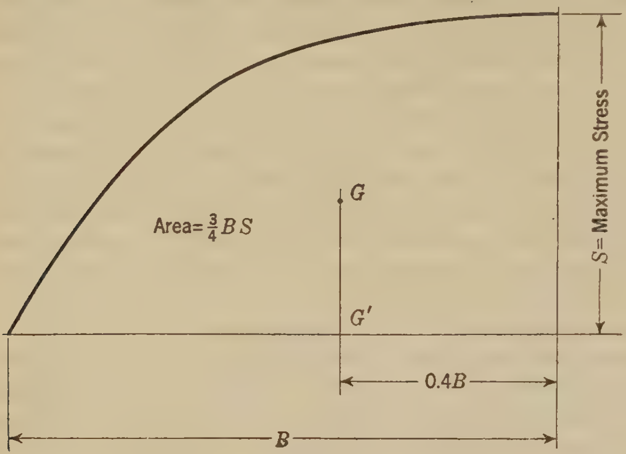

FIG. 16.

LARS R. JORGENSEN,[59] M. AM. SOC. C. E. (by letter).—That the stress distribution in the cross-section of a gravity dam is such as will make the internal work the least possible, is undoubtedly the best assumption. Mr. Jakobsen has made a solution of the problem which is a decided step forward in dam engineering. This paper takes the same position for gravity dams as the work of the late Professor Cain does for arch dams.

The curved shape of the stress distribution diagram appeals to the instinct as being more correct than the linear. The inside of a great body should exert greater resistance than the edges. The curved shape of the stress distribution made by the author checks the English tests; there is considerable satisfaction in this. The material in the English tests evidently had a constant value of E whether wet or dry.

---

[59] Cons. Hydro-Elec. Engr., Berkeley, Calif.

The writer has come to the conclusion that for tests, the model ought to be of the same material as the dam itself. Even then it is difficult to reproduce equality. One reason is that the modulus of elasticity for concrete is extremely variable, between the wet and the dry faces, for sustained load. On a straight gravity dam this fact may not have much influence on the stress distribution, but it will have great influence on the deflection in a down-stream direction.

Mr. Jakobsen refers to tests made by R. E. Davis, M. Am. Soc. C. E., in connection with the concrete in the Stevenson Creek Dam. The writer regards these tests as most valuable, since they are made with dam construction in view. Professor Davis finds the instantaneous deformation and the plastic flow after, say, 300 days of loading, the two deformations are added together and give an expression for the working modulus of elasticity of the material for sustained load. The interesting and valuable part of the tests is that it is shown that E for sustained load is from 60 to 63% higher for wet than for dry concrete for stresses between 600 and 900 lb. per sq. in.

If the dam body is either entirely dry or entirely water-soaked, the working value of E will be constant to all intents and purposes for the entire dam body, and the stress distribution on the horizontal plane will be, as found by Mr. Jakobsen, in accordance with the theory on the principle of least internal work.

For arch dams the worst case and the most plausible one (and, therefore, the one to reckon with) is when the concrete is wet on the up-stream side and dry on the down-stream side, with a more or less uniform distribution between the two faces, then the value of E of the material is approximately 60% higher along the up-stream face than along the down-stream face.

This large variation in the working value of the modulus of elasticity between the wet and the dry faces will materially affect the stress distribution. It will cause the arch stresses to move in an up-stream direction, so to speak, in the horizontal arch section, relieving the maximum compressive stress at the abutments, where the compression is greatest. The water-soaking effect will relieve the tensile stresses, if any, at the abutments, due to the expansion of the up-stream face relative to the down-stream face.

The change in stress distribution does not alter the arch deflection appreciably, whereas on a straight gravity dam a variable working value of E may not change the stress distribution appreciably, but will materially alter the deflection of the dam in a down-stream direction.

As indicated previously, the assumption of a more or less uniform distribution of the water-soaking effect between the up-stream and down-stream faces is most plausible. This is in line with the ordinary assumption made for the action of uplift.

When computing maximum arch stresses in accordance with Professor Cain's formulas, it seems best to neglect any help as to better distribution obtainable from the water-soaking effect and the variation in the value of E between the two faces for sustained load, since their values can not be definitely measured; but if that is done, there is no reason why the maximum compression could not be run up to, say, 1 000 lb. per sq. in., provided the engineer insisted upon a 28-day strength of the concrete of 3 000 lb. per sq. in. The 1-

year strength of this concrete would be about 5 000 lb. per sq. in. and, therefore, the load stress would be carried with a margin of five.

It is not possible to design really high dams economically using maximum stresses as low as, or lower than, 600 lb. per sq. in., and since the maximum stresses only exist in parts of the dam, it should be entirely practical to make these parts of a better grade of concrete. Such parts would be near the abutments and near the bottom of high dams. Since E is not constant anyway and is least on the down-stream side, it seems perfectly logical to introduce a higher value where this is mostly effective in the form of richer concrete. With good material and good workmanship a 28-day strength of 3 000 lb. per sq. in. can be obtained in most cases, with but little more than 1 bbl. of cement per yd. of concrete.

The concrete in the Diablo Dam, on the Skagit River, in Washington, has a 28-day strength of 4 200 lb. per sq. in. This strength was insisted on, and it took 5 sacks of cement per cu. yd. of concrete to produce it. In the writer's opinion this strength was unnecessarily high since the maximum stresses in the dam were moderate, but the engineers for the City of Seattle decided it was worth while. Concrete with a 28-day strength of 3 000 lb. per sq. in. can be depended upon for good lasting qualities; high dams should be built of such material only. Such dams would have an ample safety factor even with an apparent compression of 1 000 lb. per sq. in. in some of their parts.

With Mr. Jakobsen's assumptions of $k = 0.645$ at 100 ft. below the crest and no uplift, it is apparent from Table 1 and Fig. 4, that in order to eliminate tension in the up-stream face entirely, k would have to be increased to about 0.70. This is of rather great importance. Since uplift is an unknown factor and since the most positive way of taking care of it is by adding to the weight of the dam, to the base width, or to both, a further change of k would be necessary.

The writer feels that nothing less than $k = 0.75$ should be adopted for a triangular section of a gravity dam. For very high dams, and for dams in which it is necessary to assume considerable uplift pressure, k will be still greater, but a minimum of $k = 0.75$ ought to be established by the Engineering Profession, for dams of moderate height on good foundations. Mr. Jakobsen has shown that for full uplift it is necessary to make $k = 0.844$.

C. A. P. Turner,[60] M. Am. Soc. C. E. (by letter).—Mr. Jakobsen's effort to analyze the stresses in gravity dams seems predicated upon fundamental misconceptions of the ordinary theory of flexure. For example, he refers to the ordinary theory of flexure as "classical". The customary lack of precision in stating the assumptions on which this theory is based combined with a total disregard of elementary principles by textbook writers in its elucidation, seems to predicate an antiquity of thousands of years, although its origin in fact dates back less than two and one-half centuries.

The earliest effort to investigate the resistance of beams is found in Galileo's "Discoursi e Dimostrazioni Mathematiche" published in 1638. Erroneously Galileo assumed stresses of one kind only, with an axis of rotation at the bottom of the cantilever beam considered. In 1686, Mariotte published results of tests showing that Galileo's theory was not in accord with experiment. He noted that while part of the fibers are stretched, others are compressed, and assumed without proof ("on peut concevoir") that one-half the fibers are stretched and one-half are compressed. Discussing the tests of Mariotte, Leibnitz concluded that the resistance of the fibers was in proportion to their extension.

---

[60] Cons. Engr., Minneapolis, Minn.

The further development of this theory embodying the hypothesis that the extension of the fibers is in proportion to the bending moment and to their distance from the center of gravity of the section as well is the Bernoulli-Eulerian theory or the common but inaccurate theory of flexure taught in engineering schools to-day. The assumptions involved for a rectangular section are:

1.—As many fibers are stretched as compressed.
2.—The neutral plane is the gravity axis of the section.
3.—A plane section normal to the gravity axis before bending remains normal to this axis after bending.
4.—A plane section normal to the gravity axis before bending remains a plane section after bending.
5.—The material of the beam obeys Hooke's law that strain is proportional to stress.

Internal horizontal shearing stress is correctly treated as the reaction to the summation of the horizontal fiber stresses. The center of action of the fiber stresses is 0.7071 times the half depth above the gravity axis and that of the half parabolic shear stress area is approximately 0.348 times the half depth above the same axis. Hence, the summation of a triangular fiber stress area results in a parabolic shear stress area and the neutral plane must be lowered 0.179 times the half depth below the gravity axis at the end of the beam, so that the reaction of the shearing stresses may be opposite the action of the fiber stresses, as required by Newton's third law.

Therefore, there are, in fact, more fibers compressed than are stretched in a simple beam, and the linear law of fiber stress intensity in the tension zone differs from that in the compression zone except at sections of zero internal shear strain. Since the positive shear in the compression zone at the neutral plane must equal the negative shear in the tension zone, the rate of increase of the fiber stress must be greater in the tension zone than in the compression zone except at that normal section at which the true neutral plane is tangent to the gravity axis of the beam, namely, the center of a symmetrically loaded simple beam and at the support of a cantilever.

Weisbach in his "Mechanics of Engineering", appears to have been the first to note that equilibrium of the shearing stresses must be taken into account in the problem of determining the position of the neutral plane, but he failed to solve the problem.

Assumptions (3) and (4) of the ordinary theory are inconsistent with and contradictory of Assumption (5). They present the grotesque presumption that the shearing modulus may be treated as infinitely great in lieu of its normal finite value of $\frac{3}{8} E$ for homogeneous materials.

Assumption (4) is largely innocuous; thus a normal plane before bending remains substantially plane after bending in the web of a wide flanged I-beam, yet the anti-clockwise rotation of the plane from the normal renders the error in computing the elastic deflection by the ordinary theory equal to from 15% for ordinary spans to 50%, dependent upon the relative length to depth of the beam considered.[61] By disregarding shear strain the deflections of simple beams are computed as less, and those of continuous beams as greater, than actually occurs.

For the development of the exact theory of flexure it is necessary only to assume that the material obeys Hooke's law. The linear law of fiber stress distribution upon the normal central cross-section of a symmetrically loaded simple beam and a like section at the supports of a cantilever follows inevitably from this hypothesis.

For equilibrium under internal shear the sum of the compressive fiber stresses parallel to the neutral plane must equal the sum of the tensile stresses parallel to the same plane acting upon any section normal to the neutral plane along x. Because these positive and negative forces form a couple, the moment of which is the same about any point in its plane of action, the hypothesis of a neutral plane at the gravity axis is unnecessary in developing exact summation equations of flexure.

Let the tensions and compressions parallel to the neutral plane be defined as moment stresses. Then, for a simply supported uniformly loaded beam, if w equals the uniform load per unit of length; S, the external shear force at any section; M, the applied moment; a', the slope; and D, the deflection caused by moment stresses: $S = \Sigma\, w$; $M = \Sigma\, S$; $a' = \sum \frac{M}{E\,I}$; and $D = \Sigma\, a$. The moments, slopes, and deflections of the ordinary theory are then determined at once by simple arithmetic, noting the geometrical relation that a parabolic moment area is two-thirds of its rectangle and that the third degree slope area is five-eighths of its rectangle in the computation.

It appears therefore that the ordinary theory of flexure is an exact analysis of the slopes and deflections accruing from moment stresses, that is, those parallel to the true neutral plane. Such stresses in a horizontal beam cause a clockwise rotation with respect to the vertical of every plane section normal to the true neutral axis when looking toward the left side of the simply supported beam. Shear strain, on the contrary, gives rise to anti-clockwise rotation tending to relieve the moment stresses; hence increased deflection follows until static equilibrium is restored at mid-span. Therefore, a, the true slope, is greater than $\sum \frac{M}{E\,I}$ in the simple beam or cantilever.

Because shear strain at the neutral plane is the reaction to the moment stresses and because the anti-clockwise rotation results therefrom and is limited by the relative cross-section and elastic properties of the material, the following relations may be written: True slope, a, equals moment slope, $a' \times 1 + g$; and true deflection, Δ, equals moment deflection, $D \times (1 + g)$, which constitute the only modification that need be made in the ordinary summation equations of beam theory to reduce them to values in accord with exact analysis.

---

[61] These ratios apply to steel I-beams with broad flanges.

The factor, g,[62] is a fraction that is positive for simple and cantilever beams, but negative for continuous and restrained beams. It is a constant for a given beam regardless of kind or character of loading, but varies for different beams dependent upon relative length and cross-sections of flange and web.

Shearing strains, by exact analysis, differ from those determined under the arbitrary assumptions of the common theory far more widely than the moment stresses. In the common theory of flexure the assumption that internal shear strain may be disregarded is false, because shear failure occurs in short beams and must be accounted for somehow. Accepting this assumption, textbook writers and building code authors again resort to the erroneous procedure of disregarding Newton's third law.

Although recognizing that horizontal shear strains furnish the necessary stress reactions to the positive and negative moment stresses, in order to permit their joint action as a couple, they assume, erroneously, that internal shearing stress is the reaction to external shear force because rotational strain (pure shear) presents the same rotational resistance through 360°, as shown by Cauchy; that is, horizontal shear = vertical shear at the neutral plane.

Because the horizontal shears are reactions equal to the summation of the moment stresses they cannot be equal also to the vertical external shear force since the moments under the accepted equations are equal to the summation of the shears and, therefore, cannot in general equal the external shear force at a section. To state the criticism with Euclidian finality, "two things which are not equal to the same thing cannot be equal to each other".

A graphic diagram of an unsymmetrically loaded beam best illustrates this divergence. With a concentrated load at P, in Fig. 17, distant $0.3\,L$ from the left support, the external shear passes through zero and changes sign under the load, P, and there the moment is a maximum; but at AA, a plane which divides the moment area in equal parts, internal shear strain must pass through zero where the bending moment is not a maximum and the external shear force is not zero.

Because the moment area to the left of AA equals the moment area to the right, the summation of bending to the right and left of AA must be equal as action and reaction and the shear stress parallel to the neutral plane is zero at AA and sums to the right and left toward the end of the beams. Likewise in a horizontal cantilever the summation of the horizontal shear stresses commences from zero at the support, increasing toward the free end in a manner analogous to the summation from the mid-span toward the end of the simply supported beam.

In a cantilever, horizontal shear strain passes through zero at the neutral surface at the support and the external shear force is a maximum at this point.

---

[62] The computation of g is given in Section II, "Elasticity," pp. 16 to 21.

On the contrary, in a simply supported beam the internal shear strain at the support is a maximum and the external shear force is also a maximum. Therefore, the simply supported beam is capable of resisting much smaller unit shear forces per unit of cross-section area than the cantilever, the continuous, or the restrained beam of the same cross-section. In the case of the cantilever or a continuous beam, where the internal shear at the neutral axis is zero, the external shear force must be resisted by the components of the principal stresses and the diagonal tensions and compressions due to the sharpness of curvature.

Mr. Jakobsen's painstaking investigation proceeds on the common but erroneous practice of confusing external shear force with internal shear strain.

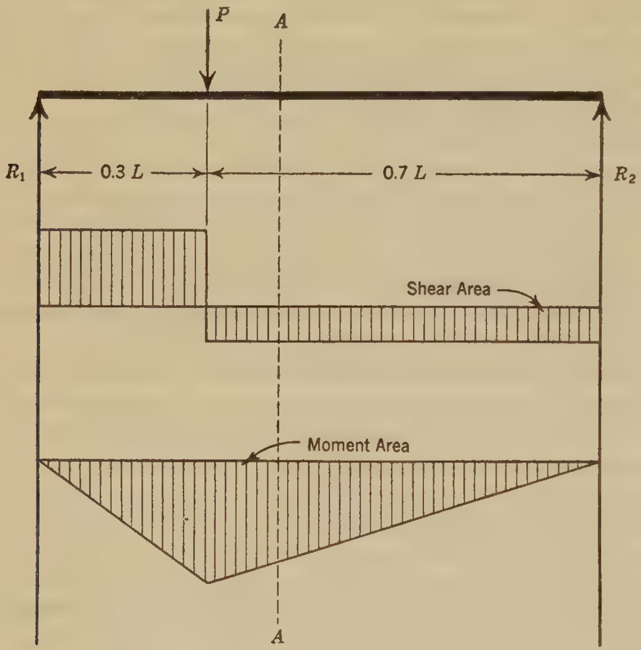

FIG. 17.

Unfortunately, therefore, it is founded on the theoretical "quicksand" of the differential calculus of assumptions and the integral calculus of presumptions rather than on the bed-rock of fundamental principles and the sound logic of the "Principia".

The linear law of fiber stress intensity at a section normal to the neutral plane is an inescapable consequence of the assumption of homogeneous elastic material subject to Hooke's law. Any supposed proof to the contrary indicates error. In the case of Mr. Jakobsen the error is embodied in the misapplication of both the common theory and exact theory of flexure to the triangular dam. The linear law applies to a section normal to the neutral plane which, at the base, coincides with the gravity center of the mass. By erroneously assuming a horizontal plane diagonal to the gravity axis the designer concludes that fiber stresses of flexure are much less than their maximum intensity; and the linear law of fiber stress intensity does not apply, and is not presumed to apply, to a section diagonal to the normal under the ordinary theory.

From the preceding discussion it appears that whether the exact theory of flexure or the common approximate theory is applied, the maximum bending stresses in the triangular dam will be determined to be of like magnitude.

The first step is to locate the critical section. The gravity axis of the triangular mass makes an angle, $\frac{1}{2}\phi$, with the vertical. The critical section inclines upward from the bed at the base of the dam at an angle of $\frac{1}{2}\phi$ to the horizontal. Obviously, this resisting section is smaller in area than the horizontal section considered by Mr. Jakobsen; the lever arm of the dead weight is less and the maximum stresses will be greater than those erroneously computed on the assumption that the critical section is horizontal and diagonal to the gravity axis. The variation in stress must follow the linear law on the critical section if the material is elastic and obeys Hooke's law. Its rate of variation on the diagonal section is an academic matter without practical interest to the busy constructor.

In attempting to point out some of the misconceptions and erroneous assumptions presented in textbook theory, it will be well to call attention to the general misunderstanding of the exact nature of Poisson's ratio.

The lateral contraction of elastic material under longitudinal strain is brought about by the inclination of the planes of greatest shear to the axial direction of the stress. This inclination is a constant at 45° in all cases of homogeneous strain, but it differs from 45° in all cases of heterogeneous strain. Therefore, $\frac{1}{m}$ for a case of heterogeneous strain is different and distinct from $\frac{1}{m}$ in the case of homogeneous strain, a fundamental relation which is lost sight of in Mr. Jakobsen's discussion.

The determinate structure is one in which the reactions are determined by the law of gravitation and the principle of the simple lever; hence the deflection and work of deformation are the greatest that the resistance of the material permits under the principle of the lever.

The indeterminate structure, on the contrary, is governed by the principle of rigidities, which asserts that where there are different paths by which the load may travel to the support, it divides itself between these several paths strictly in proportion to the respective rigidities, and when so divided the work of deformation will be less than with any other or different division. Thus arises the so-called "law of least work."

The old preparatory school algebras taught that if a function of the two variables is plotted when the value of Y along X is a maximum, the tangent to the curve becomes parallel to the axis of abscissas; that is, its angle thereto equals zero and its tangent, $\frac{dy}{dx}$, is also zero. In like manner where the value of Y along X is a minimum the tangent to the curve is likewise parallel to the axis of abscissas and its angle therewith passes through zero.

These relations comprise the old-fashioned criterion for maximum and minimum values. Men of the modernistic school and textbook writers insist upon treating this old and familiar principle in the theory of work as the derivative of the work function and render it so mysterious that maximum values are confused with minimum, and the precise mathematical distinction between the determinate and indeterminate structure is lost sight of, as appears in Mr. Jakobsen's discussion.

Thus, at the outset, Mr. Jakobsen correctly classifies the section of the gravity dam as determinate under the law of gravitation and principle of the lever. Then he proceeds to derive equations of resistance upon this basis and, finally, assumes that they may be inserted in his work equations and solved by the "principle of least work", thus confusing the diverse characteristics of the determinate and indeterminate structure.

If gravity dams are to be built, the maximum stresses at the critical section should be computed with a reasonable or practical degree of accuracy. This cannot be done if sections other than the critical are selected. Taking a horizontal section of the dam, when the normal to the neutral plane makes an angle thereto, results in a moment of inertia far greater than at the critical section; so that there is a large error on the unsafe side in the computation so made; and this, according to Mr. Jakobsen, is the ordinary but inaccurate procedure of hydraulic engineers in general.

The writer's opinion of the gravity dam is that it may be regarded as reasonably economical where the head of water to be impounded does not much exceed 15 or 20 ft. For a higher dam the gravity type which has been handed down from an ancient period is highly uneconomical. It lacks the fundamental characteristics that are desirable from the standpoint of safety. Thus, with the gravity type, as the head increases the over-turning resistance decreases, but with a properly designed reinforced concrete dam having an inclined up-stream face, on the contrary, as the pressure increases the overturning resistance by that pressure increases in like ratio, and the rational elements of stability are combined with greater economy. Why hold on to that which is obsolete instead of that which is up to date and modern? This is a question to which hydraulic engineers should give consideration in the light of the wastefulness and reduced safety in their customary manner of building.

Donald P. Barnes,[63] Jun. Am. Soc. C. E. (by letter).—The accumulated evidence that the assumption of linear stress distribution is in error may be regarded as conclusive. Mr. Jakobsen's analysis is theoretical proof for the case of a dam on a rigid foundation, and the various experimental results cited by him are factual evidence of the inaccuracy of the old theory. That this inaccuracy is appreciable, and that the real maximum stresses are materially greater than indicated by the straight-line theory are likewise justifiable inferences. There remains, however, considerable uncertainty as to the closeness with which the results obtained by Mr. Jakobsen's method approximate the true stresses.

---

[63] Instr., Civ. Eng. Dept., Missouri School of Mines and Metallurgy, Univ. of Missouri, Rolla, Mo.

This uncertainty arises, perhaps primarily from the assumption of a rigid foundation. The author has himself observed in the closing paragraph of Appendix III that no account is taken of irregularities of the base, and also that "* * * as Dr. Vogt has shown, the foundation does not remain plane when the stresses are linear." The philosophy of the principle of least work is probably entirely acceptable, but the statement of its application should be the condition that the sum of the internal work of the dam and of the foundation shall be a minimum. It does not follow that the work of either, alone, would be minimum.

The inclusion of the internal work of the foundation may be an insurmountable mathematical obstacle. Its neglect, however, would seem to render the utility of Mr. Jakobsen's results largely dependent upon experimental confirmation. In this connection, the results of a physical investigation recently completed on a celluloid model may be of interest.[64]

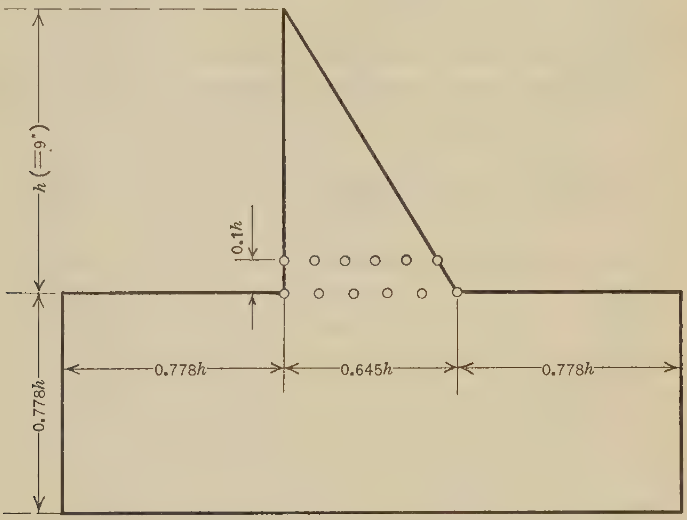

FIG. 18.—SHAPE OF MODEL AND POSITION OF POINTS THE DISPLACEMENTS OF WHICH WERE MEASURED.

The model was cut in the proportions shown in Fig. 18, the dam portion being exactly the same shape as the first profile analyzed by Mr. Jakobsen, but cut in one piece with the base, in order to include the effect of the elasticity of the foundation as nearly as practicable. Loads graduated to simulate water pressure were applied to the the up-stream face. The weight of the structure itself (gravity load) was neglected, as was also the vertical water pressure on that part of the foundation under the reservoir. The condition was that discussed by Mr. Jakobsen in Article VIII.

---

[64] "On Stresses in Gravity Dams," Thesis presented at California Inst. of Technology, June, 1930.

The vertical components of the displacements of the points shown were measured with micrometer microscopes. These distances were plotted to an exaggerated vertical scale and curves drawn through the points. The curve of the upper row of points was extrapolated at the down-stream end. Differences between ordinates to points lying in the same vertical line on the two curves, divided by the interval between the rows, were assumed to equal the unit vertical deformations, δ, of corresponding points on the intermediate section (one-twentieth of the height from the base).

From the application of Hooke's law, considering Poisson's ratio,

$$\delta = \frac{n_y}{E} - \frac{n_x}{E} \frac{1}{m} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

in which, n_y, n_x, E, and $\frac{1}{m}$ are the vertical and horizontal unit stresses, the modulus of elasticity, and Poisson's ratio, respectively, for celluloid. From Equation (46) and the measured values of δ, assuming $E = 295\,000$ lb. per sq. in., $\frac{1}{m} = 0.32$, and $n_x = 58$ lb. per sq. in. (approximate average, assumed constant across the base), a stress curve similar in shape to that of Fig. 19 was found for which the equilibrium equations, $\Sigma\, n_y = 0$, and $\Sigma\, M = 0$, constituting a check, were completely satisfied. However, George E. Beggs, M. Am. Soc. C. E., gives[65] $E = 263\,750$ lb. per sq. in., and $m = 2.38$ $\left(\frac{1}{m} = 0.42\right)$ for celluloid. This circumstance, combined with the fact that no check of these values was made for the model in question, detracts somewhat from the value of the check noted.

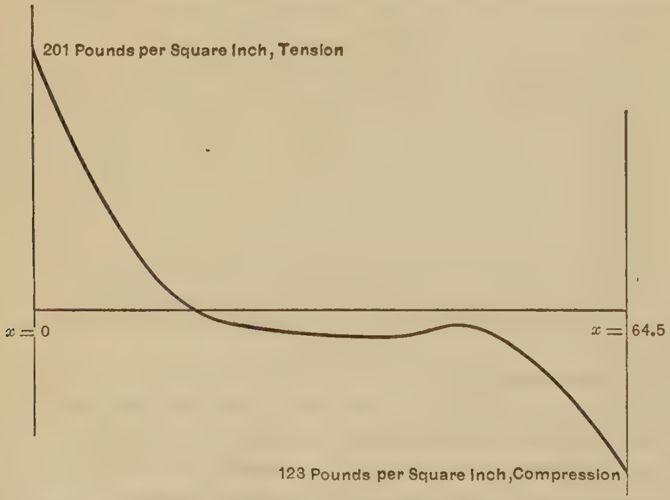

FIG. 19.—BENDING STRESSES AS EXPERIMENTALLY DETERMINED.

---

[65] Report on Arch Dam Investigation, *Proceedings*, Am. Soc. C. E., Pt. 3, May, 1928, p. 219.

The stresses in the hypothetical concrete dam were obtained from the stresses in the celluloid by applying the constant ratio, 0.651, obtained from the relations of the dimensions and loads of the dam and model. Fig. 19 is the curve of these stresses.

For this case of horizontal loads only, it will be seen that the experiment referred to, indicates a maximum tensile stress about twice as great as that found by the straight-line theory and a compressive stress about 25% greater. Mr. Jakobsen's analysis gives a tensile stress about 43% greater and a compressive stress about 20% less than those found by the linear theory.

It does not appear that the experimental confirmation of Mr. Jakobsen's method at present available is sufficient to warrant its use in practical design, particularly inasmuch as its fundamental assumption, that of the principle of least work, is not so applied as to include the effect of the foundation. His paper is, however, a strong argument for the use of much greater conservatism in the selection of a profile than is the present practice.

ANTHONY HOADLEY,[66] ASSOC. M. AM. SOC. C. E. (by letter).—The author has thrown considerable doubt on the validity of the "middle-third" rule which has been widely used in the design of dams. The results of his theoretical investigations form another piece of evidence, in addition to several others which have been brought sharply to the engineer's attention in the last few years, calling for a conservative viewpoint in the design of gravity dams. In order to obtain a workable set of equations it has been necessary to set up a formidable array of restrictions. These restrictions are analogous to those used in developing the theory of stress distribution in reinforced concrete. Although the actual stress distribution in either dam or reinforced concrete member will differ from the theoretical distribution, it seems to the writer that the theory is still a useful tool to the designer.

The theory developed by Mr. Jakobsen indicates that many existing dams must be in tension at the up-stream face. That this is possible has been indicated[67] by Searcy B. Slack, M. Am. Soc. C. E., in reporting strain measurements which indicate stresses as high as 250 lb. per sq. in. in tension. In commenting on the Yadkin River Bridge tests, Clyde T. Morris, M. Am. Soc. C. E., states,[68]

> "2.—The calculated compressive stress at any section of the rib checks the observed stress more closely when it is assumed that the concrete takes tension, than when it is assumed that the concrete is not active in resisting tensile stresses, even when high tensile stresses have caused cracks in the concrete."

How much stress a horizontal construction joint (which destroys the homogeneity of the mass, and, consequently, limits the applicability of Mr. Jakobsen's equations) will carry, is another question.

The use of a factor of safety of one in the design of dams seems to the writer to be unsafe. He is glad to see a theory presented, which calls for increasing the base width. In 1928, the writer was doing some experimental work in which a silk line (50-lb. test) was used to carry the load. The consequences of a break in the line were not severe. It meant merely an half hour spent in putting in a new piece of line plus the possibility of a cut or bruised hand; but even at that, a very uncomfortable feeling was produced each time the load approached the 50-lb. mark, which would give a "factor of safety" of one. Surely the designer of a dam should protect himself from that "uncomfortable feeling"—or worse—by using a factor of safety materially greater than one. It may be argued that the loads acting on a dam are static and definitely known, but this does not seem to be borne out by evidence produced in two papers published by the Society.[69]

[66] Asst. Prof., Civ. Eng., Union Coll., Schenectady, N. Y.

[67] "Behavior of an Arch During Construction", *Proceedings*, Am. Soc. C. E., November, 1929, Papers and Discussions, pp. 2291–2293.

[68] *Proceedings*, Am. Soc. C. E., March, 1929, Papers and Discussions, p. 611.

It is very interesting to notice the slight change in stress-distribution (Table 9) caused by assuming widely different values for Poisson's ratio. The writer wonders what the effect would be if Poisson's ratio varied from one section of the dam to another.

The writer found that, according to the theory developed by Mr. Jakobsen, the width of the base of a dam of triangular section should be 0.82 times the height if the tension is to be avoided at the heel; or, expressed in another way, the resultant force should not fall on the down-stream side of the middle thirteenth of the base. This section closely approximates that suggested by Maurice Levy. Equations (16), (17), (25), and (26) were solved for the constants A', B', C', and F', with the results shown in Table 13.

TABLE 13.—VALUES OF CONSTANTS FOR VARIOUS VALUES OF k.
($g = 62.5$; $w = 150.2$; and $m = 8$)

Constants.	$k = 0.70$.	$k = 0.75$.	$k = 0.80$.
A'	0.22617	0.11718	0.02993
B'	−4.9998	−4.4528	−4.0436
C'	8.5316	7.7501	7.1513
D'	−4.5640	−4.0027	−3.5916

Values of n_y at the up-stream face of the dam were then obtained for $k = 0.70$, 0.75, and 0.80. These values, together with those given by Mr. Jakobsen for $k = 0.645$ and 0.844, were plotted against k. This curve gave $k = 0.82$ for $n_y = 0$. The distribution of the n_y-stress was then investigated. The results, together with those obtained by Mr. Jakobsen are shown in Fig. 20.

Comparing the n_x-curve for $k = 0.645$ (Fig. 4), with the n_x-curve for $k = 0.844$ (Fig. 7), it is seen that the general shape is very closely the same. This is also true of the corresponding t stress-distribution curves. For this reason the writer has computed values of n_x and t at the toe only. These values, including those given by Mr. Jakobsen for $k = 0.645$

---

[69] "Hydrostatic Uplift in Pervious Soils", by H. de B. Parsons, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1317; and "Upward Pressure Under Dams: Experiments by the United States Bureau of Reclamation", by Julian Hinds, M. Am. Soc. C. E., *Loc. cit.*, p. 1527.

and $k = 0.844$, together with data showing the relationship between n_x n_y and t^2 are shown in Table 14.

The n_y-stresses have been obtained for a dam of triangular section which would be modified in construction by placing additional material at the top. The stress distribution in this modified section could be determined in the following manner, which is based on the fact that Mr. Jakobsen has shown the stresses due to the weight of the dam alone as computed by the theory of least work to be nearly the same as those computed on the assumption of a linear stress distribution. Compute n_y by the author's method for the triangular section. The stresses due to the added mass of concrete are then computed on the straight-line, stress-distribution theory. The resultant vertical stress will be very closely the algebraic sum of these two.

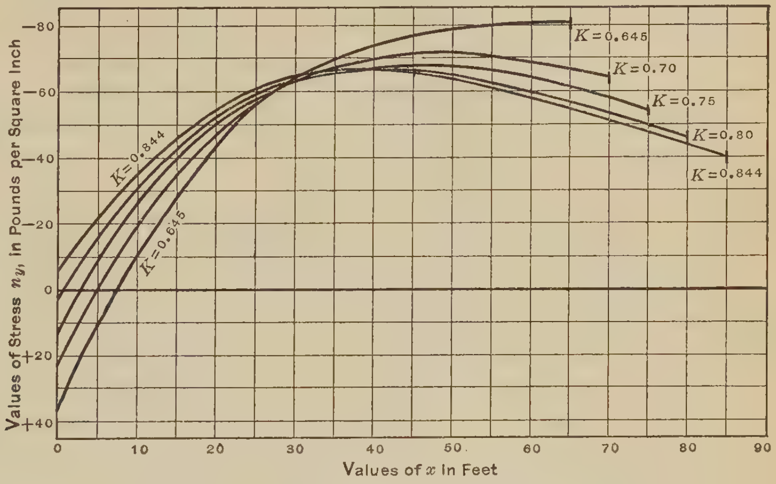

FIG. 20.—DISTRIBUTION OF STRESS, n_y, FOR SECTIONS WITH VARYING BASE WIDTH.

TABLE 14.—STRESSES AT TOE OF DAM FOR DIFFERENT WIDTHS OF BASE.

($y = 100$ ft.; $b = 100\ k$; $g = 62.5$; $w = 150.2$; $m = 8$; and stress is in pounds per square inch.)

k.	n_y.	n_x.	t.	$n_y\ n_x$.	t^2.
0.645..........	−80.81	−33.62	−52.12	2716.0	2716.0
0.70.	−65.87	−32.27	−46.10	2125.6	2125.2
0 75...........	−55.16	−31.03	−41.37	1711.6	1711.5
0.80...........	−46.70	−29.89	−37.35	1395.8	1395.0
0.844..........	−40.55	−28.90	−34.24	1171.9	1172.4

Mr. Jakobsen is to be congratulated on having made a valuable addition to present knowledge of the stress distribution in gravity dams.

FRED W. ELY,[70] M. AM. SOC. C. E. (by letter).—The author is to be commended for re-opening the discussion of stresses in gravity dams. By attacking the problem from a new angle he apparently has proved that the vertical pressures on a horizontal plane of a gravity dam do not vary in a linear relation. The popularity of the arch dam has withheld from the gravity dam the consideration that it merits, particularly as more than twenty years have passed since in 1909 the first English model tests suggested the incorrectness of the assumption of linear stress distribution. Attention also may be called to some recent tests of 8 by 8 by 12-in. prisms loaded at the edge of the middle third of the cross-section, made by Slater and Lyse[71] in connection with studies for determining the compressive strength of concrete in flexure. These are of interest in that tension was indicated on the face farthest from the loading point, particularly at the higher stresses, again indicating a non-linear stress distribution.

Further study may indicate that the author's stress equations require some modification. The results disclosed by the computations and graphs present some very startling results which suggest that Equation (15) may not be of the proper form to represent the stress relation correctly. At least, the computation of the total elastic work in some selected examples, using a basic equation of a different form, would throw additional light on the problem. As the author states, his proposed solution is only an approximation, limited by the equation assumed for n_y. This is not a general equation, even for the limited number of terms, since all the exponents of x are positive integers. There is some indication that fractional exponents might give results more in line with the results of theory and experiment in the flexure of beams.

Referring to Fig. 6 the shape of the curve for bending stress with $w = 0$ appears to be somewhat inconsistent with the assumption of similar elastic properties in tension and compression. This assumption would logically presuppose a point of inflection at the place where the stress passes through zero, the two ends of the curve having similar curvature with respect to the X-axis. This would be in line with the stresses in a beam after the material has reached the elastic limit[72] and also with the **S**-shaped foundation deformation mentioned by Vogt.[73] A tendency in this direction is also indicated in the plotting of the results of the English tests, as shown on Section 5-5 of Fig. 8. The apparent inconsistency of the shape of this curve as well as that disclosed between Equations (27) and (36) might easily be due to the fact that Equation (15) cannot represent the stress relation properly.

The writer has worked through several numerical examples by the author's method, which indicate that, for a triangular section of an average specific weight, a base width of approximately 81% of the height would be required to prevent tension at the heel, even disregarding uplift. If this stress distribution is correct, practically no existing gravity dam is free from tensile stresses and, in the majority of gravity dams more than 150 ft. high, the tendency toward tension would be so great that the horizontal joints must have opened at some elevation, thereby assuring uplift which would tend to extend the cracks. The freedom from excessive leakage through the drainage wells which have been placed in many high dams, casts further doubt on the correctness of this stress distribution.

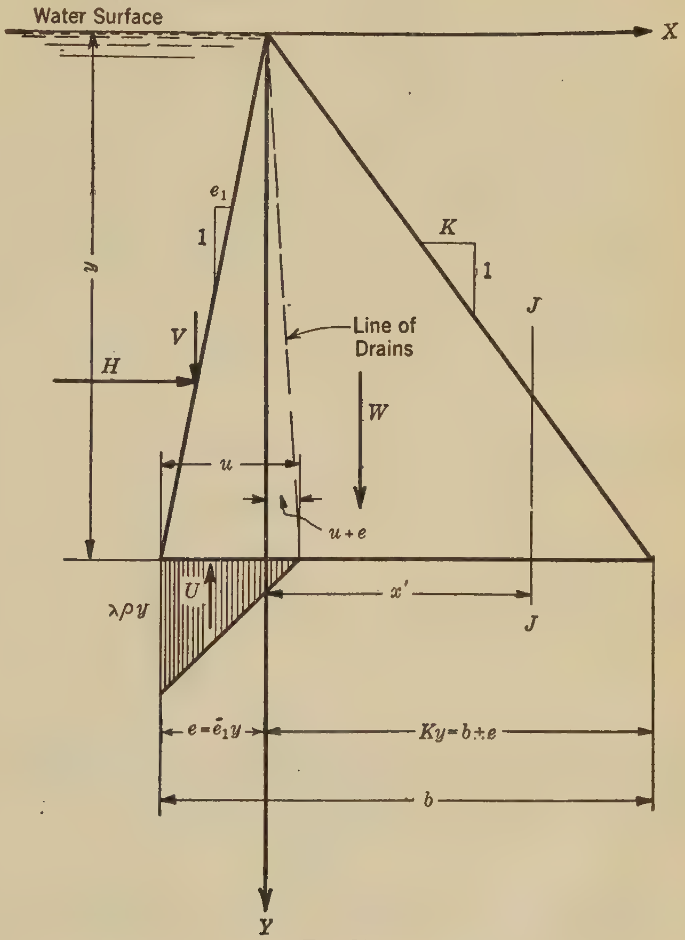

FIG. 21.

In order to obtain a more comprehensive insight into the stress distribution under the author's assumptions when applied to less usual types of section, the writer extended the method to include dams with a sloping up-stream face and has included in the general equations the effect of uplift. The additional nomenclature required is as follows (see Fig. 21):

e = minimum value of x for any given value of y (negative for the section shown in Fig. 21).

e_1 = batter of up-stream face $= \dfrac{e}{y}$.

k = batter of down-stream face $\left(\text{not equal to } \dfrac{b}{y} \text{ unless } e = 0\right)$.

ρ = unit water pressure in masonry units $= \dfrac{g}{w}$.

u = distance from up-stream face to point where uplift pressure is assumed equal to zero.

λ = proportional part of the base, perpendicular to the plane of the paper, over which uplift pressure is assumed to act.

The uplift condition assumed is that of full hydrostatic pressure at the heel, decreasing by a linear relation to zero at some distance from the heel where the drainage system is assumed to offer full relief. For the usual assumption of "full uplift", $u = b$ and $\lambda = 1$. It may be noted that e and e_1 would be positive in numerical value for an overhanging up-stream face.

An outline of the method of deriving the general equations, together with numerical results for one example, is given.

Based on the assumption of Equation (15), the vertical reaction of the foundation (or part of dam below any horizontal plane) at any point, x, y, is

$$p = A\,y + B\,x + C\,\frac{x^2}{y} + F\,\frac{x^3}{y^2} \qquad \text{(47)}$$

To obtain the vertical stress in the concrete the uplift pressure at the point, $\left(= -\lambda\,\rho\,y\,\dfrac{u + e - x}{u}\right)$, must be added to the value of p in Equation (47). If $\lambda = 0$, $p = n_y$.

Considering the forces acting to the right of a vertical plane, J-J, the requirements for equilibrium of the severed portion are:

$$\int_{x'}^{Ky} p\,dx + W_1 - \left[\int_{x'}^{u+e} \lambda\,\rho\,y\,\frac{u + e - x}{u}\,dx\right] = S_1 \qquad \text{(48)}$$

in which, W_1 is the weight of the severed portion to the right of the plane, J-J, and S_1 is the total shear along the plane, J-J. The portion within the brackets should be considered only when x' is less than $(u + e)$.

The intensity of shear at the point, x', y, will be,

$$t = \frac{dS_1}{dy} \qquad \text{(49)}$$

Again, the total horizontal pressure against the plane, J-J, will be represented by,

$$N_1 = \int_{x'}^{Ky} t\,dx \qquad \text{(50)}$$

and the intensity of horizontal pressure at the point, x', y, will be,

$$n_x = \frac{dN_1}{dy} \qquad \text{(51)}$$

A solution of Equations (47), (48), (49), (50), and (51), gives the following stress relations in masonry units for the general case:

$$n_y = A\,y + B\,x + C\,\frac{x^2}{y} + F\,\frac{x^3}{y^2} - \lambda\,\rho\,y\,\frac{u + e - x}{u} \ldots\ldots (52)$$

$$\begin{aligned} n_x = {} & A\,(3\,K^2\,y - 2\,K\,x) + B\,(2\,K^3\,y - K^2\,x) \\ & + C\left(\frac{3}{2}\,K^4\,y - \frac{2}{3}\,K^3 x + \frac{x^4}{6\,y^3}\right) + F\left(\frac{6}{5}\,K^5\,y - \frac{K^4\,x}{2} + \frac{3}{10}\,\frac{x^5}{y^4}\right) \\ & + K^2\,y - K\,x - \lambda\,\rho\,\frac{(u + e)^2}{u\,y}\,(u + e - x) \ldots\ldots\ldots\ldots (53) \end{aligned}$$

and,

$$\begin{aligned} t = {} & A\,(2\,K\,y - x) + B\,K^2\,y + C\left(\frac{2}{3}\,K^3\,y + \frac{x^3}{3\,y^2}\right) + F\left(\frac{K^4\,y}{2} + \frac{x^4}{2\,y^3}\right) \\ & + K\,y - x - \lambda\,\rho\,\frac{u + e}{u}\,(u + e - x) \ldots\ldots\ldots\ldots\ldots\ldots (54) \end{aligned}$$

For values of x greater than $(u + e)$, the last term of Equations (52) to (54), inclusive, must be omitted. When no uplift is assumed, $\lambda = 0$, and the last term of each equation drops out.

The equations corresponding to Equations (3) and (4) are:

$$\int_{e_1 y}^{K y} p\,dx = \frac{y^2}{2}\,[e_1\,(\rho + 1) - K + \lambda\,\rho\,u_1] \ldots\ldots\ldots\ldots (55)$$

and,

$$\int_{e_1 y}^{K y} p\,x\,dx = -\frac{y^3}{6}\,[\rho + K^2 - e_1^{\,2} - 2\,\rho\,e_1^{\,2} - \lambda\,\rho\,u_1\,(u_1 + 3\,e_1)] \ldots (56)$$

in which, $u_1 = \frac{u}{y}$. The boundary conditions are:

At the toe,

$$t^2 = n_y\,n_x \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

At the heel,

$$n_y\,e_1 + \rho\,y\,e_1\,(1 - \lambda) - t = 0 \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

and,

$$n_x + \rho\,y - t\,e_1 = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (59)$$

Equations (19) and (20) are modified only by changing the limits of integration with respect to x. These become $e_1\,y$ to $k\,y$ instead of 0 to b. These modified equations together with Equations (55) and (56) suffice to determine the parameters A, B, C, and F. A considerably greater amount of numerical computation is required in the solution than for the simple case of a vertical up-stream face, but it is lengthy rather than difficult.

The following equations show the stress relations in masonry units for a specific case, in which, $\lambda = 0$; $\frac{b}{y} = 0.80$; $k = 0.60$; $e_1 = -0.20$; $\rho = 0.416025$; and $m = 6$; thus,

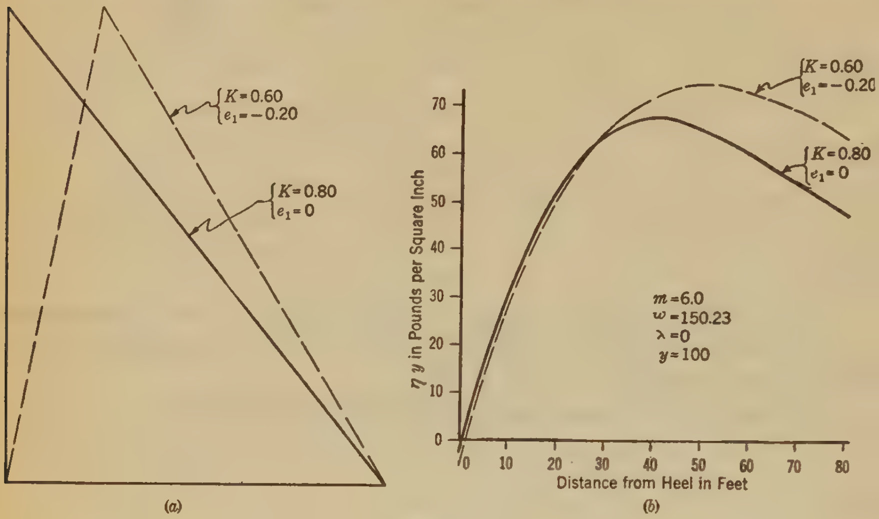
$$n_y = -0.47905\;y - 1.7814\,x + 4.0734\,\frac{x^2}{y} - 2.4214\,\frac{x^3}{y^2} \ldots\ldots (60)$$

$$n_x = -0.36102\;y + 0.18650\,x + 0.67890\,\frac{x^4}{y^3} - 0.72643\,\frac{x^5}{y^4} \ldots (61)$$

and,

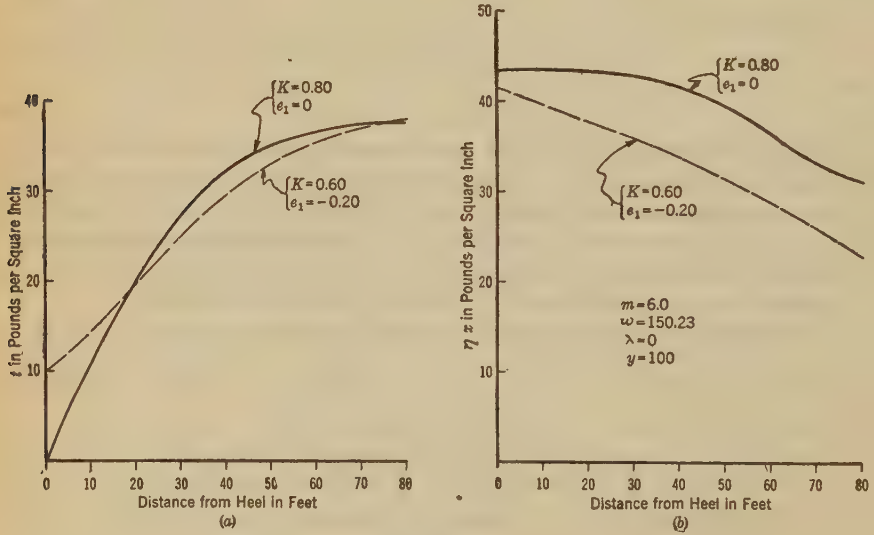
$$t = -0.18650\,y - 0.52095\,x + 1.3578\,\frac{x^3}{y^2} - 1.2107\,\frac{x^4}{y^3}\ldots\ldots(62)$$

The stresses from Equation (60) for $y = 100$, reduced to pounds per square inch, are plotted to scale in Fig. 22, which also shows the n_y-curve for a section of identical base width, but with a vertical up-stream face. A comparison of the two sections is shown in the upper part of the diagram. Fig. 23 shows a plotting of the horizontal stress and shearing stress for the two sections.



(a) (b)

FIG. 22.



(a) (b)

FIG. 23.

It is interesting to note the close correspondence of the two vertical stress curves in Fig. 22(*b*), throughout the up-stream 30 ft. of base width. The conditions at the heel are more favorable for the inclined up-stream face as compared to a vertical face than would be the case with linear stress distribution.

If the stress distribution assumed in Equation (15) is confirmed by further theoretical analysis and experiment, gravity dams with an appreciable upstream slope would appear worthy of more consideration because of their greater resistance to sliding on the foundation.

M. H. GERRY, JR.,[74] M. AM. SOC. C. E. (by letter).—This paper is important to engineering science, because it directs attention to certain fundamental principles underlying the transmission of stress through a mass. It does not of itself, however, offer a solution of stress distribution in actual dams, but is rather a mathematical discussion based on an assumed state of unknown facts. Nevertheless, it is of value because it points the way to further progress and calls to notice some common errors.

The manner in which stress acts on and through bodies of various kinds is unknown in any exact sense and no general solution is possible until far more is learned of the molecular state of matter. Moreover, stress acts in three dimensions and not only in two, as assumed for convenience of computation in this paper. The mathematical difficulties of the problem are very great, but by no means insuperable. The crux of the situation is the insufficiency of knowledge concerning physical facts and this can be overcome only by long and extensive laboratory research; there is no short cut.

The theory of "least work" is apparently a sound and scientific method of approach, but more than mere assumptions must be available before general conclusions of value can be determined from its application.

The present methods of treating stress distribution in structures are well known to be empirical and approximate only, and it is most important that this fact be fully and constantly recognized by designing engineers.

The so-called elastic theory is such a case and it should never be applied outside the known limits of actual experiment. A definite "modulus of elasticity" is a mathematical fiction in so far as it represents a positive condition of a material. Over any considerable range it is quite commonly a variable and at best the modulus is merely a constant of experiment, its correctness being limited to the special physical conditions and dimensions at which it was determined.

Concrete is elastic in only a very limited way. It is not a distinct material, but rather an artificial conglomerate of which little is known in a scientific sense. It has no true elastic limit, and it flows and yields inelastically under moderate loadings. At all ages, concrete when passing from a dry to a wet state expands and its strength and elasticity materially change, while time, temperature, stress, and vibration further alter its character. Thus, it is idle to attempt an exact general analysis of stress distribution in an uncertain mass, such as a dam, as long as the profession remains intensely ignorant of the basic facts concerning stress in highly uniform and far more elastic materials.

---

[74] Cons. Engr., San Francisco, Calif.

At present, the design of gravity dams is purely empirical; attempts to cloak certain phases in a mathematical fog have only resulted in serious errors, causing many failures. Unfortunately, there has been a tendency to follow a fetish and to place total reliance on a margin of safety in one particular only, while overlooking entirely, weakness in other directions. All modern gravity dams of concrete, having triangular sections and bases of more than two-thirds the height, provide good margins of safety as to stress, but all too frequently they are close to the danger line in other respects. The proper limiting of stress in gravity dams is important, and, in future very high dams, it may control; but for present-day structures, it does not enter to the same degree as other important conditions for safety.

FREDRIK VOGT,[75] ASSOC. M. AM. SOC. C. E. (by letter).—Gravity dams are now designed to heights which surpass those of all previous dams, and hence stresses are approaching the allowable limit. For such large dams an eventual saving by reducing the ratio, base width to height, is so great that it pays to improve the analysis in order to find the lower limit of this ratio which can be used without danger, and to ascertain the actual value of the safety factor. It is fortunate, therefore, that the author has chosen for discussion the stress problems for gravity dams and has thus broadened the knowledge of engineers on this subject.

The principal question is whether or not the classical theory, which supposes a linear distribution of the vertical normal stresses, is on the safe side. The tensile stresses are the most dangerous, particularly those at the up-stream face, since the tensile strength of concrete is not to be trusted, and since horizontal tensile cracks at the up-stream face will eventually cause uplift forces from water penetrating into such cracks. The greatest emphasis, therefore, should be laid on a correct computation of the stresses at the up-stream face, and the design should be executed so that all possibilities of vertical tensile stresses at the up-stream face are eliminated as far as possible for all dams in which stability depends mostly on gravity action.

According to the classical theory, the triangular-shaped dam in Fig. 1 will be exposed to maximum principal stresses, $n_1 = -g\,y\left(1 + \frac{1}{k^2}\right)$, at the down-stream face when loaded, and $n_2 = -w\,y$, at the up-stream face when unloaded.

Smaller ratios of base width to height, than $k = \sqrt{\frac{g}{w}}$ are never used. With $g = 62.5$ and $w = 150$ lb. per cu. ft., this gives $k = 0.645$, and a maximum compression of 600 lb. per sq. in. is then obtained for $y = 407$ ft. Even if the classical theory is not accurate, this will suffice to prove that the magnitude of the compressive stresses in gravity dams has no direct significance in the design before the height is approaching or surpassing 400 ft., assuming that first-class concrete and rock foundation are obtained.

---

[75] Prof. of Mechanics, Norges Tekniske Höiskole, Trondhjem, Norway.

It seems desirable to study in detail the solution by the classical theory for comparison with the author's method. Using the notations from Fig. 1 the author gives the stresses according to the classical theory in Equations (13), and these stresses satisfy the equilibrium equations and the boundary conditions both at the up-stream and the down-stream faces. Let e_x and e_y be the displacements of a point, x, y. For the two-dimensioned system the compatibility equations are, therefore,

$$E\,\frac{\delta\,e_x}{\delta\,x} = n_x - \frac{n_y}{m} \qquad \text{(63)}$$

$$E\,\frac{\delta\,e_y}{\delta\,y} = n_y - \frac{n_x}{m} \qquad \text{(64)}$$

and,

$$t = G\left(\frac{\delta\,e_x}{\delta\,y} + \frac{\delta\,e_y}{\delta\,x}\right) \qquad \text{(65)}$$

in which, $m\,E = 2\,(m + 1)\,G$.

The displacements, e_x and e_y, can be eliminated after derivation of Equation (63) for e_x twice with respect to y, of Equation (64) twice with respect to x, and of Equation (65) twice with respect to x and y. By introducing the equilibrium Equations (6) and (7), t and the derivative of n_x with regard to x can also be eliminated, and the following compatibility equation is obtained:

$$\frac{\delta^2\,n_y}{\delta\,x^2} + 2\,\frac{\delta^2\,n_y}{\delta y^2} + \frac{\delta^2\,n_x}{\delta\,y^2} = 0 \qquad \text{(66)}$$

By a repeated double derivation n_x also can be eliminated, but the form of Equation (66) is convenient for the purpose in question.

The stresses, Equations (13), satisfy the compatibility equation, and the displacements, e_x and e_y, can be found, therefore, by integration:

$$e_x = \frac{1}{E}\left[\left(\frac{g}{k^3} - \frac{w}{2\,k}\right)y^2 - \left(g + \frac{g}{m\,k^2} - \frac{w}{m}\right)x\,y + \left(\frac{g}{m\,k^3} - \frac{w}{2\,m\,k}\right)x^2 - a\,y + c\right] \qquad \text{(67)}$$

and,

$$e_y = \frac{1}{E}\left[\left(\frac{g}{2\,m} + \frac{g}{2\,k^2} - \frac{w}{2}\right)y^2 - \left(\frac{2\,g}{k^3} - \frac{w}{k}\right)x\,y - \left(\frac{g}{k^2} + \frac{g}{2\,m\,k^2} - \frac{g}{2} + \frac{w}{2\,m}\right)x^2 + a\,x + d\right] \qquad \text{(68)}$$

The coefficients, a, c, and d, give only the position of the deformed section relative to the co-ordinate system, but have no influence on the stresses or on the deformation of the section.

The dead load is placed successively during the construction period, and part of the dead load deformation, therefore, is obtained before the section is completed. Equation (68) is, therefore, not valid for the dead load. The fresh concrete also will be partly plastic and not elastic; and the modulus of elasticity is lower for fresh than for aged concrete. Hence, it seems better to consider the stresses and deformations due to water load only, which are found by making w equal to zero in the equations. The author's criticism of the classical theory also mainly concerns the stresses due to water load only.

For the foundation line of the section, y ($= h$) is a constant, and the vertical displacements are then given by a parabolic curve convex downward since the equation for e_y contains a term, x^2, with a negative coefficient. Assuming that $m = 6$ and $k = 0.645$, the rise of the curve is found to be,

$$\frac{1}{4}\left(1 + \frac{1}{2\,m} - \frac{k^2}{2}\right)\frac{g\,h^2}{E} = 0.22\,\frac{g\,h^2}{E} \ldots\ldots\ldots\ldots\ldots (69)$$

At the same time, the width of the base line is reduced with $k\,\dfrac{g\,h^2}{E} = 0.645\,\dfrac{g\,h^2}{E}$.

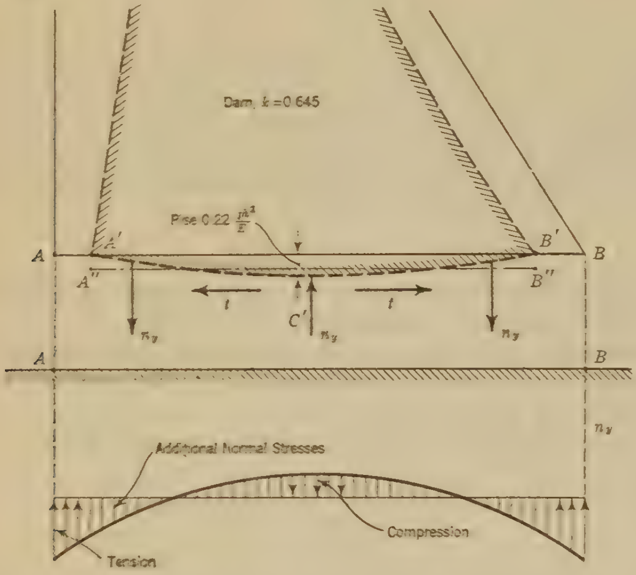


FIG. 24.—DEFORMATION OF DAM SECTION DUE TO WATER LOAD ONLY, ACCORDING TO CLASSICAL THEORY, AND ADDITIONAL STRESSES TO BE APPLIED IN ORDER TO MAKE DAM SECTION FIT AN UNYIELDING FOUNDATION

If the foundation is unyielding, additional stresses would have to be applied, as shown in Fig. 24, in order to straighten the line, $A'\,C'\,B'$, and to lengthen it to fit the line, $A\,B$, of the foundation. Shearing stresses directed from the center toward A and B are necessary in order to increase the length, but these acting alone would increase the rise. Hence, the additional normal stresses must be tensile stresses near both faces and compressive stresses at the center; that is, the corrected normal stresses due to water load only must be tensile stresses, greater than those found by the classical theory near the up-stream face, and compressive stresses, less than those found by this theory at the down-stream face. The tendency of these corrections is the same as that found by the author (Fig. 6).

The stresses represented by Equations (13) resulting from the water load only, will lengthen the height, h, of the up-stream face with $\frac{g\,h^2}{2\,k^2\,E} = 1.2\,\frac{g\,h^2}{E}$. To straighten the line, $A'\,C'\,B'$, so that it coincides with the line, $A''\,B''$, when the distance, $A'\,A''$, equals $\frac{2}{3}$ times $0.22\,\frac{g\,h^2}{E}$, an average change in stresses at both faces equal to $\frac{2}{3}$ times $\frac{0.22}{1.2}$, or 12%, approximately, is required. Because of uneven distribution of these additional stresses over the height, and because of additional curving due to shearing stresses, the corrections to be added may be somewhat larger at the base.

The foregoing remarks are based on the assumption that the foundation is unyielding, but it will always yield elastically, and the deformations can be computed for any given load on a plane foundation, as shown in a paper by the writer.[76] It is convenient to consider three different types of loads on the foundation, namely, the direct pressure, $g\,h$, per unit area on the foundation at the left of A, the shearing stresses from the dam between A and B, and the bending stresses from the dam between A and B.

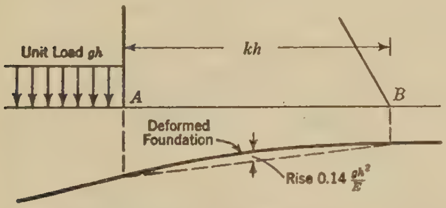

FIG. 25.—VERTICAL DEFORMATION OF FOUNDATION DUE TO DIRECT WATER LOAD

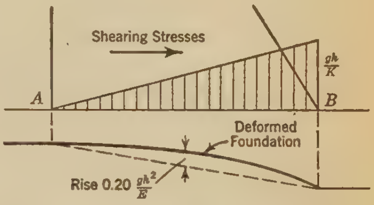

FIG. 26.—VERTICAL DEFORMATION OF FOUNDATION DUE TO SHEARING STRESS

The direct load applied at the left of A will bend the line, $A\,B$, of the foundation so that it becomes convex upward (see Fig. 25). The middle ordinate of the curve for this length can be computed by assuming that the length, $A\,B$, is small compared with the length of the dam and the width of the reservoir.[77] The equation for this purpose is,

$$\frac{m^2 - 1}{m^2} \times \frac{1\,n\,2}{\pi} \times k\,\frac{g\,h^2}{E_r} = 0.14\,\frac{g\,h^2}{E_r} \ldots\ldots\ldots\ldots (70)$$

in which, E_r is the modulus of elasticity for the rock, and m and k are introduced with the values used before.

The shearing stresses, with distribution, as given by Equations (13), will also curve the foundation line, $A\,B$, the same way (see Fig. 26). The middle ordinate in this case is computed by means of the general formula:[78]

$$\frac{(m - 2)\,(m + 1)}{4\,m^2}\,\frac{g\,h^2}{E_r} = 0.20\,\frac{g\,h^2}{E_r} \ldots\ldots\ldots\ldots\ldots (71)$$

[76] "Ueber die Berechnung der Fundamentdeformation," Det Norske Videnskaps Akademi, Oslo, 1925.

[77] *Loc. cit.*, p. 7.

[78] *Loc. cit.*, p. 26.

Both these curvings of the foundation line increase the disagreements already shown in Fig. 24. The total rise of the different curves is (assuming that $E_r = E$), $(0.22 + 0.14 + 0.20) \frac{g\,h^2}{E} = 0.56 \frac{g\,h^2}{E}$. This must be compensated by stresses, as shown in Fig. 24, which will deform both dam and foundation. Since the foundation is assumed to yield, the method of estimating used in connection with Fig. 24 cannot be applied directly to this case. The writer believes that the stresses due to water load may be changed as much as 25 to 30% because of this curving. According to Table 5 the author found an increase by his method of +37% and —23% at the two faces, which checks very well with the writer's estimate.

The bending stresses on the foundation due to water load on the dam are, according to the classical theory, $\pm \frac{g\,h}{k^2}$ at both faces (see Fig. 27). These stresses will deform the foundation to an **S**-shape, as shown in Fig. 27. The average tilting is represented by a line, $A'\,B'$, or,

$$A\ A' = B\ B' = \frac{m^2 - 1}{m^2} \, \frac{3}{2\,\pi\,k} \, \frac{g\,h^2}{E_r} = 0.72 \, \frac{g\,h^2}{E_r} \ldots\ldots\ldots\ldots (72)$$

FIG. 28.—STRESSES AT CONVEX CURVED DOWN-STREAM FACE

The maximum deviation from the straight line, $A'\,B'$, is found at A and B by the formula,

$$A'\ A'' = B'\ B'' = \frac{A\ A'}{3} = 0.24 \, \frac{g\,h^2}{E_r} \ldots\ldots\ldots\ldots\ldots (73)$$

which in this case is equal to 20% of the total tensile deformation at the upstream face. In order to adjust the dam and foundation so that they fit together, additional stresses must be applied as shown in Fig. 27. It is difficult to estimate the magnitude of these stresses. However, since they change from maximum tension to maximum compression in a much shorter length than the additional stresses shown in Fig. 24, it is obvious that they must also decrease to zero at depths which are correspondingly smaller. In order to obtain a large deformation in a short distance, the additional stresses (Fig. 27), must be rather large, but the effect will be negligible at a comparatively small distance from the foundation joint.

The base width, *A B*, will be changed by the deformation of the foundation, which again may cause some new redistribution of the stresses.

All the foregoing computations concern the stresses due to water load only. If the dead load stresses were applied after the construction was completed, the total difference between the deformed dam and foundation was reduced to about one-half. Furthermore, the additional stresses due to these disagreements then would be reduced to one-half. However, for reasons previously discussed, such computations for the dead load deformations cannot be considered to be correct.

The author's method is based on the assumption that the stresses, n_y, are distributed in the same manner for two joints at different elevations and that the magnitude at two points similarly located in these joints is proportional to y. Two points are similarly located in the horizontal joints if the ratio, $z = \frac{x}{y}$, is the same for both points, and this assumption, therefore, can be expressed by the formula,

$$n_y = y\, f\,(z) \qquad \text{(74)}$$

in which, $z = \frac{x}{y}$.

Equation (15) can be found from Equation (74) by developing $f\,(z)$ in series, neglecting all terms after the fourth. By introducing n_y, as given in Equation (74), in the equilibrium Equations (6) and (7), these can be integrated. For convenience, let $F\,(z)$ be a function of $z = \frac{x}{y}$, and let the derivatives thereof with regard to z be $F'\,(z)$, $F''\,(z)$, etc., and let this function be defined so that $F''\,(z) = f\,(z)$. Then, by integration,

$$n_y = y\, f\,(z) = y\; F''\,(z) \qquad \text{(75)}$$

$$n_x = y\,[6\,F\,(z) - 4\,z\,F'\,(z) + z^2\,F''\,(z)] + h\,(y) - x\,g'\,(y) \qquad \text{(76)}$$

and,

$$t = y\,[-w\,z - 2\,F'\,(z) + z\,F''\,(z)] + g\,(y) \qquad \text{(77)}$$

in which, $g\,(y)$ and $h\,(y)$ are two independent functions of y. The correctness of Equations (75), (76), and (77) can easily be checked by introducing in Equations (6) and (7), which are satisfied since $\frac{\delta\, z}{\delta\, x} = \frac{1}{y}$ and $\frac{\delta\, z}{\delta\, y} = -\frac{z}{y}$.

At the down-stream face, $z = k$, and for this value of z Equations (75) to (77) must satisfy the boundary conditions defined by Equations (8) and (9), whereby the functions, $g\,(y)$ and $h\,(y)$, are restricted to the forms,

$$g\,(y) = a\,y \qquad \text{(78)}$$

and,

$$h\,(y) = b\,y \qquad \text{(79)}$$

in which, a and b are constants. After introducing these functions in Equations (75) to (77), both t and n_x can be expressed by y times the functions of z only; that is, by equations of the type given in Equation (74).

The stresses must satisfy the compatibility Equation (66), and by introducing the stresses defined by Equations (75) to (79) in Equation (66), the latter is reduced to,

$$\frac{(z^2 + 1)^2 F'''' (z)}{y} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

Since the squared polynom cannot become zero, the compatibility equation is reduced to,

$$F'''' (z) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

which, integrated twice, gives

$$F'' (z) = A + B z \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

in which, A and B are constants, and, hence,

$$n_y = y F'' (z) = y \left(A + B \frac{x}{y}\right) = A y + B x \ldots\ldots\ldots (83)$$

This equation is identical with Equation (10) representing the classical theory.

In this manner it has been proved that no stress functions exist, except those given by the classical theory, which satisfy the condition of equilibrium, the compatibility equations, and the boundary conditions, and which at the same time give stresses proportional to the depth, y, at the joint considered. The writer has proved that the classical theory does not satisfy the compatibility equation at the foundation line. Hence, no exact solution can be found at all by means of stress functions of the type of Equation (74), or by Equation (15), which is only a special case of Equation (74).

The classical theory gives stresses which are greatly in disagreement with the compatibility equation at the foundation joint, and several large corrections are required. For non-triangular sections the classical theory does not satisfy the compatibility equation even in the dam proper.

The author's theory gives stresses which include approximately a number of necessary corrections, namely, all except those due to the S-shaped deformation of the foundation. It has been proved that the method can be only approximate since the compatibility equation is not satisfied. An exact solution can be obtained only by stress functions of a more complicated type. However, even an approximate solution means a great step forward.

The deformation of the foundation is the key of the correct solution since a change in this deformation will also change the stresses in the dam proper. Exact solutions including this point are difficult to find, particularly because of the corners at the heel and the toe of the dam, which represent singular points.

The best check on the theory can be obtained by model tests. The English tests indicate large tensile stresses at the heel of the dam in agreement with the author's theory and with the additional stresses shown in Fig. 27, but in disagreement with the classical theory. Furthermore, at some distance from the base, these tests give a slight curving of the diagram for the vertical stresses in agreement with the author's theory. The writer has been connected with tests on models of arch dams, and such a curving of the stress diagrams was found probable. However, these tests were conducted with other problems in view, and the results regarding this particular problem are rather indirect and should not be taken as a definite proof. It is to be hoped that the model tests demanded by the Consulting Board for the Hoover Dam may give final solutions of some of these problems.

Tensile stresses may also be produced by volumetric changes in the concrete, not only in longitudinal, but also in vertical, directions. Horizontal cracks have developed in a number of dams,[79] and such cracks have been observed even at the up-stream face of the Barberine Dam, in Switzerland, the Saint-Marc Dam, in France, and the small Tömmerholt Dam, in Norway. These cracks are obviously caused by non-uniformity in shrinkage and temperature in the mass. Such non-uniformities, therefore, have a significance comparable with that of the tensile stresses found by the author.

Another danger of tensile stresses is introduced by a convex curving of the down-stream face in a vertical plane, as shown in Fig. 28. If principal compressive stresses, n_1, are acting parallel to the face, the convex curving will eventually be followed by tensile stresses, n_2, normal to the face. On the surface of the hatched element, $A\ B\ C\ D$ (Fig. 28), no shearing stresses are acting, and the equilibrium demands that,

$$dn_2\ R\ d\alpha + w\ dz\ R\ d\alpha \sin \alpha = n_1\ dz\ d\alpha$$

or,

$$\frac{dn_2}{dz} = \frac{n_1}{R} - w \sin \alpha \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (84)$$

That is, if n_1 is larger than $R\ w \sin \alpha$, $\frac{dn_2}{dz}$ will be positive, and tensile stresses, n_2, will be developed normal to the face, increasing from zero at the very face to a maximum some place in the interior. This maximum value depends on the direction and the magnitude of the first principal stress, n_1, in the interior. The greatest danger of such tensile stresses is obtained for dams with a sharply curved steep down-stream face, that is, for small values of R and $\sin \alpha$.

Such curving of the down-stream face has been suggested in order to reduce the maximum compression in high dams, but a reduction of the compressive stresses accompanied by development of tensile stresses is no better than going from "the frying pan into the fire". Furthermore, the English tests (Fig. 8), indcate that the compressive stresses can be reduced by curving in the opposite direction, and this opposite curving shown on Fig. 8 will not introduce any tensile stresses. The suggestion to curve the face, as shown in Fig. 28, is based on the assumption that the classical theory is correct not only for a triangular section, but for all sections regardless of shape, which is certainly not true.

---

[79] "Shrinkage and Cracks in Concrete of Dams," by Fredrik Vogt, Det Kgl. Norske Videnskabers Selskab, Nidaros, Norway, 1930, No. 3.

Eugene Kalman,[80] M. Am. Soc. C. E. (by letter).—In this paper Mr. Jakobsen introduces a new method for studying stress distribution in gravity dams, which like any new method must be judged from two points of view, as expressed in the questions: What is the intrinsic value of the method as applied to problems of structures in general, and of dams in particular; and, what results was the author able to derive in making use of it?

The so-called Ritz method has been applied very successfully in the solution of many problems in modern engineering. Some time ago, this method, which is an adaptation of the Principle of Least Work, was first used in dam theory by the writer[81] as a means of determining radial shear acting between arch slices, or between the cut faces of sections in cantilevers of arch dams.

The writer applied the same method to the analysis of stresses in curved or straight gravity dams at least as early as 1926. Mr. Jakobsen's presentation is the first that has appeared in published form and hence the credit for its introduction into the literature of gravity dams is due him.

As to the results of the paper, there are two distinct fundamental defects in the author's use of the Ritz method, which prevent him from deriving all the value that may be obtained by its proper application.

The principle of least work is applied when the unknown stress distribution is sought in a given structure. Many times, the probable or possible stress distribution can be guessed. Sometimes, two or more different stress distributions appear to be probable or possible. The most correct among them must then be selected in some way. Since a selection is involved, the assumed group of different possible stress distributions may be termed (in accordance with current usage in problems of variation) a "competing" group. The various, assumed stress distributions may be termed, "competing individuals". Making use of this terminology, the principle of least work states that among all individuals of a given competing group, in which the true stress distribution is also included, this true stress distribution yields a smaller value for the work of deformation than any other individual of this group. This formulation of the principle of least work presumes that the true system of stress is included in the competing group, and this condition is generally satisfied in the more elementary applications of the principle. As a simple example consider a beam with two equal spans acted upon by a uniform load. Any numerical value whatever chosen for the reaction at the middle support will be statically consistent with the given system of loads if the corresponding values of the end reactions are selected accordingly.

In other words if the three reactions are $p\,l - \frac{1}{2}X$, X, and $p\,l - \frac{1}{2}X$, respectively (in which, X may vary), the result will always be consistent with the given load. The competing values for the reaction, X, of the middle support include any number whatever between $-\infty$ and $+\infty$. Each of these numbers is an indvidual of the competing group. The corresponding end reactions are defined by the expression, $p\,l - \frac{1}{2}X$. If $X = 0$, for instance, the end reactions would equal $p\,l$, etc.

---

[80] Visiting Prof., Civ. Eng., California Inst. of Technology, Pasadena, Calif.

[81] "Sulle piastre curve," R. Rendiconti, Inst. Lomb. Scienze, Serie II, Vol. LXII, Fasc. VI, x.

To obtain the true reaction of the middle support, the principle of least work may be used and thus the reactions are found to be $3\ p\ l : 8$, $5\ p\ l : 4$, $3\ p\ l : 8$, respectively, a result which may be verified by other means. Hence, the principle of least work permits an absolutely exact selection of reactions because the true one is present in the competitive group of sets.

An entirely different condition arises when the given competitive group of stress systems does not actually contain the true stress system. Then, the principle of least work must be modified so as to state that, of all competing systems, the one that gives the smaller value for the work of deformation than any other stress system in the group under consideration, will constitute the best possible approximation to the real working stress system, unless another group of supplementary stress systems is considered.

In the ordinary problems of elementary statics, in which application of the so-called theorem of Castigliano is involved, there is always a definite number of unknowns present, such as the reactions. Any of the unknowns may vary from $-\infty$ to $+\infty$, as X in the foregoing example. Since the parameter may assume any value whatever it is obvious that this range of possibilities must include the correct one, which is to be determined.

On the other hand, in all problems of advanced statics or elasticity, in which the so-called Ritz method of the principle of least work is applicable, an infinite number of tentatively assumed values in an infinite number of points must be taken into consideration. For instance, in the case cited herein, parameters should be introduced for the values of the unknown stresses at all points of the triangular profile which represents a two-dimensional region containing a number of points designated ∞^2. It is clearly impossible to deal with so many parameters. Hence, Ritz proposed the method of introducing a limited number of parameters or unknowns which will yield an approximation to the true stress system, the exact representation of which would require an infinite number of parameters. The underlying principle is the same as in the case of the approximation of a function by the first n terms of a Fourier or power series.

It is easy to see, therefore, that there is a basic difference between the two. In one case, the designer is sure that the individual selected by application of the method represents the correct solution. In the other case, he is sure that the individual selected does not represent the correct solution; it represents merely an approximation.

This fact raises the question as to how to estimate the degree of approximation and how to secure satisfactory results in all cases involving the application of the Ritz method.

Consider a beam fixed at one end and acted upon by a single load, P, at the free end, as shown in Fig. 29. Assume that the longitudinal stresses are distributed in accordance with the following equation:

$$\delta_x = \left(a \sin \frac{11\,\pi}{h}\,y + b \sin \frac{9\,\pi}{h}\,y\right) x \ldots\ldots\ldots\ldots\ldots (85)$$

The parameters, a and b, may be assumed to be any value whatever consistent with the condition of equilibrium for the given load. The most satisfactory combination may be found by applying the principle of least work.

The integral of work will reduce to the simple expression,

$$\int\int \delta_x^2\, dx\, dy = \int_{-\frac{h}{2}}^{+\frac{h}{2}} \int_0^c \left(a \sin \frac{11\,\pi}{h} y + b \sin \frac{9\,\pi}{h} y\right)^2 x^2\, dx\, dy$$

$$= \int_0^c x^2\, dx \int_{-\frac{h}{2}}^{+\frac{h}{2}} \left(a^2 \sin^2 \frac{11\,\pi}{h} y + b^2 \sin^2 \frac{9\,\pi}{h} y + 2\, a\, b \sin \frac{11\,\pi}{h} y \sin \frac{9\,\pi}{h} y\right) dy . (86)$$

The form of Equation (85) indicates that the stresses are in equilibrium. In addition, they must balance the bending moment caused by the load, and this requires that,

$$\int_{-\frac{h}{2}}^{+\frac{h}{2}} x \left(a \sin \frac{11\,\pi}{h} y + b \sin \frac{9\,\pi}{h} y\right) y\, dy = P\, x \ldots\ldots\ldots (87)$$

Equation (86) integrated and simplified becomes,

$$\frac{1}{2} h\, a^2 + \frac{1}{2} h\, b^2 = P \ldots\ldots\ldots\ldots\ldots\ldots\ldots (88)$$

and Equation (87) becomes,

$$-\frac{2\, a\, h^2}{11^2\, \pi^2} + \frac{2\, b\, h^2}{9^2\, \pi^2} = P \ldots\ldots\ldots\ldots\ldots\ldots\ldots (89)$$

In other words, the most satisfactory combination of a and b is that in which $a + b$ is a minimum, and $9^2\, a^2 - 11^2\, b^2 = \frac{9^2\, 11^2\, \pi^2}{2\, h^2}$. Therefore, the proper values are, respectively,

$$a = \frac{9^2}{9^4 + 11^4} \frac{\pi^2}{2\, h^2} P$$

and,

$$b = -\frac{11^2}{9^4 + 11^4} \frac{\pi^2}{2\, h^2} P$$

Accordingly, the most logical approximation of the true stress system is expressed by the following equation:

$$\delta_x = \frac{1}{9^4 + 11^4} \frac{\pi^2}{2\, h^2} P \left(9^2 \sin \frac{11\,\pi}{h} y - 11^2 \sin \frac{9\,\pi}{h} y\right) x \ldots\ldots\ldots (90)$$

The curve of this equation as plotted in Fig. 30 is a very complex one. No engineer would ever attempt to apply this kind of distribution as a substitute for Navier's linear law. Nevertheless, of all competing stress systems represented by Equation (85), this is the best approximation to the true stress system.

From this example it follows that even the correct application of the principle of least work may yield the most absurd results. In other words, prudence is required when the principle of least work is used in the form known as the Ritz method. The result thus obtained will be only a more or less satisfactory approximation of the actual conditions. This is in contrast to the result secured by means of the Castigliano theorem.

The principle of least work operates in a manner similar to an automatic machine. It will select the most acceptable item from a group of items put before it; but the quality of the selection will depend on the material offered. It is clear from what has been explained in the foregoing remarks that the results obtained by the author will depend upon the skill used in constructing his competing group of stress systems.

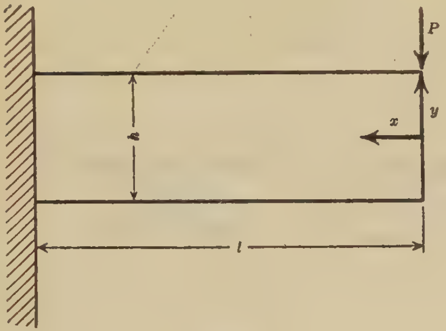

FIG. 29

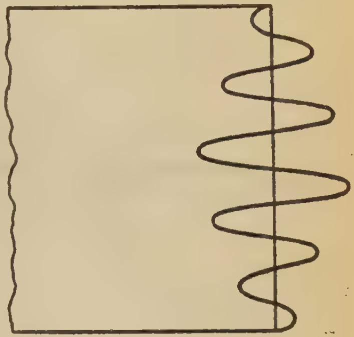

FIG. 30

Mr. Jakobsen's choice of a stress system is represented by Equations (15), (21), and (22). These equations do not define elastic stress systems, because they do not satisfy Equation (43), as given by the author. *Vice versa,* as a matter of fact the stress systems that actually apply in the case of a dam will be those of elasticity. This difference in the characters of the two stress distributions, which may be large quantitatively, constitutes the first fundamental defect, or imperfection in the author's analysis.

A more correct way would have been to assume all competing stresses as elastic systems acting in the profile of the dam. Of course, these should be chosen so as to be statically consistent with the boundary stresses defined in accordance with Equations (15), (21), and (22), by n_y and t along the base of the dam. Each stress system defined by n_y and t on the base, determines one elastic stress system in the profile of the dam and of all these elastic stress systems the most convenient should have been determined by means of the principle of least work.

Of course, there was an extremely difficult problem to be solved, namely, how to determine in all those elastic stress systems the stresses acting in the interior of the dam, thus making possible their substitution in the integral of work and the evaluation of that integral. The author did not attempt to attack this problem, and, consequently, he was forced to assume a certain stress system in the dam, consistent with conditions of stress along the base. That, however, is an arbitrary assumption which might differ radically from actual conditions.

After having selected his competing group of equations, the author computes the work of deformation in the profile of the dam and obtains the stress system which furnishes the smallest value of the work. He then states that this is the most probable stress distribution in the dam. The writer feels, however, that the result obtained, without considering at all the effect of the foundation, will not represent even a reasonable approximation of the true stress distribution in the dam.

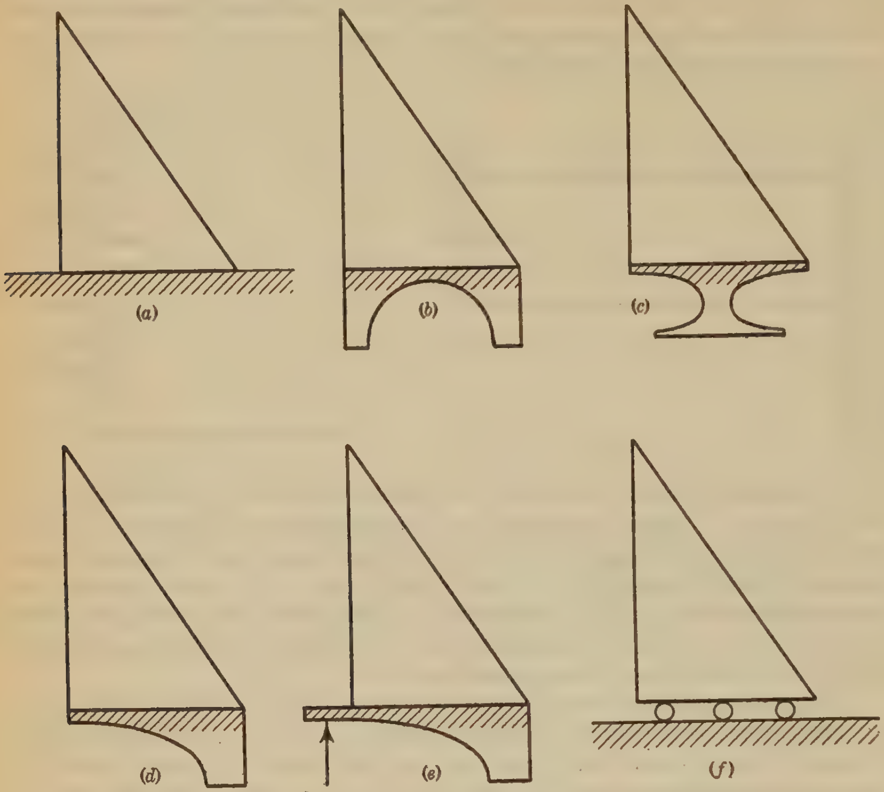

FIG. 31

Evidently, stress conditions in the triangular cross-section of a dam will be entirely different if the dam is considered as a homogeneous solid block with different types of foundation supports as shown, for example, in Fig. 31. Not only will the different structural shape of the supports have its influence on the resulting stress system in the combined or integral section of dam and foundation, but the presence of incidental loads acting directly on the foundation, as shown in Fig. 31, will also have its effect. The author does not consider this phase of the problem. According to him the principle of least work applied to the dam separated from the foundation, furnishes the best stress distribution in the dam, in any case, for any shape of foundation, and for any system of independent load acting directly on the foundation. It is obvious from Fig. 31 that in actual cases the stress distributions will differ completely from each other and from that found by Mr. Jakobsen. This constitutes the second defect in the use of Ritz's method by the author.

The author's aim was to furnish a stress distribution that would be an improvement over that of Lévy, which he claims to be unsatisfactory because of the deflection conditions in the foundation. He states that Lévy's stress distribution is not acceptable because it implies a sine-shaped curving of the foundation. Will the author's distribution cause the deflection to appear less curved? Is he satisfied that his result is an improvement over that of Lévy in this respect? If so, why?

After this preliminary criticism of the author's general principles, some remarks should be made referring to a few particular statements contained in the paper under consideration.

Under Article IV, entitled "Stress Distribution by the Principle of Least Work", Mr. Jakobsen states,

> "The writer has shown that the arch stresses found from the tests on the Stevenson Creek Dam agree remarkably well with the Cain formulas, when the deformation and displacements of the abutments are included in the calculations in the manner suggested by Dr. Vogt. (See Article III.) These tests are, therefore, an experimental verification of the Principle of Least Work as applied to the stresses in an arch dam."

The writer cannot agree with this statement. By means of the principle of least work, certain formulas or relations between two quantities may be derived, as, for example, between load and stresses, or between load and deflections, etc. For example, the Cain formulas express a relation between load and stresses. When the load is given, the stresses may be determined by means of those formulas, or, conversely, the load may be determined from the stresses given.

How can the exactness of a formula be checked? Obviously, by comparing the values of the right and the left-hand members obtained by independent measurements. For example, the load and the stresses may be measured directly; then the two parts of the Cain formula may be compared; and if they agree, one could declare that the formula is experimentally checked.

In the case under consideration, Mr. Jakobsen takes the stresses found experimentally for the arch at Elevation 30 of the Stevenson Creek Dam and compares them with a certain load (depending on several parameters) which he determines by using the Cain formulas. It follows then that the load data at his disposal do not represent measured quantities. They represent values derived by reasoning from the stress data. In the writer's opinion this does not constitute an experimental check of the Cain formula. Mr. Jakobsen has merely applied the Cain formula to evaluate the load.

Suppose, furthermore, that the experiments had revealed variable horizontal load. This might have occurred in the case of an arch dam with central angles of the magnitude of those normally used; that is, central angles considerably larger than those which unfortunately were chosen in the Stevenson Creek Dam.

In that case, the author would follow the same procedure as outlined in his paper and would find no acceptable agreement between the measured stresses and those obtained by Cain's formula which assumes a constant load. Logically, he would then have to state that the principle of least work does not hold in the case of arch dams. On the contrary, however, the principle does hold also in this case as it does in all phenomena thus far encountered in the field of mechanics. The correct conclusion to be drawn, therefore, would be that the load distribution is different from that implied by the Cain formula.

In Appendix II, Mr. Jakobsen states that "Equation (27) does not satisfy Equation (43); and, according to Föppl, it should not".

Now, he is dealing with stress systems of a competing group without requiring from them anything except that they be consistent with the given system of load, that is, water pressure and dead load. An infinite number of elastic stress systems may be found that satisfy this prerequisite, all of which would satisfy Equation (43). Consequently, the foregoing statement should be revised to read, "and according to Föppl it need not".

In Appendix III, the author places considerable emphasis on the fact that in the interior of a thin plate which is loaded by lateral forces and is free from any load on the two parallel faces, there may be, or will be, stresses acting normally to the plane of that elementary plate.

The writer believes that it is of no use to attempt to provide for those stresses at the actual beginning stages of a research. Consider, for example, two horizontal sections in the profile of a dam, and assign to them the stresses indicated in Equations (15), (21), and (22), respectively. The two horizontal sections may be a considerable distance apart. It is clear that the nature of the elastic stresses may change infinitely more between these two sections that are relatively far apart than between the two limiting parallel faces of the thin plate mentioned that are infinitely close together. On the latter the normal stresses are equal to zero and this implies an exceedingly small margin for the development of stresses in the interior of the plate normal to the faces.

Nevertheless, the author neglects the possibly wide differences between his system and the true system in the region between those two horizontal sections, while he devotes considerable space to the treatment of the normal stresses in the plate of elementary thickness. The effect is similar to that of making refinements based on possible variation in the fifth decimal place of a number when the numeral in the first decimal place is open to question.

The author states that horizontal sections are not normal sections, and that, therefore, in his opinion, they could not be used as a basis for the application of the trapezoidal rule. He also states that according to his analysis of gravity dams, however, the customary horizontal sections give "practically" the same result as normal sections.

While the concept of a section and the application of Navier's linear distribution law, are entirely satisfactory for beams of limited height, it has no meaning in the analysis of dams. If the stress distribution on the base of a triangular section is assumed to be linear, then the entire elastic system or the condition of stresses in the interior of the section is linear, as stated by Lévy many years ago.[82] Hence, in that case there is no difference at all between normal, horizontal, or inclined sections. The trapezoidal rule applied to any of these sections will furnish the same result exactly, and not only "practically", as the author says.

If conversely the distribution of stresses on the base is assumed not to be linear, then it will not be linear on any section whatever in the interior of the entire profile. The conceptions of the terms "section", "resistance against overturning", etc., are incompatible with modern stress analysis. Mr. Jakobsen deserves credit for having abandoned in the present paper the conception of the section, on which his paper quoted previously was based, introducing instead the stress system defined along every point in the profile by means of Equations (15), (21), and (22).

---

[82] The writer's exposition in *Beton und Eisen*, 1930, Heft 9, p. 174.

In Appendix I, the author states:

> "The question now arises whether Equation (15) can represent a curve similar to Fig. 10 [which is the stress distribution of Ottley and Brightmore], so that in case this is the correct stress distribution, the constants could be determined so as to give a curve similar to Fig. 10."

Then the author proceeds to determine the constants for that case.

The writer cannot understand the significance of that statement. Since for $y = H$ the author's stress system represents a parabola of the third degree in x, and since every curve whatever may be approximated by such a parabola when the parameters are conveniently selected, it is self-evident that such an approximation may also be made for the Ottley-Brightmore stress curve. Therefore, the writer is unable to understand the reasons for and the aim of such computations in connection with the problem under consideration.

From Equations (25) and (26), the author deduces the fact that the four parameters are independent of the height, H. This fact can be recognized without the use of these equations since it simply follows from the fact that the competing stress system is homogeneous. Using polar co-ordinates instead of Cartesian co-ordinates, all stresses appear to be functions of r and β, in the form of $r\ f\ (\beta)$. In other words, the parameters have nothing to do with r, and will be independent of the longitudinal dimensions of the dam.

The homogeneity of the competing stress system represents a weak point in the author's choice. It has the apparent advantage that it simplifies the computations, but on examination it proves to be one of the less favorable among all possible selections. In fact, since all stresses are of the form, $r\ f\ (\beta)$, they correspond to the type of elastic stress distribution defined by Lévy. This is fundamentally in opposition to the conception of the integral profile composed of the dam and the foundation. It involves simply repeating the stresses in the foundation at an ever-increasing rate, due to the presence of an ever-increasing r, while it is evident that the stresses will decrease and disappear toward the interior of the foundation. Stress conditions in the foundations as encountered by the author's system are shown schematically in Fig. 32.

Finally, in his closing remarks Mr. Jakobsen makes the statement that, according to Mach, only actual tests can determine whether or not the principle of least work applies in any specific case.

The writer differs with this opinion in that he believes speculative research is as important as experimental research. They both help to advance science. The author's findings may be compared conveniently with results of tests made by Mr. E. Barnes at the California Institute of Technology in 1929 and 1930. In the writer's opinion, all such tests supply unreliable information as to the actual stress distribution in dams due to the influence of an infinitely extensive foundation and of the direct water pressure on the rock with its indirect effect on the stresses in the dam itself. These factors are and must be neglected in all these tests.

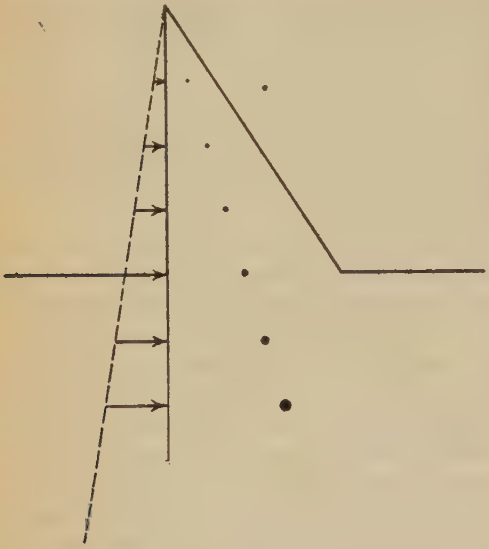

FIG. 32

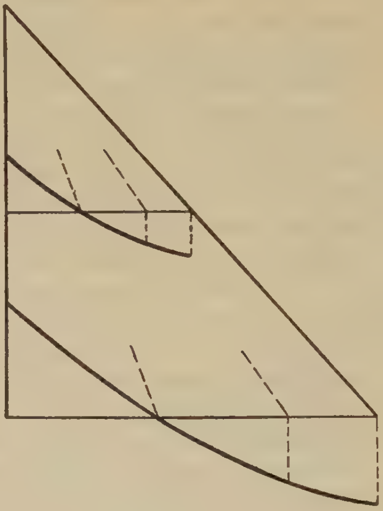

FIG. 33

This opinion is based on rigorous theoretical considerations contained in a previous paper by the writer, entitled "The Validity of Lévy's Elastic Regimen in Gravity Dams",[83] in which paper the deflection curves of the foundation (considered as unlimited), were determined and plotted both with and without the influence of direct water pressure at the bottom of the reservoir. Since the time of its presentation European authorities have shared this opinion fully. This was evident, for example, in a paper on dams presented by Professor Probst at the World Power Conference.[84]

The foregoing general objections refer similarly to the experiments by Mr. Barnes on a model having a moderately wide base, rectangular in shape, and clamped along three sides. The water pressure was represented by a relatively small number of concentrated loads applied normally to the up-stream face.

Mr. Barnes' stress diagram was a kind of regular curve of third degree with a point of contraflexure, whereas Fig. 6, as presented by Mr. Jakobsen, has the general form of a second-degree curve. Both curves agree, inasmuch as they involve an increase of stress at the up-stream face. On the down-stream face, however, Mr. Barnes found an increase of stress, while the author's diagram shows a decrease when compared with the linear distribution. This is a basic difference. Furthermore, the magnitude of the maximum stresses on the up-stream face is quite different in the two diagrams. The author's diagram involves an increase of stress of 50%, while Mr. Barnes' diagram indicates the increase as being equal to 200 per cent.

---

[83] *Energia Elettrica,* March and April, 1927.

[84] *Zeitschrift* des Vereins Deutscher Ingenieure, 1930, Nos. 13 and 15.

Evidently, one of the two diagrams is entirely in error. The difference in the character of the diagrams is peculiarly striking, because the author disposes of four parameters, that is, of a virtual third-degree parabola, which fact would have permitted a selection of a diagram of the type given by Mr. Barnes.

This difference cannot be explained by stating that Mr. Jakobsen's Fig. 6 represents conditions at the base of the profile studied by Mr. Barnes, while Mr. Barnes' diagram refers to a horizontal section of the profile at the level of one-twentieth of the height. In fact, owing to the special structure of the stress system, introduced by Mr. Jakobsen, $\sigma = r f(\beta)$, his diagram retains its character of a second-degree curve in all horizontal sections of the profile, and thus, also, in the section considered by Mr. Barnes, as shown in Fig. 33.

A paper by Wolf, published in 1914,[85] introduces a method which gives results that are considerably superior to those obtained by Mr. Jakobsen. Wolf deals with a perfectly elastic stress system, and also takes into consideration, at least to a certain extent, the interaction between the dam and its foundation.

After having pointed out the imperfections of the author's analysis, the writer wishes to explain, briefly, how the same method of Ritz may yield satisfactory results if properly applied.

The effect of interaction between the dam itself and a limitless foundation must be taken into consideration. Furthermore, the water pressure acting directly on the bottom of the reservoir will have considerable influence on the deformation of the foundation and, consequently, it will effect the stress distribution in the dam, especially in the more important lower elevations. Hence, the principle of least work must be applied to the entire structure as a unit, including not only the dam, but also the limitless foundation upon which it stands. This phase of the problem must be considered in evaluating the integral of work:

$$A = \frac{1}{2\,G} \int\!\!\int \left[\frac{1}{2} (\delta_x{}^2 + \delta_y{}^2) - \frac{1}{2\,(m+1)} (\delta_x + \delta_y)^2 + \tau_{xy}{}^2 \right] dx\,dy \ldots (91)$$

The principle of least work provides for the selection of a stress system from a given group which selection represents the best approximation to the true stresses. In other words, the average of the differences between the true stresses and the selected ones in all points of the dam, is smaller than the average of the differences between the true stresses and those determined by any other stress system of the given group.

It is possible, however, that in certain isolated regions of the profile such differences between the true and the selected stresses may be considerably greater than those between the true stresses and the stresses determined by some other unselected system of the given group. The stress system selected by the principle of least work will supply the best average approximation to the actual stresses; but it may also supply results that represent the actual stresses much less correctly in certain parts of the profile (as, for example, along the base) than some or many others of the systems that were not so selected.

---

[85] "Zur Integration der Gleichung $\nabla \nabla 0 = 0$ durch Polynome im Falle des Staumauer Problems," *Sitzungsberichte* der Kaiserlichen Akademie der Wissenschaften in Wien, 1914, v. 123, No. 2.

Relatively, designers are not so much interested in conditions at the higher elevations, but rather in the lower parts of the dam, especially along the base. Therefore, the writer proposes to use parameters referring to the points of the base only. The tentative stress system will be applied only on the base. In this way, the source of error previously mentioned is practically eliminated. Besides, the possibility of another group of errors is greatly reduced as may be seen from the following: The author prescribes at every point of the profile the stresses which, in reality, should be determined, while the writer prescribes them only on the base.

The assumption of tentative stresses along the base alone has still another advantage, namely, that the actual elastic stress system corresponding to a certain load and boundary stress is absolutely fixed; hence, there are no indeterminate stresses to be encountered in the interior of the section. On the other hand, a tentative stress distribution with four or five parameters may be expected to furnish results that agree quite closely with the actual stress condition at the base.

The only remaining problem is to determine, according to the principles of elasticity, the stresses in the interior if the load and the stresses along the base are known, since these values must be substituted in their proper place in Equation (91), in order to compute the work of deformation. This is a very difficult problem, even when boundary conditions are most simple. To solve it analytically for the more complicated systems of normal and shearing stresses prescribed along the base would appear to be almost hopeless. Furthermore, the design of gravity dams is not limited to triangular sections. Other shapes, including some that cannot be treated analytically, should be analyzed by some method, and there are no analytical means available for performing such a formidable task.

In his research work the writer reached this stage at the beginning of 1927, and reported on it to J. L. Savage, M. Am. Soc. C. E., of the U. S. Bureau of Reclamation, more than two years ago He determined upon a solution somewhat later, describing it fully to Franklin Thomas, M. Am. Soc. C. E., in July, 1929. The new concept of the exterior work of deformation was substituted for the usual concept of an interior work of deformation. Suppose, for example, that a system of loading is tentatively applied to the dam along the base line. This load will cause stresses in the interior of the section and the work of the deformation will be as expressed in Equation (88). However, the work performed by the interior stresses is equal to that performed by the load. On the other hand, the work performed by the load (that is, by a group of forces), is measured by the sum of products formed by the single forces and the displacement of their points of application in their various directions.

These deflections may be determined experimentally by the use of an elastic model, and thus the work performed by a trial set of forces may be evaluated without the necessity of knowing all the stresses in the interior.

Computing the work performed by every individual unit of a competing stress system, both in the dam itself and in the limitless half plane that represents the foundation, the particular stress system that involves the least work will be selected.

FERNAND CAMPUS,[86] ESQ. (by letter).—Since the paper is purely theoretical, the writer will first consider the question from that point of view. He believes that the author does not make correct use of the principle of least work. This principle gives rise to great difficulties in interpretation and application. Föppl expressly warns against the errors it may induce.[87] The author gives a faulty interpretation of Föppl's text in the final reference in Appendix II.

The theorem of least work is only applicable in the case of elasticity. This point is duly established in the works of Clapeyron, Lamé, Castigliano, Menabrea, Boussinesq, Maurice Lévy, Bertrand de Fontviolant,[88] Föppl,[89] and others. The principle of least work and the principle of virtual velocities are not, as the author seems to consider them, essentially different; they are identical or, more correctly, they are only slightly different expressions for one and the same principle or assumption—the hypothesis of elasticity. This is demonstrated clearly by de Fontviolant and especially by Föppl's treatise.[90] Föppl states the principle of virtual velocities in the form of the law of least work of deformation, and he proves beyond any possible doubt that these two principles are only valid when the hypothesis of elasticity is assumed.

If so, the stresses must satisfy the author's Equation (43)[91] which has not the same meaning as Föppl's compatibility equations;[92] or Airy's stress function may be determined, which must satisfy Equation (42). The author improperly identifies this formula with the compatibility equation in plane elasticity. As a matter of fact, Equations (42) and (43) are identical, but quite different from the compatibility equations.

In the last statement of Appendix II, the author has misinterpreted Föppl's text. Föppl states[93] explicity that the stresses, n_x, n_y, n_z, t_{xy}, t_{yz}, and t_{zx}, satisfy the hypothesis of elasticity, thus, also, the compatibility equations, and he mentions very small variations, δn_x, δn_y, δn_z, δt_{xy}, etc., which do not satisfy them, but satisfy the equilibrium equations. He proves then that the corresponding value of δL is zero; therefore, the work done by the stresses, n_x, n_y, n_z, t_{xy}, etc. is a minimum. This relates only to the stresses satisfying the elasticity equations, and not to the other internal forces. It is true[94] that the stresses computed by the Ritz method do not satisfy the elasticity equations; but this method is only approximate; it cannot exactly satisfy the laws of elasticity and all the formulas and principles derived from these laws.

In other words, the basic principle is that of elasticity. The elasticity equations, the author's Equation (43), the Airy function (the author's Equation (42)), the principle of virtual velocities, the principle of least work (which states that the total differential of the work is zero and not certain partial differentials as in the Ritz method)—all these formulas and principles are but slightly different forms for the expression of one and the same fundamental hypothesis—elasticity. The principle of the superposition of effects depends also upon this fundamental hypothesis. This principle is necessarily true in this case, when elasticity is assumed to apply. The writer will now prove that the author did not properly consider these fundamental facts in his paper.

Arbitrarily, Mr. Jakobsen assumes the law,

$$n_y = A_y + B_x + C\frac{x^2}{y} + F\frac{x^3}{y^2}$$

which is homogeneous. In order to determine A, B, C, and F, he uses the equations of static equilibrium and to these he joins, by means of the Ritz method, the relations, $\frac{dL}{dC} = 0$ and $\frac{dL}{dF} = 0$.

There is nothing to justify him in considering this the principle of least work; it is only an approximation commonly designated as the Ritz method. The author arrives at formulas for n_y, n_x, and t, and he ascertains that these quantities do not satisfy the compatibility equations, which means exactly that they do not harmonize with the hypothesis of elasticity. As a matter of fact, they should not, because they were obtained by the Ritz method. Consequently, the formulas and principles derived from elasticity are not applicable to these stresses, although the author assumes that elastic deformations occur. For instance, the work of 16 653 000 ft-lb. in Table 3, is not a minimum. The minimum is 17 218 000 ft-lb., as computed by means of the linear solution. If the work calculated, using the author's stresses, is 3.26% less than the minimum, this is due entirely to the inaccuracy of the computation. Equations (14), (29), (30), and (31), for the work, only have a bearing upon stresses that satisfy the assumption of elasticity. The internal forces as given by Mr. Jakobsen do not satisfy this condition. This also explains the noticeable differences between the stresses given in Articles VII and VIII.

If they satisfy, actually, the principle of superposition, it results only from the fact that Equations (16), (17), (25), and (26) (which determine the constants, A, B, C, and F) are linear and homogeneous functions of w and g.

Now, examine the differences between the principle of elasticity and the author's formulas. It can be proved by accepting the author's assumptions, that the exact solution is linear (ignoring all lateral deformations, in accordance with Appendix III, which is applicable to every condition).

The writer has pointed out that the law chosen by the author (Equation (15)) is homogeneous. In the case of a straight line, $x = ky$, in the interior of the dam:

$$n_y k = y\,(A + Bk + Ck^2 + Fk^3) = Ky \ldots\ldots\ldots\ldots\ldots (92)$$

The validity of this statement is not limited to the up-stream face as given by the author in Article VI; it is general. Furthermore, $n_x k = K' y$ and $t k = K'' y$. This variety of stress distribution is designated homothetic, that is, similar and similarly placed.

The summit of the triangular section of the dam is the homothetic center. In cases of homothetic stress distribution it is easy to prove that the solution satisfying the hypothesis of elasticity and all its consequences—for example, least work—is the linear solution. A very simple demonstration is given in the work by Pigeaud.[95]

When the author assumes his homogeneous law, he implicitly assumes a homothetic condition. In this case the exact solution satisfying elasticity is the linear law; and this is the only solution that verifies the elasticity equations and the formula of work, and the principles of least work and of superposition. The stresses found by the author by means of the Ritz method show great divergence from the exact solution. This demonstrates the degree of error that the Ritz method may involve. It is sufficiently illustrated by Figs. 4, 5, 6, and 7, of the paper.

In Article II, Mr. Jakobsen seems to consider the assumption of linear stress distribution as arbitrary; and, in Article III, he maintains that it is equivalent to stating that horizontal planes remain plane. It is possible that this opinion is based on a memoir by Lévy[96] which is now becoming obsolete. Incidentally, the author mentions the consideration of normal instead of horizontal sections, thus referring to the work of Résal.

These points of view have been displaced by a more precise conception of the linear law. Consider a triangular dam of infinite height, infinite resistance, and infinite elasticity; the stress distribution is a plane and a homothetic one. Each unit of volume weighs exactly as much as any other; the pressure is hydrostatic and the water level is at exactly the same height as the ridge of the dam. Under these conditions the general equations of internal equilibrium and of elasticity lead to a linear stress distribution which is identical to that of Lévy. The demonstration of this theorem is to be found in the works of many authors. The writer needs only to mention Pigeaud's treatise,[97] in which the starting point is the equation,

$$\frac{d^2\,(n_x + n_y)}{dx^2} + \frac{d^2\,(n_x + n_y)}{dy^2} = 0 \dots\dots\dots\dots\dots\dots (93)$$

Mr. S.-D. Carothers, of London, England, has given a new and very elegant demonstration of this theorem. He has applied the Airy function and polar co-ordinates in accordance with Love's "Treatise on Elasticity" (4th Edition).[98]

It should be noted that this theorem does not imply any assumption as to the deformations or the conservation of plane horizontal sections. On the

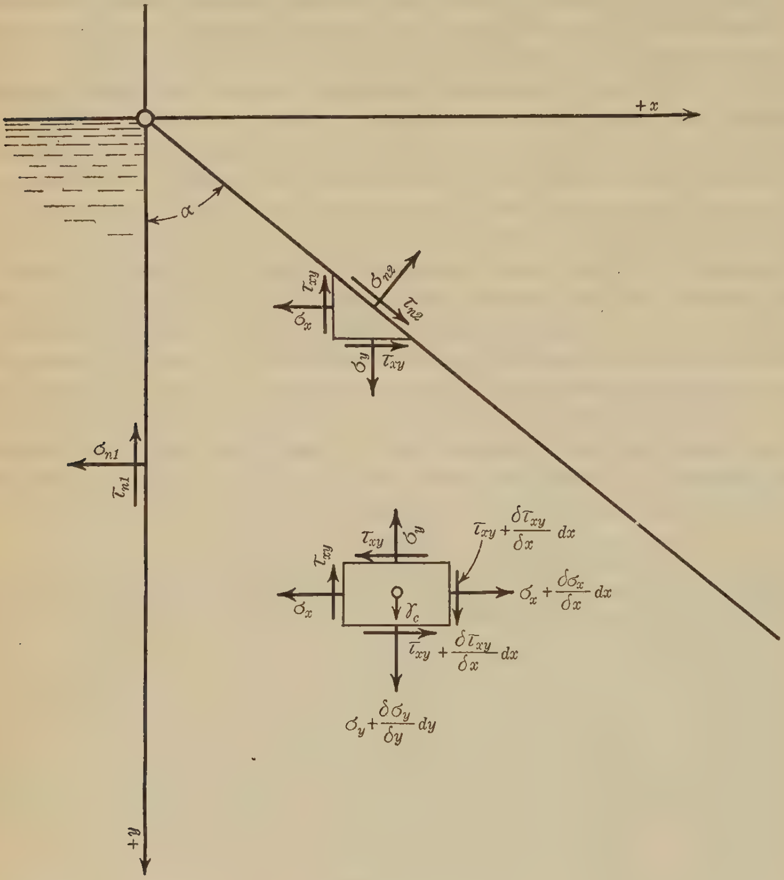
Fig. 34 illustrates a dam with a triangular profile. It has a vertical up-stream face and unlimited height, and a thickness equal to unity. The water surface is assumed to be level with the top of the dam which is also the origin of the co-ordinates, x and y. The equations for the up-stream and down-stream boundaries are, respectively, $x = 0$ and $x = \tan \alpha\, y = \kappa\, y$. Furthermore, assume that the stress distribution in the interior follows the linear law as expressed by the formulas,



+x
α
τ_{xy}
σ_{n2}
τ_{n2}
σ_x
σ_y
τ_{xy}
σ_{n1}
τ_{n1}
τ_{xy}
σ_y
$\tau_{xy} + \frac{\delta \tau_{xy}}{\delta x} dx$
τ_{xy}
σ_x
γ_c
$\sigma_x + \frac{\delta \sigma_x}{\delta x} dx$
$\tau_{xy} + \frac{\delta \tau_{xy}}{\delta x} dx$
$\sigma_y + \frac{\delta \sigma_y}{\delta y} dy$
+y

FIG. 34

$$\sigma_x = a\,x + b\,y \tag{94}$$

$$\sigma_y = c\,x + f\,y \tag{95}$$

and,

$$\tau_{xy} = e\,x + h\,y \tag{96}$$

Consider a rectangular element, as shown in Fig. 34, in the interior of the dam. From the condition that the horizontal and vertical forces acting on this element must be in equilibrium, the following equations may be written:

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} = 0 \ldots\ldots (97)$$

$$\frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{xy}}{\partial x} + \gamma_c = 0 \ldots\ldots (98)$$

The boundary condition will be expressed by the equations:

$$\sigma_{n1} = \sigma_x = -\gamma_w y \ldots\ldots (99)$$

$$\sigma_{n2} (x, \kappa x) = 0 \ldots\ldots (100)$$

$$\tau_{n1} = \tau_{xy} = 0 \ldots\ldots (101)$$

and,

$$\tau_{n2} (x, \kappa x) = 0 \ldots\ldots (102)$$

In these equations, γ_c and γ_w are the specific weights of the dam and of the water, respectively. If the stresses, σ_x, σ_y, and τ_{xy}, in two mutually perpendicular planes are known, then the stresses in a plane forming an angle, α, with the vertical will be given by the following equations:

$$\sigma_n = \sigma_x \cos^2 \alpha + \sigma_y \sin^2 \alpha - 2 \tau_{xy} \cos \alpha \sin \alpha \ldots\ldots (103)$$

and,

$$\tau_n = (\sigma_x - \sigma_y) \sin \alpha \cos \alpha + \tau_{xy} (\cos^2 \alpha - \sin^2 \alpha) \ldots\ldots (104)$$

For the down-stream boundary:

$$\sin \alpha = \frac{\kappa}{\sqrt{1 + \kappa^2}} \ldots\ldots (105)$$

and,

$$\cos \alpha = \frac{1}{\sqrt{1 + \kappa^2}} \ldots\ldots (106)$$

in which, $\kappa = \tan \alpha$, as before.

Introducing in Equations (103) and (104) the values of Equations (94), (95), (96), (105), and (106), Equations (107) and (108) are obtained, for the down-stream boundary, as follows:

$$\sigma_{n2} = [a \kappa + b + c \kappa^3 + f \kappa^2 - 2 e \kappa^2 - 2 h \kappa] y = 0 \ldots\ldots (107)$$

and,

$$\tau_{n2} = [a \kappa^2 + b \kappa - c \kappa^2 - f \kappa + e (1 - \kappa^2) \kappa + h (1 - \kappa^2)] y = 0 . (108)$$

Because these expressions are valid for all values of y, it follows that:

$$a \kappa + b + c \kappa^3 + f \kappa^2 - 2 e \kappa^2 - 2 h \kappa = 0 \ldots\ldots (109)$$

and,

$$a \kappa^2 + b \kappa - c \kappa^2 - f \kappa + e (1 - \kappa^2) \kappa + h (1 - \kappa^2) = 0 \ldots\ldots (110)$$

The same expressions in a somewhat modified form may be derived more easily by making use of the following theorem which holds true for all points of a boundary free from loads in any arbitrary two-dimensional domain:[106]

$$\sigma_x = \kappa \tau_{xy} = \kappa^2 \sigma_y \ldots\ldots (111)$$

Equation (111) may be written as two equations:

$$\sigma_x - \kappa \tau_{xy} = 0 \ldots\ldots (112)$$

and,

$$\tau_{xy} - \kappa \sigma_y = 0 \ldots\ldots (113)$$

---

[106] "Sulla validità dell' ipotesi Navier nelle mensole," by E. Kálmân, Reale Instituto Lombardo di Scienze e Lettere, Estratto dai Rendiconti, Vol. LXI, Fasc. XVI–XX, 1928.

As before, substitute Equations (94), (95), and (96), into Equations (112) and 113. The result will be:

$$a\,\kappa + b - e\,\kappa^2 - h\,\kappa = 0 \qquad (114)$$

and,

$$-c\,\kappa^2 + e\,\kappa - f\,\kappa + h = 0 \qquad (115)$$

Combining Equations (94), (96), (99) and (101):

$$\sigma_x = -\gamma_w\,y = -(a\,\kappa + b\,y)_{\kappa=0} = -b\,y \qquad (116)$$

and,

$$\tau_{xy} = 0 = (e\,\kappa + h\,y)_{\kappa=0} = h\,y \qquad (117)$$

from which, $b = -\gamma_w$ and $h = 0$.

Differentiating Equations (94), (95), and (96) with respect to x and y and introducing the resulting values into Equations (97) and (98), the following expressions are derived:

$$a + h = 0 \qquad (118)$$

and,

$$f + e + \gamma_c = 0 \qquad (119)$$

Hence, $a = 0$. By introducing the values, $b = -\gamma_w$, $h = 0$, and $a = 0$, into Equations (109) and (110):

$$-\gamma_w + c\,\kappa^3 + f\,\kappa^2 - 2\,e\,\kappa^2 = 0 \qquad (120)$$

and,

$$-\gamma_w\,\kappa - c\,\kappa^2 - f\,\kappa + e\,\kappa\,(1 - \kappa^2) = 0 \qquad (121)$$

Solving for e:

$$e = -\frac{\gamma_w}{\kappa^2} \qquad (122)$$

Substituting this value of e in Equation (119),

$$f = -\left(\gamma_c - \frac{\gamma_w}{\kappa^2}\right) \qquad (123)$$

Introducing Equations (122) and (123) into Equation (120):

$$c = \left(\gamma_c - 2\,\frac{\gamma_w}{\kappa^2}\right)\frac{1}{\kappa} \qquad (124)$$

Making use of the parameter, $b = -\gamma_w$, $h = 0$, and $a = 0$, as well as those expressed by Equations (122), (123), and (124), the general expressions in Equations (94), (95), and (96), respectively, will take the final form,

$$\sigma_x = -\gamma_w\,y \qquad (125)$$

$$\sigma_y = \left(\gamma_c - 2\,\frac{\gamma_w}{\kappa^2}\right)\frac{x}{\kappa} - \left(\gamma_c - \frac{\gamma_w}{\kappa^2}\right)y \qquad (126)$$

and,

$$\tau_{xy} = -\frac{\gamma_w}{\kappa^2}\,x \qquad (127)$$

Thus, it is proved that the tentative linear stress distribution, as defined by Equations (94), (95), and (96), can be fitted to the boundary conditions of the problem by choosing its six parameters properly. For the special case, $\alpha = 45°$, $\gamma_w = 1$ and $\gamma_c = 2$, Equations (125), (126), and (127), respectively, become $\sigma_x = -y$; $\sigma_y = -y$; and $\tau_{xy} = -x$.

The linear expressions with respect to x and y given by Equations (125), (126), and (127) define the stresses at any point of the dam regardless of whether horizontal or inclined sections are used.[107] These equations express Lévy's well-known stress regimen.

The foregoing analysis shows in an unequivocal manner that, under the influence of water pressure and the weight of the dam, the stresses in a triangular profile must be linearly distributed if an additional straight-line section (either horizontal or inclined) is considered as a third boundary. The author prescribes a parabolic distribution of stress for this third boundary without attempting to prove that such a distribution will hold equally true in the interior of the profile. The up-stream and down-stream boundary conditions in both the author's and Lévy's cases are the same.

In applying the method introduced by W. Ritz, it is not merely sufficient to minimize the work by choosing arbitrarily a function belonging to a competitive system; it is also necessary to take care that this system is correctly chosen from the infinite number of possible choices, any one of which might supply a minimum function by a proper choice of the parameters. For example, among n competitive systems, there are n solutions which satisfy the condition of least work. In all problems of this nature it is necessary to give the characteristics of the functions that are permitted to compete. For this purpose the shape of the curve that represents these functions is assumed only approximately and upon this choice the correct solution of the problem depends to a large extent. Otherwise, in order to obtain the correct solution, it would be necessary to take into consideration all competitive systems that contain a sufficient number of functions in series, each series having a sufficient number of terms.

For the reasons explained in the foregoing remarks, the writer is forced to conclude that the results of the author's theory are, unfortunately, misleading. The Ritz method of least work has been applied successfully to the design of circular tanks[108] and arch dams,[109] but the writer considers that stress analysis of triangular gravity dam profiles of unlimited height is not possible by this method.

To prove the correctness of his theory, the author refers to the well-known English tests on models. It is questionable whether the analysis of these two divergent cases can be made to agree. The stress distribution in the models was influenced considerably by the foundation conditions at the dam. This influence was disregarded entirely by Mr. Jakobsen. In the upper parts of the models the stresses seem to follow a linear rather than a parabolic law. This is in agreement with theory because, according to Saint-Venant's principle, the stresses in these models cannot be influenced materially at elevations considerably above the base. The stresses will follow the linear law quite closely, so that Lévy's regimen will be approximately correct at such elevations.

[109] "Sulle piastre curve", Nota dell' Ing. Prof. Kálmán, Estratto dai Rendiconti del R. Instituto, Lombardo di scienze e lettere, Adunanza dell 11 Aprile, 1929, Serie II, Vol. LXII, Fasc. VI–X.

The writer doubts very much whether progress can be made in the analysis of a triangular dam profile when the influence of the foundation upon the dam is neglected. The important problem that still remains to be solved is that of considering the dam and its unlimited rock foundation acting together as an elastic body. This is impossible at present, however, due to the great mathematical difficulties involved. Therefore, it is necessary to make certain assumptions regarding the deformation of the rock or to be guided by the results of experiment.

As is well known, the stress components in any two-dimensional domain can be expressed by means of the Airy stress function satisfying a partial differential equation of the fourth order under given boundary conditions. (See the author's Equations (40) and (42).) Among the particular solutions of this differential equation are also those that can be expressed in the form of polynomials.

Professor Karl Wolf has expressed the normal loads (water pressure) at the up-stream boundary of a triangular dam profile by an arbitrary polynomial of the nth degree with respect to y.[110] It is evident in this case that the tangential loads are zero. On the other hand, the down-stream boundary of the dam is free from loads while the rigid foundation represents the third boundary of the triangular profile.

The coefficients can be determined in such a way that the polynomial will express with sufficient accuracy not only the water pressure within the limits, $y = 0$ (at the top) and $y = h$ (at the bottom), but, also (because of the assumed rigidity of the foundation), the vertical displacements for $x = h$ shall be a minimum. This can be accomplished in the following manner. The height and the base of the profile are each divided into n equal parts. For each of the n intervals of the height of the profile, the integral of the polynomial is made approximately equal to the corresponding water pressure (by the method of least squares). For each n interval of the base ($y = h$), the integral of the vertical displacements is made equal to zero, in order to satisfy the condition imposed by assuming that the base is rigid. This procedure supplies n linear equations for the determination of n unknown coefficients in the assumed polynomial.

Consider a polynomial of the fifth degree with respect to y, in which the down-stream face of the dam makes an angle of 45° with the up-stream face, and the assumed height of the profile as well as the specific weight of water are assumed equal to unity. Let the specific weight of the dam equal 2. For this case, Professor Wolf determines the following expression for the horizontal normal stress at the up-stream face:

---

[110] "Zur Integration der Gleichung $\Delta \Delta F = 0$ durch Polynome im Falle des Staumauern-problems", von Karl Wolf, *Sitzungsberichte* der Kaiserl. Akademie der Wissenschaften in Wien, February, 1914.

$$(\sigma_x)_{x=0} = -y + 0.116\,y - 1.101\,y^2 + 3.325\,y^3 - 4.000\,y^4 + 1.668\,y^5 \text{..(128)}$$

At the base of the dam, that is, for $y = h$, Equation (128) gives a value for σ_x which differs from the water pressure by only 7 per cent. The first term of this equation corresponds to the stress given by Equation (125) for the special case, namely, $\sigma_x = -y$.

The remaining stresses at the base and at the mid-height of the dam are, respectively,

$$(\sigma_y)_{y=1} = -0.836 - 0.939\,x + 0.829\,x^2 + 0.904\,x^3 - 2.452\,x^4 + 1.766\,x^5 \text{.(129)}$$

$$(\tau_{xy})_{y=1} = -1.288\,x + 1.677\,x^2 + 3.495\,x^3 + 1.898\,x^4 + 0.490\,x^5 \text{.(130)}$$

and,

$$(\tau_{xy})_{y=0.5} = -1.123\,x + 0.321\,x + 0.459\,x^3 - 1.057\,x^4 + 0.490\,x^5 \text{.(131)}$$

Equation (129) corresponds to the rule of the trapezoid in Lévy's regimen. For different values of x in Equation (129), corresponding values of σ_y are, as follows:

x	$(\sigma_y)_{y=1}$
0	0.836
0.1	0.930
0.3	1.035
0.5	1.084
0.7	1.080
0.9	0.903
1.0	0.730

When plotted, these values appear in the form of a parabolic curve concave upward. At the up-stream or down-stream faces the stress is smaller than that resulting from Equation (126) ($\sigma_y = -y$), while at the middle of the section the stress is somewhat greater. In Equation (129) y does not appear because the expression is valid only for $y = 1$. For $x = 0$, in Equation (129), $\sigma_y = -0.836$, while for $y = 1$ in the special case of Equation (126), $\sigma_x = -1$. It is important to note that the shearing stress toward the top of the dam rapidly approaches that determined by Lévy's linear law. Even at the base the distribution of the shearing stress does not differ radically from that given by Lévy's regimen. For example, in both cases, the shearing stresses vanish at the up-stream face (for $x = 0$) throughout the height of the dam.

It is true that Professor Wolf's solution may be open to certain objections. However, it represents an elastic state which is correct while Mr. Jakobsen's solution is not. Furthermore, the results obtained by this method are not extreme so that they cannot be rejected as useless. Unfortunately, the same reasoning cannot be applied to the author's findings. Before accepting a new theory in which there are substantial differences when compared with methods influence was disregarded entirely by Mr. Jakobsen. In the upper parts of the models the stresses seem to follow a linear rather than a parabolic law. This is in agreement with theory because, according to Saint-Venant's principle, the stresses in these models cannot be influenced materially at elevations considerably above the base. The stresses will follow the linear law quite closely, so that Lévy's regimen will be approximately correct at such elevations.

The writer doubts very much whether progress can be made in the analysis of a triangular dam profile when the influence of the foundation upon the dam is neglected. The important problem that still remains to be solved is that of considering the dam and its unlimited rock foundation acting together as an elastic body. This is impossible at present, however, due to the great mathematical difficulties involved. Therefore, it is necessary to make certain assumptions regarding the deformation of the rock or to be guided by the results of experiment.

As is well known, the stress components in any two-dimensional domain can be expressed by means of the Airy stress function satisfying a partial differential equation of the fourth order under given boundary conditions. (See the author's Equations (40) and (42).) Among the particular solutions of this differential equation are also those that can be expressed in the form of polynomials.

Professor Karl Wolf has expressed the normal loads (water pressure) at the up-stream boundary of a triangular dam profile by an arbitrary polynomial of the nth degree with respect to y.[110] It is evident in this case that the tangential loads are zero. On the other hand, the down-stream boundary of the dam is free from loads while the rigid foundation represents the third boundary of the triangular profile.

The coefficients can be determined in such a way that the polynomial will express with sufficient accuracy not only the water pressure within the limits, $y = 0$ (at the top) and $y = h$ (at the bottom), but, also (because of the assumed rigidity of the foundation), the vertical displacements for $x = h$ shall be a minimum. This can be accomplished in the following manner. The height and the base of the profile are each divided into n equal parts. For each of the n intervals of the height of the profile, the integral of the polynomial is made approximately equal to the corresponding water pressure (by the method of least squares). For each n interval of the base ($y = h$), the integral of the vertical displacements is made equal to zero, in order to satisfy the condition imposed by assuming that the base is rigid. This procedure supplies n linear equations for the determination of n unknown coefficients in the assumed polynomial.

Consider a polynomial of the fifth degree with respect to y, in which the down-stream face of the dam makes an angle of 45° with the up-stream face, and the assumed height of the profile as well as the specific weight of water are assumed equal to unity. Let the specific weight of the dam equal 2. For this case, Professor Wolf determines the following expression for the horizontal normal stress at the up-stream face:

---

[110] "Zur Integration der Gleichung $\Delta \Delta F = 0$ durch Polynome im Falle des Staumauern-problems", von Karl Wolf, *Sitzungsberichte* der Kaiserl. Akademie der Wissenschaften in Wien, February, 1914.

$$(\sigma_x)_{x=0} = -y + 0.116\,y - 1.101\,y^2 + 3.325\,y^3 - 4.000\,y^4 + 1.668\,y^5 \quad ..(128)$$

At the base of the dam, that is, for $y = h$, Equation (128) gives a value for σ_x which differs from the water pressure by only 7 per cent. The first term of this equation corresponds to the stress given by Equation (125) for the special case, namely, $\sigma_x = -y$.

The remaining stresses at the base and at the mid-height of the dam are, respectively,

$$(\sigma_y)_{y=1} = -0.836 - 0.939\,x + 0.829\,x^2 + 0.904\,x^3 - 2.452\,x^4 + 1.766\,x^5 \quad .(129)$$

$$(\tau_{xy})_{y=1} = -1.288\,x + 1.677\,x^2 + 3.495\,x^3 + 1.898\,x^4 + 0.490\,x^5 \quad .(130)$$

and,

$$(\tau_{xy})_{y=0.5} = -1.123\,x + 0.321\,x + 0.459\,x^3 - 1.057\,x^4 + 0.490\,x^5 \quad .(131)$$

Equation (129) corresponds to the rule of the trapezoid in Lévy's regimen. For different values of x in Equation (129), corresponding values of σ_y are, as follows:

x	$(\sigma_y)_{y=1}$
0	0.836
0.1	0.930
0.3	1.035
0.5	1.084
0.7	1.080
0.9	0.903
1.0	0.730

When plotted, these values appear in the form of a parabolic curve concave upward. At the up-stream or down-stream faces the stress is smaller than that resulting from Equation (126) ($\sigma_y = -y$), while at the middle of the section the stress is somewhat greater. In Equation (129) y does not appear because the expression is valid only for $y = 1$. For $x = 0$, in Equation (129), $\sigma_y = -0.836$, while for $y = 1$ in the special case of Equation (126), $\sigma_x = -1$. It is important to note that the shearing stress toward the top of the dam rapidly approaches that determined by Lévy's linear law. Even at the base the distribution of the shearing stress does not differ radically from that given by Lévy's regimen. For example, in both cases, the shearing stresses vanish at the up-stream face (for $x = 0$) throughout the height of the dam.

It is true that Professor Wolf's solution may be open to certain objections. However, it represents an elastic state which is correct while Mr. Jakobsen's solution is not. Furthermore, the results obtained by this method are not extreme so that they cannot be rejected as useless. Unfortunately, the same reasoning cannot be applied to the author's findings. Before accepting a new theory in which there are substantial differences when compared with methods in current use, it is necessary that such theory be proved to be correct beyond doubt.

Further advance can be made in the theory of stress distribution in triangular gravity dams by modifying Lévy's stress regimen at the base to take care of the conditions actually existing at that place.

In analyzing the stress condition in triangular dam profiles near the foundation, Professor Kálmán has proved that the water pressure at the bottom of the reservoir has an appreciable influence on the stresses in the dam itself.[111] This is a fact that has been overlooked in the English tests and in all theoretical investigations on stresses in dams. Furthermore, Professor Kálmán shows by a vigorous analysis that the stresses at the bottom of a triangular profile cannot be linear. By cutting the dam just above its foundation and applying Lévy's stresses at the cut surfaces as loads, Professor Kálmán finds that both surfaces do not remain congruent after deformation; and this fact proves conclusively that the stresses in that part of the dam cannot be linear. If they were linear, the separated surfaces must remain congruent after deformation. In reality, of course, the dam is not cut at this place, and both surfaces must remain congruent before and after deformation. Therefore, the stresses developed therein must necessarily differ from those given by Lévy's regimen.

Basing his thesis on the theory that the two separated surfaces must be congruent, Professor Kálmán investigates the application of corrective stresses on these surfaces. This should be done in such a way that the added stresses will assist in improving the conditions of congruence as stated. Obviously, this method of attack, which will correct Lévy's stress regimen, is a marked advance in the design of gravity dams. It is an outstanding contribution to the design of these structures which, perhaps, will yield results of far-reaching consequence.

ROBERT E. GLOVER,[112] ESQ. (by letter).—In Part IV[113] of his paper Mr. Jakobsen states that,

> "Instead of the simple Equation (10) for n_y, the condition that Equation (14) must be a minimum is now introduced. This is a problem in variational calculus, but instead of treating it as such, which would be very complicated, a method of approximation may be resorted to, * * *."

The writer has observed that a certain amount of perplexity exists among engineers as to what is to be expected of the variational calculus. This is not surprising since the subject is not included among the courses of study usually prescribed for students in engineering colleges.

It is believed, therefore, that it would be helpful to solve the variational problem presented, in order to have the results available for comparison with those obtained by other methods.

---

[111] "Sulla validità del regime Lévy nelle dighe del tipo di gravità," by E. Kálmán, *L'Energia Elettrica*, March and April, 1927.

[112] Engr., U. S. Bureau of Reclamation, Denver, Colo.

[113] A statement of the theorem of minimum energy may be found in Paragraph 119 of Love's "Treatise on the Mathematical Theory of Elasticity," Fourth Edition.

Equation (14) is the expression for the potential energy of deformation. If z = unity, it reduces to,

$$L = \int\int\left[\frac{n_y^2 + n_x^2}{2} - \frac{(n_y + n_x)^2}{2\,(m+1)} + t^2\right] dy\,dx \ldots\ldots\ldots (132)$$

It will be convenient to express the stresses in terms of an Airy's function, F, which is connected with the stresses by the relations:

$$n_y = \frac{\partial^2 F}{\partial x^2} - w\,y\;;\; n_x = \frac{\partial^2 F}{\partial y^2}\;;\;\text{and } t = -\frac{\partial^2 F}{\partial x\,\partial y}$$

This form of expression will be permissible, providing it is consistent with the author's equilibrium Equations (6) and (7). This may be ascertained by direct substitution, as follows:

$$\frac{\partial n_y}{\partial y} = \frac{\partial^3 F}{\partial x^2\,\partial y} - w\;;\; \frac{\partial n_x}{\partial x} = \frac{\partial^3 F}{\partial x\,\partial y^2}\;;\; \frac{\partial t}{\partial x} = -\frac{\partial^3 F}{\partial x^2\,\partial y}\;;$$

$$\text{and } \frac{\partial t}{\partial y} = -\frac{\partial^3 F}{\partial x\,\partial y^2}$$

Then,

$$\frac{\partial n_y}{\partial y} + \frac{\partial t}{\partial x} + w = \frac{\partial^3 F}{\partial x^2\,\partial y} - w - \frac{\partial^3 F}{\partial x^2\,\partial y} + w = 0 \ldots\ldots (133)$$

$$\frac{\partial n_x}{\partial x} + \frac{\partial t}{\partial y} = \frac{\partial^3 F}{\partial x\,\partial y^2} - \frac{\partial^3 F}{\partial x\,\partial y^2} = 0 \ldots\ldots\ldots\ldots\ldots (134)$$

and,

$$L = \int\int\left[\frac{\left(\frac{\partial^2 F}{\partial x^2} - w\,y\right)^2 + \left(\frac{\partial^2 F}{\partial y^2}\right)^2}{2} - \frac{\left(\frac{\partial^2 F}{\partial x^2} - w\,y + \frac{\partial^2 F}{\partial y^2}\right)^2}{2\,(m+1)} + \left(\frac{\partial^2 F}{\partial x\,\partial y}\right)^2\right] dx\,dy \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (135)$$

The writer's computations indicate that if,

$$L = \int\int \phi\left[F, x, y, \frac{\partial F}{\partial x}, \frac{\partial F}{\partial y}, \frac{\partial^2 F}{\partial x^2}, \frac{\partial^2 F}{\partial y^2}, \frac{\partial^2 F}{\partial x\,\partial y}\right] dx\,dy$$

the condition for a minimum is,

$$\frac{\partial \phi}{\partial F} - \frac{d}{d\,x}\left(\frac{\partial \phi}{\partial p}\right) - \frac{d}{d\,y}\left(\frac{\partial \phi}{\partial q}\right) + \frac{d^2}{d\,x^2}\left(\frac{\partial \phi}{\partial r}\right) + \frac{d^2}{d\,y^2}\left(\frac{\partial \phi}{\partial s}\right) + \frac{d^2}{d\,x\,d\,y}\left(\frac{\partial \phi}{\partial t}\right) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (136)$$

in which, $p = \frac{\partial F}{\partial x}$; $q = \frac{\partial F}{\partial y}$; $r = \frac{\partial^2 F}{\partial x^2}$; $s = \frac{\partial^2 F}{\partial y^2}$; $t = \frac{\partial^2 F}{\partial x\,\partial y}$; and ϕ is a symbol used to denote that the integrand is a function of the variables in the brackets. In the present case, F, x, $\frac{\partial F}{\partial x}$, and $\frac{\partial F}{\partial y}$, are absent, and, therefore,

$$\phi\left[F, x, y, \frac{\partial F}{\partial x}, \frac{\partial F}{\partial y}, \frac{\partial^2 F}{\partial x^2}, \frac{\partial^2 F}{\partial y^2}, \frac{\partial^2 F}{\partial x\,\partial y}\right]$$

$$= \frac{\left(\frac{\partial^2 F}{\partial x^2} - w\,y\right)^2 + \left(\frac{\partial^2 F}{\partial y^2}\right)^2}{2} - \frac{\left(\frac{\partial^2 F}{\partial x^2} - w\,y + \frac{\partial^2 F}{\partial y^2}\right)^2}{2\,(m+1)} + \left(\frac{\partial^2 F}{\partial x\,\partial y}\right)^2$$

Then,

$$\frac{\partial \phi}{\partial r} = \frac{\partial^2 F}{\partial x^2} - w\,y - \frac{\left(\dfrac{\partial^2 F}{\partial x^2} - w\,y + \dfrac{\partial^2 F}{\partial y^2}\right)}{(m+1)} \qquad \text{(137)}$$

$$\frac{\partial \phi}{\partial s} = \frac{\partial^2 F}{\partial y^2} - \frac{\left(\dfrac{\partial^2 F}{\partial x^2} - w\,y + \dfrac{\partial^2 F}{\partial y^2}\right)}{(m+1)} \qquad \text{(138)}$$

$$\frac{\partial \phi}{\partial t} = 2\,\frac{\partial^2 F}{\partial x\,\partial y} \qquad \text{(139)}$$

and,

$$\frac{d}{d\,x^2}\left(\frac{\partial \phi}{\partial r}\right) = \frac{\partial^4 F}{\partial x^4} - \frac{\left(\dfrac{\partial^4 F}{\partial x^4} + \dfrac{\partial^4 F}{\partial x^2\,\partial y^2}\right)}{(m+1)} \qquad \text{(140)}$$

$$\frac{d^2}{d\,y^2}\left(\frac{\partial \phi}{\partial s}\right) = \frac{\partial^4 F}{\partial y^4} - \frac{\left(\dfrac{\partial^4 F}{\partial x^2\,\partial y^2} + \dfrac{\partial^4 F}{\partial y^4}\right)}{(m+1)} \qquad \text{(141)}$$

$$\frac{d^2}{d\,x\,d\,y}\left(\frac{\partial \phi}{\partial t}\right) = 2\,\frac{\partial^4 F}{\partial x^2\,\partial y^2} \qquad \text{(142)}$$

The condition for a minimum states that the sum of Equations (140), (141), and (142), must equal zero; therefore, the condition for a minimum of potential energy of deformation is,

$$\frac{\partial^4 F}{\partial x^4} + 2\,\frac{\partial^4 F}{\partial x^2\,\partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0 \qquad \text{(143)}$$

Note that the result of the solution of the variational problem is a condition, expressed in terms of a differential equation. This is generally the case.

The problem may be approached from another angle; namely, by basing the argument on the ideas of equilibrium and continuity. As in the previous case, it will be assumed that Hooke's law applies. Mr. Jakobsen has supplied the equations of equilibrium required, Equations (6) and (7). The equation of continuity, or of compatibility, expresses the condition that if the x, y surface in its unstressed state is marked off into squares by closely spaced lines parallel to the x and y-axes, each of the squares so defined will maintain contact with its neighbors on all four sides after deformation has taken place. The equation of continuity may be arrived at by expressing the strains in terms of the displacements and eliminating the displacements from the equations. To accomplish this let,

u = the displacement of points in the x-direction.
v = the displacement of points in the y-direction.
ϵ_x = the unit strain in the x-direction.
ϵ_y = the unit strain in the y-direction.
γ_{xy} = the unit shearing strain.

Then,

$$\epsilon_x = \frac{\partial u}{\partial x}\,;\ \epsilon_y = \frac{\partial v}{\partial y}\,;\ \text{and } \gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}$$

Differentiate as follows, and add:

$$\frac{\partial^2 \varepsilon_x}{\partial y^2} = \frac{\partial^3 u}{\partial x \partial y^2}$$

$$\frac{\partial^2 \varepsilon_y}{\partial x^2} = \frac{\partial^3 v}{\partial x^2 \partial y}$$

$$-\frac{\partial^2 \gamma_{xy}}{\partial x \partial y} = -\frac{\partial^3 u}{\partial x \partial y^2} - \frac{\partial^3 v}{\partial x^2 \partial y}$$

then,

$$\frac{\partial^2 \varepsilon_y}{\partial x^2} - \frac{\partial^2 \gamma_{xy}}{\partial x \partial y} + \frac{\partial^2 \varepsilon_x}{\partial y^2} = 0 \dots\dots\dots\dots\dots (144)$$

Equation (144) is the required equation.[114]

Introduce Hooke's law in terms of the ordinates to Airy's surface, as follows:

$$\varepsilon_x = \frac{1}{E}(n_x - \mu\, n_y) = \frac{1}{E}\left(\frac{\partial^2 F}{\partial y^2} - \mu \frac{\partial^2 F}{\partial x^2} + \mu\, w\, y\right) \dots . (145)$$

$$\varepsilon_y = \frac{1}{E}(n_y - \mu\, n_x) = \frac{1}{E}\left(\frac{\partial^2 F}{\partial x^2} - w\, y - \mu \frac{\partial^2 F}{\partial y^2}\right) \dots\dots . (146)$$

$$\gamma_{xy} = \frac{2(1+\mu)\, t}{E} = \frac{2(1+\mu)}{E}\left(-\frac{\partial^2 F}{\partial x \partial y}\right) \dots\dots\dots . (147)$$

Note that, in Equations (145), (146), and (147), $\mu = \frac{1}{m}$. If these expressions are substituted into the equation of continuity (Equation (144)):

$$\frac{\partial^4 F}{\partial x^4} + 2\frac{\partial^4 F}{\partial x^2 \partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0 \dots\dots\dots\dots\dots (148)$$

As a result of this work it may be seen that, not only does Equation (148) imply that the equations of compatibility, as stated by the author in Appendix II, are satisfied, but it also implies the satisfaction of the equations of equilibrium. Furthermore, the variational calculus indicates that if this equation is satisfied the potential energy of deformation will be less than that of any other distribution whatever, which will hold the forces in equilibrium.

A specification may be written, therefore, for a solution of the problem of finding the stress distribution in a two-dimensional elastic structure. The specification is, solve Equation (148) subject to the boundary conditions. This test may be applied to the solutions in the author's paper. Equations (13) satisfy Equation (148). That Equations (27) do not, is not conclusive in this case, since the author does not pretend that these equations represent an exact solution. Neither Equations (13) nor (27), however, recognize explicitly any elastic action of the foundation and, therefore, it must be concluded that neither is entitled to acceptance as a true solution of the problem. The objection may be stated specifically in the case of Equations (27). The limits given for the integrals in Equations (19) and (20) show that the integration was carried over the section of the dam only. This being the case, one may conclude that Mr. Jakobsen has succeeded in solving, approximately, the problem:

---

[114] Compare Love's "Mathematical Theory of Elasticity," Paragraph 17, Fourth Edition.

To find, among all possible stress distributions which satisfy the boundary conditions at the up-stream and down-stream faces of a triangular profile, that distribution which shall make the potential energy of deformation within the section of the dam a minimum.

The problem to be solved in case the law of least work is to be complied with, is:

To find among all possible stress distributions which satisfy the boundary conditions at the surface of the dam and foundation, that distribution which shall make the total potential energy of deformation in the dam and foundation, a minimum.

P. Wilhelm Werner,[115] Assoc. M. Am. Soc. C. E. (by letter).—The author's contribution to the development of the theory of gravity dams is interesting. Especially in view of the tendency toward ever-increasing height of dams, it is important that the methods on which the design is based should be reviewed. It is well known that the theory now generally used is not strictly correct from the standpoint of the general theory of elasticity.

In discussing the paper, the writer wishes to call attention to an aspect of the problem that has special relation to one of the boundary conditions at the base of the dam.

Under the usual assumption that,

$$n_z = t_{zy} = t_{zx} = 0 \quad\ldots\ldots(149)$$

and that the material in the dam is homogeneous and isotropic and follows Hooke's law, the exact solution of the problem involves finding a stress function, F, which satisfies the homogeneous partial differential equation:

$$\frac{\partial^4 F}{\partial x^4} + 2\,\frac{\partial^4 F}{\partial x^2\,\partial y^2} + \frac{\partial^4 F}{\partial y^4} = 0 \quad\ldots\ldots(150)$$

and which, furthermore, satisfies all the boundary conditions, when the coordinates of the edges of the cross-section are introduced into the following general expressions for the stresses, n, and the displacements, u:

$$n_x = \frac{\partial^2 F}{\partial y^2} \quad\ldots\ldots(151)$$

$$n_y = \frac{\partial^2 F}{\partial x^2} \quad\ldots\ldots(152)$$

$$t = -\frac{\partial^2 F}{\partial x\,\partial y} - w\,x \quad\ldots\ldots(153)$$

$$\frac{\partial u_x}{\partial x} = \frac{1}{E}\left(n_x - \frac{1}{m}\,n_y\right) \quad\ldots\ldots(154)$$

$$\frac{\partial u_y}{\partial y} = \frac{1}{E}\left(n_y - \frac{1}{m}\,n_x\right) \quad\ldots\ldots(155)$$

---

[115] AB. Vattenbyggnadsbyran, Stockholm, Sweden.

As pointed out by the author, the solution given in Equations (27) does not satisfy the general differential equation, Equation (150). As regards the boundary conditions, it is evident that neither Equations (27) nor Equations (13) fulfill the conditions for the displacements at the base of the dam. The author discusses the condition for u_y, that is, the displacement in the direction of the y-axis, but he does not discuss the condition for u_x, that is the displacement in the direction of the x-axis. In the writer's opinion, however, the boundary condition for u_x at the base is also of rather great importance.

The first conception one has regarding the boundary condition for u_x at the base is that,

$$\left.\frac{\partial u_x}{\partial x}\right]_{y=H} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (156)$$

that is, that all the points of the base, under loaded conditions, retain their positions in relation to each other in the direction of the x-axis. The extent to which this is actually true, is, of course, impossible to determine. A certain foundation deformation may exist even in the direction of the x-axis. Such deformation (if it does exist), may be influenced by irregularities in the foundation, etc. However, the strain condition expressed by Equation (156) should be found more nearly to correspond to the actual conditions at the base of the dam than any arbitrarily chosen distribution of the shearing stress, and, in any case, Equation (156) must be considered as a possible limiting case.

It is easy to verify the fact that neither Equations (13) nor Equations (27) satisfy the boundary condition expressed by Equation (156). In spite of this, both theories give (in accordance with St. Venant's principle) very nearly correct values for the stresses in points at some distance from the base of the dam. Near the base, however, there might be considerable discrepancy between the actual stress conditions and the stresses computed according to either theory, as long as the boundary conditions along the base are not fulfilled. Unfortunately, the inaccuracy of the methods applies to the most vulnerable part of the dam, that is, the base.

It is interesting to compare the values of the strain, $\varepsilon = \frac{\partial u_x}{\partial x}$, at the base, computed on the basis of Equations (13) and Equations (27). In a no-uplift section and under the assumption that $m = \infty$, the following values are determined by substitution in Equation (154):

(1) By the straight-line theory:

$$\varepsilon_1 = \frac{1}{E}\, g\, H = -\,0.4340\,\frac{H}{E} \ldots\ldots\ldots\ldots\ldots\ldots (157)$$

(2) By the author's least work theory:

$$\varepsilon_2 = -\,0.4340\,\frac{H}{E} + k^4\, z^4\, (1.584 - 1.579\, k\, z)\,\frac{H}{E} \ldots\ldots (158)$$

in which, $z = \frac{x}{b}$.

Evidently, for $k < \frac{1.584}{1.579}$ — that is, if k is less than about unity — the numerical value of ϵ_2 is always less than that of ϵ_1, except at the up-stream face ($z = x = 0$), where the two values are exactly equal, or,

$$\varepsilon_1 = \varepsilon_2 = -0.4340 \frac{H}{E} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (159)$$

At the down-stream face of the dam ($x = b$, $z = 1$), the difference between ϵ_2 and ϵ_1 is greatest, amounting to about 22% for $k = 0.645$.

In the writer's opinion a revision of the theory for gravity dams, and for buttresses of hollow dams as well, must aim at the fulfillment of the boundary condition for u_x at the base. The author's trial function, as expressed by Equations (27), leads to considerably more dangerous stresses than the trial function according to the old theory, as expressed by Equations (13). However, the writer has shown in the foregoing remarks that the author's least work theory affects the boundary condition for u_x at the base only to a very moderate extent. If the same proportion for a complete fulfillment of the boundary condition for u_x at the base exists, it would seem to indicate disastrous stresses in the dam. The writer is fully aware that this same proportion might not exist, but the question certainly seems worth while investigating.

In general, it is very difficult, if not impossible, to find, in a given case, the solution of the general differential Equation (150) which at the same time satisfies all the boundary conditions. As a rule the engineer must be content with an approximate solution, such as that given by the Equations (27). Such approximate solutions must be carefully viewed and discussed, especially in regard to the boundary conditions.

In this special case the writer would suggest that the method outlined in the paper be verified in such a way that it can be applied to another problem of similar nature the exact solution of which, from the standpoint of the general theory of elasticity, is known beforehand.

B. F. JAKOBSEN,[116] ESQ. (by letter).—Before taking up the discussions, the writer wishes to restate his problem. This seems advisable, because several contributors, notably Professor Campus, have misundestood the writer's reference to the classical theory. The writer had the ordinary engineering theory in mind, while Professor Campus had the classical theory of elasticity in mind. The writer did not properly distinguish between these two theories, and this led to the misunderstanding. An excellent and critical résumé of the classical and engineering theories has been given by Professor Campus in another paper.[117]

The Classical Theory of Elasticity.—This assumes a homogeneous, elastic, triangular section of indefinite length. It implies, as Professor Vogt has shown in his discussion,[118] that sections horizontal before loading are curved, (concave side upward), due to the loading. When this theory is applied to ordinary dams, which are necessarily of limited height, it implies as an assumption, that the foundation is thus curved by the loading, but this implied assumption is no part of the classical theory, which does not consider any foundation.

[118] See, also, Professor Campus, "Note sur la Déformabilité des Barrages à Gravité" Extrait des *Bulletins* de l'Académie royale de Belgique (Classe des Sciences) Séance du 6 décembre 1930 (n. 12, pp. 1384–1395) (1931), and *Le Génie Civil*, January 3, 1931, p. 9.

The writer has shown that the linear stress distribution satisfies the statical conditions, Equations (3) and (4), the equilibrium Equations (6) and (7), and the boundary conditions, Equations (8) and (9). That these stresses also satisfy the continuity equations was shown in Appendix II.

The Usual Engineering Theory.—This assumes linear stresses, which satisfy the statical conditions, Equations (3) and (4). Since the bending formula is applied to horizontal sections in order to derive the magnitude of the linear stresses, it implies that these sections remain plane, when shear deformations are neglected. As already stated, this assumption is in error.

Theory of the Rigid Base.—This assumes that the foundation is unyielding in every direction. This is implied in the fact that Equations (25) and (26) were integrated from zero to H, which excludes deformations in the foundation, and, in Appendix III, the writer stated that no account had been taken of the irregularities introduced by the foundation. The late Professor Cain stated this explicitly in his discussion.

General Remarks.—The classical theory of elasticity is exact with the assumptions made. The ordinary engineering theory, which deals with a dam on a foundation, both of them elastic, is incorrect. As Dr. Vogt has shown, linear stresses curve the horizontal sections of the dam, concavity upward, while these same linear stresses curve the foundation in a complicated fashion, but in the main with the concavity downward. As stated by Dr. Vogt:

> "The classical theory gives stresses which are greatly in disagreement with the compatibility equation at the foundation joint, and several large corrections are required."

Dr. Vogt has calculated approximately the additional stresses necessary to bring about similar deformations of the dam and its foundation, and checks the writer's results on the assumption that deformation due to water load only is involved. If the weight of the dam is included, he gets a smaller additional tension at the heel. He also calls attention to the possible effect of the dam being built by degrees and of the lower part partaking in the stresses due to weight along with the foundation. This brings up another complicated problem which may bear considerably upon the actual stresses in the foundation.

The late Professor Cain derives the conditions for minimum of internal work: $\frac{dL}{dC} = 0$, and $\frac{dL}{dF} = 0$, by means of Castigliano's theory, and states:

> "These two equations show that the internal work is a minimum as stated by the author. This demonstration assumes the base of the dam unyielding."

He concludes:

> "The English experiments first proved the ordinary 'inner-third rule' inadequate, and now Mr. Jakobsen confirms it by a close theoretical analysis."

In his discussion, Mr. Gore gives additional information regarding the English tests. Fig. 14 shows the piling up of stress at the heel of the dam, when the reservoir is empty. This was to be expected, but is probably somewhat too large in the model tests, due to the overhang when the reservoir is empty, shown in Fig. 13. In that respect, the writer's assumption of a rigid base is in error, because it gives nearly linear stress (see Article VII).

Mr. Gore, in collaboration with Mr. J. S. Wilson, conducted these tests. It was not the writer's intention to detract in any way from these very skilfully made tests, which to this day have not been surpassed or equalled. The writer's interest centered largely on the stresses at and near the foundation, where the English tests show tension at the heel. Mr. Gore has correctly understood that the writer assumed a rigid base and he concludes that this is the reason for the excessive tension found by the writer. Mr. Gore further concludes that the writer's assumption of a rigid base is not much nearer satisfaction than the straight-line law. After careful study of the discussions, the writer has concluded that the truth regarding tension at the heel is probably somewhere between the straight-line law and his own results.

There is, however, this important distinction, that the writer's error is on the side of safety, while the straight-line law unquestionably errs on the side of danger. This is a matter of considerable importance, because all are agreed on the uncertainties of the stress distribution at the base and yet this is the deciding factor in determining the width of the base and, therefore, the design of a gravity dam.

Mr. Gore's conclusion in favor of the linear stress distribution disagrees with his own and other tests, which led Professor Love to question the correctness of the classical theory.[119]

Mr. Mensch refers to Equation (14) for the internal work as a hypothetical equation, thus leaving it to be inferred that something is amiss with this equation. It is, however, the usual and accepted form for the work equation and is to be found in all standard works on elasticity (see, also, Professor Cain's discussion, in which this matter and the method of determining the least work, is carefully analyzed).

To replace the writer's Equation (15) Mr. Mensch offers a cubic parabola, but he makes no effort to show that this can be made to satisfy the equilibrium equations and the boundary conditions. His proposed curve (Fig. 16) shows a maximum at the down-stream face, no matter how wide the base, which is in contradiction to all tests of which the writer has any knowledge, and is otherwise improbable. Mr. Mensch takes the writer to task for finding tension in the up-stream face and for not mentioning that it cannot exist. The writer believes tension can exist and no doubt does exist in some dams, but he is agreed that the design should be made so that it will not occur. The writer agrees with Mr. Mensch regarding the danger of designing gravity dams with no allowance for uplift, such as was the case with the St. Francis Dam.

Mr. Jorgensen calls attention to the influence of water-soaking, the large variation in the modulus of elasticity, and to the influence of uplift, all of which are factors that make for uncertainties in any stress determination. They warn, or should warn, the designer that he must provide a liberal factor of safety to include a reasonable factor of ignorance.

---

[119] "The Mathematical Theory of Elasticity," Third Edition, p. 211.

Mr. Turner gives an interesting historical account of the development of the theory of bending. His statement that the writer has confused shear force with shear strain will be found incorrect upon further study. His assertion that the linear law at a section normal to the neutral axis follows from Hooke's law, is incorrect, as a reference to any text on elasticity will show. An attempt to satisfy the equilibrium equations and the boundary conditions for an ordinary beam stressed in bending will also convince Mr. Turner of his error. Furthermore, Mr. Turner will find that the linear law applies to any section, horizontal or otherwise, of a triangular, homogeneous dam of indefinite length, and not only to the normal section. The writer noted this in his paper, "Stresses in Multiple Arch Dams",[120] and Professor Résal, in France, noted it in his paper[121] published in 1919. A few simple calculations will convince Mr. Turner of the correctness of this statement.

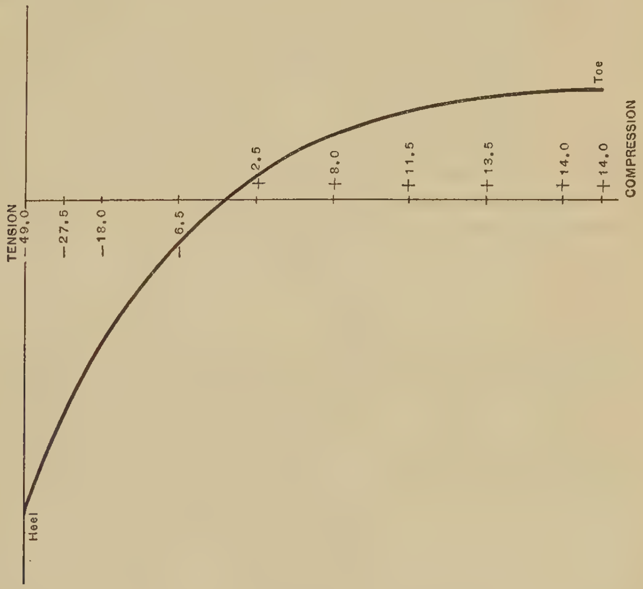

FIG. 35.

The tests by Mr. Barnes are of considerable interest. The writer has had an opportunity to check over the test data and his results are in substantial agreement with those of Mr. Barnes, except possibly at and near the down-stream toe where no deformation measurements are available. Mr. Barnes did not measure the horizontal deformations, but the assumption which he makes regarding n_x is no doubt quite close to the truth. It is also evident (see Equation (46)) that, for large values of n_y, an error in n_x is of little consequence.

[120] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 294.

[121] "Formes et Dimensions des Grands Barrages en Maconnerie," *Annales* des Ponts et Chaussées, II, 1919.

From Mr. Gore's data in Fig. 14, a stress curve for bending may be obtained, by subtracting the "reservoir-empty" stresses from the "reservoir-full" stresses. The result is shown in Fig. 35. The tension area checks the compression area within about 10 per cent. No doubt, the discrepancy is due to the small scale of Fig. 14 from which the stresses were measured, and does not reflect upon the accuracy of Mr. Gore's tests. The up-stream tension is 3.5 times the down-stream compression. The curve in Fig. 35 is of the same general shape as the writer's Fig. 6, in which the ratio between the maximum tension and the maximum compression is only 1.78. The curve in Fig. 35 is steeper in the up-stream parts of the dam and flatter in the down-stream portion than the writer's Fig. 6. The probable influence of the overhang (see Fig. 13), which is to increase the heel stresses for "reservoir empty," has already been mentioned. Both tests are in accord as to high tension at the heel near the base. Some of this tension will be compensated by high compression at the heel for "reservoir empty." On the other hand, there may be some doubt as to whether the English tests took sufficient account of the stresses due to the water load on the bottom of the reservoir (see Dr. Vogt's discussion and Fig. 25). Fig. 1, Plate 4, of the English tests[122] indicate that the reservoir load extended up stream about one-half the height of the dam. This, no doubt, is insufficient to produce even approximately full deformation caused by the reservoir load, and this loading certainly tends to produce tension at the heel.

In this connection the tests on models of arch dams to which Dr. Vogt referred, have now been made available.[123] In connection with tests on a model of the Gibson Dam, it is concluded:

> "In the analysis of the arch elements the formulas for thick arches based on the assumption that plane sections remain plane, check better than the formulas based on a linear distribution of stresses. * * * In the analysis of the cantilevers the assumption of linear distribution of stresses over the cross-section seems to lead to discrepancies in the lower parts of the cantilevers, where the down-stream face has a slope of 0.8 to 1. The down-stream stresses are decidedly less than computed by such a linear distribution of stress, thus indicating a curved distribution of the stresses. The consequences of this, again, will be higher vertical tension at the up-stream face due to water load."

These tests agree with the English tests and those of Mr. Barnes. It is interesting to note that neither the arch stresses nor the cantilever stresses are linear, but are more nearly those found by assuming that plane sections remain plane.

Professor Hoadley calls attention to the uncomfortable feeling associated with work when the factor of safety approaches one, although little is at stake, and he approves of a more conservative viewpoint in gravity dam design. There is no doubt in the writer's mind that some gravity dams are in tension at the up-stream face and especially at the heel, namely, all those which have insufficient or no allowance for uplift. A number of such dams have already failed. The writer is well aware that the leaders in the profession never have countenanced such design methods, as the discussions published by the Society show.

---

[122] *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session 1907–08, Pt. II.

[123] Engineering Foundation, Committee on Arch Dam Investigation, Sub-Committee on Model Tests, J. L. Savage, M. Am. Soc. C. E., *Chairman*, June 1, 1931, p. 271, of multigraph copy.

Mr. Ely brings up a number of interesting points. Referring to Fig. 6, it seems that the fact that the section is not symmetrical would account for the different stress distributions in the up-stream and down-stream halves of the dam. At the up-stream face the principal stress is vertical, while at the down-stream face it is parallel to that face.

Mr. Ely is no doubt correct in concluding that Equation (15) can be improved, possibly by introducing fractional exponents, as he suggests; perhaps also by writing Equation (15) so that the shape of the stress curves may vary with y.

Mr. Ely discussed uplift, and so did Professor Cain. The writer frankly admits that he is somewhat at sea as to how uplift stresses should be treated and just what effect they will have upon the stress distribution when considered in the light of the theory of least work. Recent discussions indicate that this is a complicated question, not to be answered in an off-hand manner.[124] However, dams designed on the straight-line theory should have a liberal uplift allowance; of that the writer feels certain.

The writer agrees with Mr. Gerry that the maximum compressive stress is no criterion of safety for ordinary gravity dams up to a height of 500 ft., or more, but the question of whether or not tension exists, or may exist, under the worst conditions to which the dam is exposed, is of great importance and is a question of stress. Mr. Gerry does well, however, in insisting that gravity dams must have a reasonable factor of safety against sliding.

The writer has already largely availed himself of the information supplied by Dr. Vogt, in which he explains so lucidly just why and to what extent the linear law fails at the foundation. He also shows that an equation of the form given by Equation (74), which is more general and includes the writer's assumption for n_y (Equation (15)), cannot satisfy all conditions. He also points out that convex curving of the down-stream face may produce tension; such curvature evidently should be avoided.

As a simple calculation will show Professor Kálmán's Equation (85) cannot possibly give values for the internal work as small as those found from the usual linear law. For that reason it is disqualified, *a priori,* and it is useless to determine the constants, a and b. Obviously, the writer's Equation (15) can equal Equation (10), the linear law, and, in Article VI, it was shown that the internal work found was less than that obtained from Equation (10). Professor Kálmán's repeated references to the true system leads the writer to remark that the Ritz method is of use only when the true system is not known. Fig. 31 is inapplicable, because the writer assumed a rigid base and it is immaterial how that is secured.

---

[124] See articles in *Le Génie Civil,* by E. Baticle, March 24, 1928; by G. Pigeaud, March 31, 1928; by A. and Jacques Mesnager, April 7, 1928; and by G. Pigeaud, April 21, 1928. See, also, discussion by A. Floris, in *Transactions,* Am. Soc. C. E., Vol. 95 (1931), p. 200.

Professor Campus has apparently overlooked the basic assumption made by the writer, namely, that the base is unyielding while, as he himself has shown, the linear theory implies a curving of the base. This is the reason why Equation (45) leads to Equation (41) which is the linear solution, while Equation (14) does not. In other words, when no assumption is made regarding the deformations of horizontal sections of an indefinitely high dam, the principle of least work must, and does, lead to the linear law.

Mr. Floris states that the writer has made exactly the same assumptions as were made in the classical theory of elasticity. He also has overlooked the fact that the writer assumed the base as unyielding, while the classical theory implies curvature, as shown by Dr. Vogt in Fig. 24.

Mr. Glover determines, by variational calculus, Equation (148), which is the same as the writer's Equation (42), and shows that if this equation is satisfied the internal work is a minimum. He has correctly understood that the writer assumed an unyielding base. The complete solution, of course, would have to include foundation deformations as well.

Referring to Mr. Werner's discussion, the boundary condition given by Equation (156) does not apply to the linear law, Equations (13), as both Professor Campus and Dr. Vogt have shown. It does apply to Equations (27), but since this does not satisfy Equation (150), which is the same as the writer's Equation (42), given and discussed in Appendix II, Equations (154) and (155) cannot be applied to Equation (27).

In practical application of the theory of elasticity, it is in general not possible to find an exact solution, which satisfies all the conditions of equilibrium and the geometrical continuity. One may then either determine the stresses from the equilibrium equations, in which case the geometrical continuity is not respected, and Equations (154) and (155) do not hold. If they are applied they must lead to contradictions, unless one accidentally hits upon the correct solution, or, one may find the stresses from Equations (154) and (155) and the geometrical boundary conditions, in which case the equilibrium equations are not likely to be exactly satisfied and cannot be applied.[125]

The writer has made an effort to reply to the various objections raised, but it is, of course, impossible adequately to cover the field gone over by so many able men. The discussions show a general agreement that the linear law errs on the side of danger and that there is more tension or less compression in the dam at the up-stream edge of the foundation than this law indicates. On the other hand, the writer's assumption and solution probably amounts to an over-correction, which errs on the side of safety. This is after all not such a bad feature, where so many uncertainties regarding uplift, internal tension due to shrinkage, etc., are involved, when the lives and property of so many people are at stake, and in view of the number of failures of gravity dams, which have occurred in the last decade. The assumption of a rigid base may lead to more nearly correct results by amending Equation (15) so that it allows for a change in shape of the stress curves with y, or it may be possible to include the foundation deformations in Equation (14) for the internal work. In any case, there is great need of carefully made tests which should include the water load on the reservoir and the consequent deformations at the heel.

---

[125] See Föppl's "Drang und Zwang," Vol. I, Second Edition (1924), p. 128.

In conclusion, the writer wishes to thank the many contributors for their assistance and interest and hopes that this paper will prove a contribution toward safer design, in order that the gravity dam designed so that it has insufficient or no uplift allowance, will be outlawed as it should be.

FORMULAS FOR RAINFALL INTENSITIES OF LONG DURATION[1]

BY MERRILL M. BERNARD,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. W. B. GREGORY, W. W. HORNER, ADOLPH F. MEYER, R. W. POWELL, C. E. GRUNSKY, CHARLES W. SHERMAN, AND MERRILL M. BERNARD.

SYNOPSIS

The object of this paper is to make available for any locality within the limits of the study, rainfall intensity formulas for frequencies of 5, 10, 15, 25, 50, and 100 years, applicable to rainfall duration periods of 120 to 6 000 min.

The need for some means of obtaining for a specific locality, a knowledge of rainfall intensities, durations, and frequencies, is a vital one. This is especially true of those outlying communities which do not have the advantage of long, local rainfall records.

INTRODUCTION

The following treatment of rainfall intensities has resulted from the writer's experience in applying the rational method of flood-flow analysis, so successfully utilized in storm-sewer design, to the broader field of small stream flow, particularly agricultural drains. Its scope, therefore, will be limited to that section of the United States lying between the 101st and the 81st meridians, wherein land drainage is a matter of great interest. The writer has found that while some thought[2a] has been given to this problem, much remains to be done by way of engineering research.

The rational expression of flood discharge is:

$$Q = C\,i\,A \qquad (1)$$

in which,

Q = discharge, in cubic feet per second.
C = a coefficient expressing the ratio of run-off to rainfall.
i = rainfall intensity, in inches per hour.
A = area of water-shed, in acres.

[2a] "Maximum Stream Flow", by C. E. Grunsky, Past-President, Am. Soc. C. E., *Public Roads*, June, 1926; "Run-Off from Small Agricultural Areas", by C. E. Ramser, M. Am. Soc. C. E., *Journal of Agricultural Research*, Vol. 34, No. 9; "Determining Run-Off from Local Rainfall Records," by Merrill M. Bernard, M. Am. Soc. C. E., *Proceedings*, Louisiana Eng. Soc., Vol. LX, No. 5.

Two marked distinctions between the use of Equation (1) in the field of storm sewers and that of agricultural drains are to be noted: First, the run-off coefficient, C, has an entirely different range of values; and, second, concentration periods, and, therefore, duration periods, are much longer.

It is with the rainfall intensities of storm periods longer than 120 min. that this paper deals.

Rainfall Intensity, Duration, and Frequency

With the longer concentration periods encountered in agricultural drainage areas comes the need of a more complete knowledge of rainfall intensities for duration periods longer than 120 min. One, two, three, and four-day storm periods are successions of highly intense downpours, separated by intervals of light, or of no, rainfall. In the case of sewers, each storm phase may be considered as an individual occurrence. Concentration periods are usually less than 2 hours, and the drainage system has the opportunity to clear itself before the effect of the next period of intense rainfall is felt. The higher degree of saturation throughout the remainder of the storm period is the only relating factor.

This condition does not prevail in the larger, more pervious water-sheds. The concentration time, comparable with the inlet time in storm-sewer design, will range from 50 to 1 200 min. on a water-shed of 1 000 acres, depending on the slope, the shape of the area, and the degree of development. Lower velocities are responsible for longer time of flow through the drains themselves, so that, for drainage areas of 300 sq. miles, one is dealing with concentration periods, and, therefore, with rainfall duration periods, of 4 000 min., or more.

The slow movement of run-off over the ground, through furrows and unimproved drains, and the relatively greater effect of retention and retardation, tend to equalize the rate of run-off resulting from a series of downpours, which combined make up the typical storm period of from 1 day to 4 days' duration. There is little to dispute the fact that the net effect of a 3-day storm having three to five phases, is the same as that of a hypothetical storm of average intensity, determined by dividing the total rainfall depth, in inches, by the duration of the storm, in hours. Adolph F. Meyer, M. Am. Soc. C. E., has reached this conclusion[3] regarding rainfall-duration periods of from 30 to 120 min., and the conception may be carried into the longer periods with added certainty.

A knowledge of the frequency with which a rainfall intensity of a given duration will be reached or exceeded in a locality, is as essential to the intelligent design of the conduit which is to remove the run-off resulting from such rainfall, as a knowledge of the degree of the intensity itself. Formulas which classify rainfall intensities as "maximum", "ordinary", and reached or exceeded "occasionally" or "frequently", have no place in the design of a sewer or drain where all other factors are given determinate values.

---

[3] "The Probable Frequency of Given Rates of Rainfall", *Engineering News-Record*, Vol. 87, p. 1068.

Frequency is the measure of the efficiency; it explains and justifies the occasions when the structure is taxed beyond the capacity for which it was designed.

Frequency, when applied to meteorological phenomena, does not mean that at regular intervals the phenomenon will occur. Instead, for a record covering a selected period of years, it can be expected that a rainfall of given average intensity and duration will be reached or exceeded, about once in so many years. Dividing the period by the number of such happenings, the quotient obtained is the average length of time, in years, during which the phenomenon has happened once.

This conception of frequency should not detract from its importance. In establishing the limit beyond which the designed capacity will be exceeded, the capitalized loss or damage will be no different at the end of the period analyzed whether a particular event occurred at regular intervals or in two consecutive years.

Intensity Formula Types

The almost exclusive interest in rainfall-duration periods of from 5 to 120 min. has developed the following type of rainfall intensity formula,

$$i = \frac{a}{t + b} \qquad \qquad (2)$$

in which,

t = duration of rainfall, in minutes.
a and b = coefficients having definite values for any locality.

The general application of Equation (2) to rainfall intensities for this range of duration periods is demonstrated by Mr. Meyer,[4] who has made available for the Eastern United States a series of such formula groups.

The results of this and similar studies,[5] however, show that the relation between rainfall intensity and duration is more accurately expressed by the hyperbolic formula of the type:

$$i = \frac{C}{t^n} \qquad \qquad (3)$$

in which,

C = a coefficient, depending for value on locality.
n = an exponent, depending for value on locality.

A distinction between these types may be drawn by considering Equation (2) as applying to single storm phases lasting less than 2 hours, while Equation (3) is intended to express average intensities of storm periods of longer duration.

One cannot be extended into the field of the other without confusion and error. Fig. 1 compares the Meyer curves, extended, with those of the writer for Columbia, Mo. The curve groups are in agreement between the 60-min.

[5] "Storm Rainfall of Eastern United States", Technical Repts., Miami Conservancy Dist.; "Rainfall and Run-Off Studies," by C. E. Grunsky, Past-President, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 76; "American Sewerage Practice," Vol. 1, Second Edition, p. 260; and "A Method of Determining Storm-Water Run-Off", by Charles B. Buerger, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 1182.

and 200-min. intervals, but the former rapidly falls when produced beyond its intended limit of 120 min. It will be noted, from the plotted observational data, that all but three of the points lie above the Meyer 5-year frequency curve, which, considering the length of the record, shows the position of the curve to be in error.

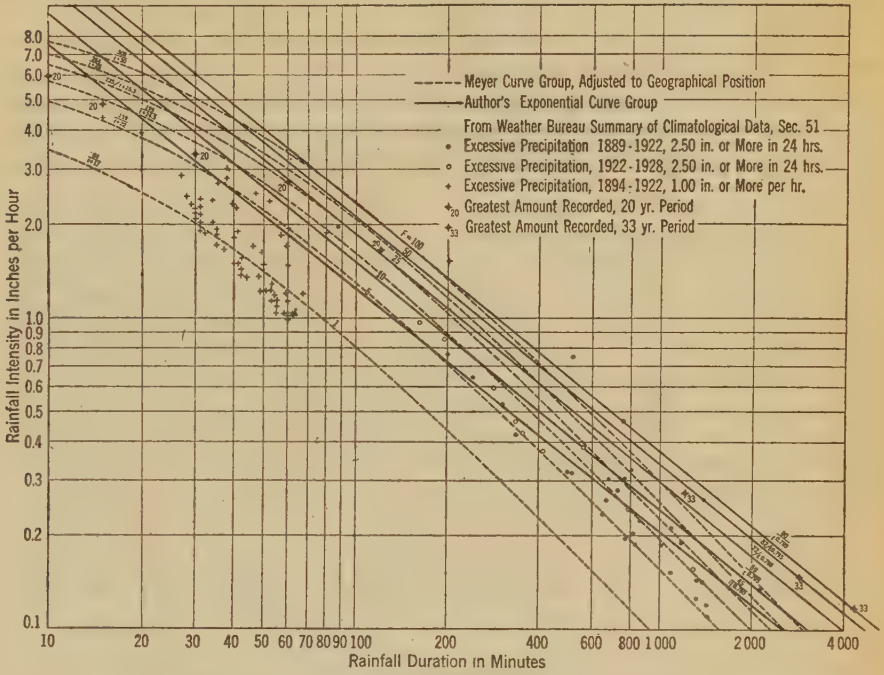

FIG. 1.—COMPARISON OF RAINFALL INTENSITIES FOR COLUMBIA, MO.

It is seen from Fig. 1 that, for duration periods shorter than 60 min., the curves separate. The exponential values increase rapidly until, at 10 min., they are about twice the Meyer values and obviously in error.

C. E. Grunsky, Past-President, Am. Soc. C. E., has made[6] a comparison of two intensity formulas: The New York formula,

$$I = \frac{150}{t + 20}$$

and the parabolic formula,

$$I = \frac{14.5}{\sqrt{t}}$$

which brings out the limitations of the former type when applied to periods longer than 2 or 3 hours.

The slight advantage involved in the easy determination of a value for t does not warrant the use of 0.5 as its exponent. The proper value ranges from 0.70 to 0.82, as will be shown.

---

[6] "Rainfall and Run-Off Studies", *Transactions,* Am. Soc. C. E., Vol. LXXXV (1922), pp. 75–76.

At several of the United States Weather Bureau stations in the area, records of rainfall intensity and duration for storms of 2.50 in., or more, in 24 hours have been kept and are tabulated to 1922. The average length of record is 32 years. Fig. 1 compares the writer's curve group with such observational data at Columbia, Mo. The time interval, 120 to 1 440 min., is well represented and the example given is representative of the eighty quadrangles studied.

Others[7] have noted the gap in both observational data and rainfall intensity studies which prevails between the 120 and 1 440-min. duration periods, as graphically shown in Fig. 2. This range of rainfall duration applies to many small flood-flow problems, and it also embraces the critical condition where two or more storm phases closely follow each other with little cessation between them.

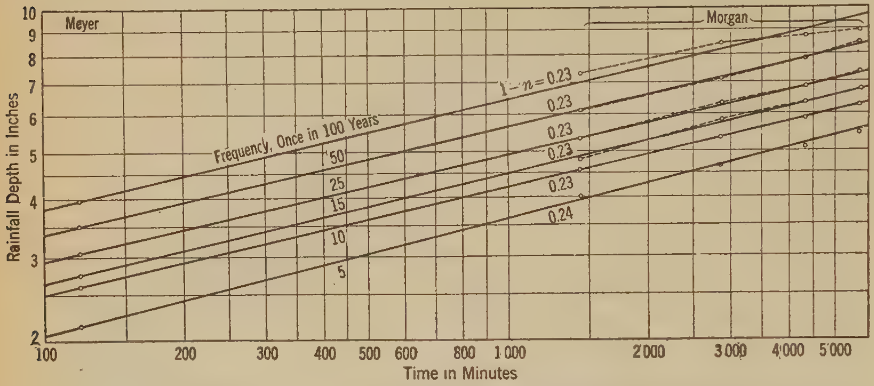

FIG. 2.—ILLUSTRATING GAP IN MEYER AND MORGAN STUDIES, QUADRANGLE 15-*E*.

BASIC DATA

Two studies of the rainfall records of the Eastern United States, outstanding in magnitude, have been made. One is by Mr. Meyer[4] who has analyzed approximately 2 000 storms and as a result has presented a series of formulas expressing the relationship between rainfall depth, intensity, and duration, and geographical location. The other is the work of Arthur E. Morgan, M. Am. Soc. C. E., who, in the interest of maximum flood flow, made an exhaustive study and analysis of the rainfall records of the Eastern United States for the Miami Conservancy District.[8]

These works are similar in the following respects:

(1) Both cover the eastern half of the United States.
(2) Both are based largely on Weather Bureau data.
(3) Both assume that, within a limited area, the sum of the records of the several stations involved is equivalent to a long-time record of one representative station.

[7] "Additional Meteorological Data Needed by Engineers", by Robert E. Horton, M. Am. Soc. C. E., *Engineering News-Record*, Vol. 82, p. 614; and "The Frequency of High Rates of Rainfall", by the late Allen Hazen, M. Am. Soc. C. E., *Engineering News-Record*, Vol. 87, p. 858.

[8] "Storm Rainfall of Eastern United States", Technical Repts., Miami Conservancy Dist.

The studies differ in that:

(*a*) Meyer's purpose was the development of intensity formulas for heavy storms of short duration, while Morgan was interested in the longer storm periods of 1 to 6 days.

(*b*) Meyer has presented his work in the form of intensity formulas. Morgan has presented his in a series of isopluvial charts which give the relation of rainfall depth to duration and frequency.

(*c*) The Meyer frequencies are once in 1, 2, 5, 10, 25, 50, and 100 years. The Morgan frequencies are once in 15, 25, 50, and 100 years.

METHOD OF ANALYSIS

In combining the Meyer and Morgan data, the writer has utilized a relationship which has proved to be consistent in eighty quadrangles of the Morgan designation, embodied in his study. The basic data are: (*a*) Meyer's rainfall depths for 120 min., for frequencies of 5, 10, 25, 50, and 100 years; and (*b*) the isopluvial charts, by Morgan,[9] for 1 to 4-day rainfall, inclusive.

The study has resulted in twelve charts (Figs. 4 to 15), from which, for any locality within the area, values of C and n may be selected, for frequencies of 5, 10, 15, 25, 50, and 100 years, for use in the general formula, Equation (3).

The development of the charts will be explained using Quadrangle 15-E as an example, this representing the average as to geographical location and the accuracy with which the curves fit the plotted points.

First.—A printed record sheet was prepared and one assigned to each quadrangle. The record sheet provided for all data shown in Tables 1, 2, and 3. Every quadrangle was rigidly treated in the same manner.

Second.—Isopluvial charts for 120-min. duration periods for 5, 10, 25, 50, and 100-year frequencies were then prepared. This was accomplished by plotting on large scale maps of the area, divided into 2° quadrangles as are the Morgan charts, lines representing the mean of each group.[10] These isopluvial lines were given the Meyer depth values for 120 min., separate charts being used for each frequency. The pluvial index for each quadrangle, referred to the center, was interpolated and recorded on the charts. This, then, made available isopluvial charts for 120, 1 440, 2 880, 4 320, and 5 760-min. duration periods.

Third.—The pluvial indices for each quadrangle were tabulated. Table 1 gives these data for Quadrangle 15-E. The numerical indices of the Morgan charts were recorded, but only the interpolated values were used in plotting the curves. In so doing the writer has taken advantage of the careful adjustment of the isopluvial lines to the weighted length of record of each quadrangle.

Fourth.—The data in Table 1 were plotted logarithmically as shown in Fig. 2. First, frequency was plotted against depth for time, 120 min. (Fig. 3), and the depth value for a frequency of 15 years was obtained by interpolation. Then, for frequencies of 15, 25, 50, and 100 years, time was plotted against depth (Fig. 2), resulting in the points controlling the upper four curves which were placed so as to fit the points best. The 120-min. depth values were allowed to control the lower ends of the curves in each case.

---

[9] Technical Repts., Pt. V., Miami Conservancy Dist.

[10] "Elements of Hydrology," 1928, p. 166.

The difference in the values given by any point and its equivalent curve value did not exceed 10% and the average difference in the eighty quadrangles was 3 or 4 per cent. As a general rule, the percentage of difference varied inversely with the record length of the quadrangle.

TABLE 1.—PLUVIAL INDEX, QUADRANGLE 15-*E*.

(*A* = interpolated values; *B* = numerical value from isopluvial charts.)

Frequency, in years	TIME, IN MINUTES.								
	120	1 440		2 880		4 320		5 760	
		A.	*B*.	*A*.	*B*.	*A*.	*B*.	*A*.	*B*.
5	2.13	....	....	....	....	....	....	....	....
10	2.60	....	....	....	....	....	....	....	....
15	2.75	4.8	5.1	5.8	5.7	6.3	6.0	6.7	6.5
25	3.05	5.3	5.6	6.3	6.2	6.8	6.8	7.3	7.5
50	3.50	6.1	6.3	7.1	7.0	7.8	7.5	8.4	8.7
100	3.97	7.3	7.8	8.4	8.8	8.7	8.9	8.9	9.2

Fifth.—As the next step (Fig. 3), the depth values given by the four upper curves in Fig. 2 have been plotted against frequency for 1 440, 2 880, 4 320, and 5 760-min. durations and the resulting curves extrapolated through the 10-year to the 5-year frequency.

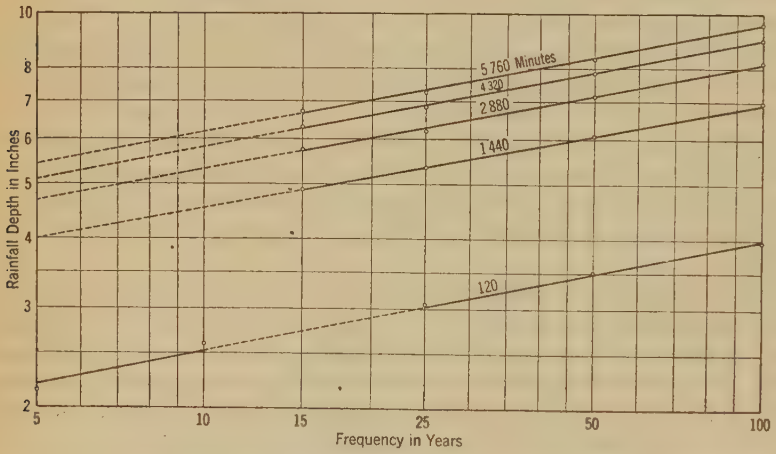

FIG. 3.—CONSTRUCTION AND EXTENSION OF RAINFALL CURVES, QUADRANGLE 15-*E*.

Sixth.—The resulting depth values for 5 and 10-year frequencies were plotted in Fig. 2, giving the two lower curves.

When it is realized that the upper and lower limits of these curves are established by separately prepared data, the writer believes the close agreement of points and curves in all of the eighty quadrangles studied to be unusual.

Seventh.—The slope of each curve in the group was measured carefully and the values for depth, corresponding to the time intervals, 500 min. and 2 000 min., were noted. From data given in Table 2 values of C and n were computed.

TABLE 2.—VALUES FOR C AND n, QUADRANGLE 15-*E*.

F.	$1 - n$.	500^{1-n}.	d.	c_1.	$2\,000^{1-n}$.	d.	c_2.	c.	C.	n.
5	0.24	4.444	3.03	0.682	6.198	4.28	0.692	0.687	41.22	0.76
10	0.23	4.176	3.60	0.862	5.744	4.93	0.858	0.860	51.60	0.77
15	0.23	4.176	3.83	0.917	5.744	5.25	0.914	0.915	54.90	0.77
25	0.23	4.176	4.21	1.008	5.744	5.73	0.998	1.003	60.18	0.77
50	0.23	4.176	4.83	1.157	5.744	6.58	1.146	1.151	69.06	0.77
100	0.23	4.176	5.49	1.313	5.744	7.52	1.311	1.312	78.72	0.77

Eighth.—The record sheet for each quadrangle was completed by noting the depth and intensity formulas for each frequency. These formulas, for Quadrangle 15-*E*, are given in Table 3.

TABLE 3.—RAINFALL DEPTH AND INTENSITY FORMULAS, QUADRANGLE 15-*E*.

Frequency.	Depth.	Intensity.	Frequency.	Depth.	Intensity.
5	$d = 0.687\,t^{0.24}$	$i = \frac{41.22}{t^{0.76}}$	25	$d = 1.003\,t^{0.23}$	$i = \frac{60.18}{t^{0.77}}$
10	$d = 0.860\,t^{0.23}$	$i = \frac{51.60}{t^{0.77}}$	50	$d = 1.151\,t^{0.23}$	$i = \frac{69.06}{t^{0.77}}$
15	$d = 0.915\,t^{0.23}$	$i = \frac{54.90}{t^{0.77}}$	100	$d = 1.312\,t^{0.23}$	$i = \frac{78.72}{t^{0.77}}$

PREPARATION OF CHARTS

The writer has selected, as a means of presenting the results of this study, a series of charts comparable with the isopluvial charts in the Miami Conservancy report. These charts will make the work of practical value, permitting a simple and rapid method of selecting intensity formulas for any locality within the area under consideration.

Lines of equal value were located by considering the variation to be uniform between the numerical values at the quadrangle centers. The resulting charts are shown in Figs. 4 to 15.

The "iso-C" and "iso-n" lines fell naturally into contours and nowhere was it necessary to disregard isolated or erratic values.

CHARACTERISTICS

The Morgan isopluvial charts, while adaptable to many uses, do not present the relation of rainfall intensity to duration and frequency in a form best suited for small stream-flow analysis or agricultural drain design. Frequency, in a particular problem, becomes a constant, being fixed by the conditions, leaving intensity to vary as, $\frac{C}{t^n}$. In the application of the rational method, t

Fig. 15.

will take all values determined by concentration periods and the relationship between time and intensity must be expressed so as to make the proper value of i quickly available for any value of t. The writer's charts are the Morgan isopluvial charts thus interpreted and extrapolated to greater frequencies and shorter duration periods, until they meet and conform with the Meyer intensity curve groups.

The effect of altitude on rainfall intensity is apparent in the Morgan isopluvial charts. Upon comparing the writer's exponential charts with a contour map of the area it is seen that the value of the exponent apparently reflects and measures the effect of altitude. It will be found that, while both values of C and n vary with altitude, they combine in the formula to give the lower intensities in the higher altitudes. A refinement of about 5% can be gained by interpolating values of n to thousandths.

Conclusion

It is to be noted particularly that the general formula, using values from the accompanying charts, is to apply to duration periods greater than 2 hours and is not intended for use within the limits of the Meyer curve groups.

The charts are subject to the limitations of the basic data, which are fully set forth in the references presenting them. The writer believes, however, that he has translated into terms of utility, covering a range of rainfall duration periods not now provided for, the results of two valuable researches and has suggested a new and practical means for the further study of rainfall intensity and its relation to the length of storm period, frequency of occurrence, and locality.

DISCUSSION

W. B. Gregory,[11] M. Am. Soc. C. E. (by letter).—Concerning problems of rainfall and run-off there is often considerable uncertainty in the mind of the designer as to the adequacy of a drainage channel to meet requirements that will represent a reasonable protection against floods. As pointed out by the author the rain that occurs as a maximum once in 50 years or 100 years may occur any time during the period. Furthermore, the rainfall and run-off data are not always at hand, and if available there may be quite a bit of work required to put them into usable form.

The subject of run-off has too often been treated in an empirical manner, with the size of drain designed purely according to the judgment of the engineer in charge or by the limitations set by the amount that may be expended. Even in the latter case it is desirable to know how often the capacity of the drains will be exceeded.

The author has made available information for intelligent design for a large part of the Mississippi Valley and portions outside. He has connected the work of Meyer and Morgan, and has shown that these two authorities agree in basic material. By this means he has given the data on which times of concentration are known in the periods that are of interest in the drainage of areas of considerable magnitude, and thus has rendered a real service to the profession.

W. W. Horner,[12] M. Am. Soc. C. E. (by letter).—In developing certain data for his personal need, the author has undoubtedly found himself in a large company of engineers thoroughly appreciative of this particular situation. The writer had occasion several years ago to make a study of rainfall frequencies in the zone just above the 2-hour limit, but under conditions which did not warrant the exhaustive study made by Mr. Bernard. The writer has also been interested in the local study of this same problem at Boston, Mass., as reported[13] by Charles W. Sherman, M. Am. Soc. C. E. There is no doubt that all over the country, as the bigger cities are spreading out and as municipal drainage problems are entering the field of the larger water-sheds, data heretofore considered accurate for design purposes have been found insufficient.

Mr. Bernard has done a remarkably fine piece of work in joining together and interpolating between developed information for short-time rains on the one hand and the "Miami Conservancy" work on the other. It is remarkable, almost surprising, that satisfactory graphs for the 1-day to 4-day frequencies can be made to pass through the 2-hour points. It is also interesting to note Mr. Bernard's belief that no satisfactory diagram for the range above 2 hours can be applicable to the ordinary rainfall curve below the 2-hour duration. In comparison with this, should be noted Mr. Sherman's belief[14] that a single formula can be developed which would cover the entire range up to several days. In a discussion[15] of Mr. Sherman's paper, the writer suggested that a formula devised for Boston did not seem to be satisfactorily in accord with the data for durations in excess of 24 hours.

---

[11] Prof. Experimental Eng., Tulane Univ., New Orleans, La.

[12] Chf. Engr., Sewers and Paving, St. Louis, Mo.

[13] "Frequency and Intensity of Excessive Rainfalls at Boston, Massachusetts," by Charles W. Sherman, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 951.

Mr. Sherman's work in Boston is based upon complete local information covering the full range of duration. In Mr. Bernard's studies no actual data are available for the duration period between 2 and 24 hours, and his results are of value because of the remarkable concurrence at the two edges of this zone. It supplies a new tool for general use in this intermediate field, a working instrument apparently much more reliable than anything that has been published before. There is no doubt that to municipal engineers as well as land drainage engineers the results of Mr. Bernard's work will be exceedingly helpful. It can be used to good advantage until the time comes when some project of the general magnitude of the Miami Conservancy work may justify the expense of determining frequencies in this intermediate zone directly from recorded rainfall information. When this time comes, authoritative studies will be available throughout the entire range, and it will be possible to determine whether any single formula will be found to be completely satisfactory. In the meantime, Mr. Bernard's work should receive the appreciation of all practicing engineers interested in storm-water drainage.

ADOLPH F. MEYER,[16] M. AM. SOC. C. E. (by letter).—It is always a pleasure to read a paper like that of Mr. Bernard which sets forth the results of an extensive study in a clean-cut manner, ready for practical application.

Of the fundamental principles referred to by the author, the writer desires to emphasize the following, expressed in his own language:

> 1.—From the viewpoint of most structures involved, the effect of actual rainstorms, varying in intensity as they do, is practically the same as if the precipitation had been uniformly distributed over the given time interval.
>
> 2.—The sum of the records of several stations within a limited area, even if of considerable extent, gives a better indication of the probable rainfall experience of a given locality than the record of a single station in that locality. Such combined records are reasonably equivalent to a long-time record for that station.

The writer hopes that these two fundamental principles, supported as they are by ample proof in the literature of hydrology, will soon receive general acceptance by the profession. Such acceptance will be in the interest of both safe and economical structural design.

Another factor in design, which the author rightfully emphasizes, but which is often neglected or cloaked in generalities, is the element of probable average frequency of recurrence of given phenomena. Although at best a prediction can only represent a probable average experience, that is no reason why the best possible prediction should not be made in reasonably specific terms and these terms used as the basis for design.

---

[14] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 954.

[15] *Loc. cit.*, p. 961.

[16] Cons. Hydr. Engr., Minneapolis, Minn.

In his opening discussion, the author concludes that the relation between rainfall intensity and duration is more accurately expressed by the parabolic formula, $i = \frac{C}{t^n}$, than by the formula, $i = \frac{a}{t + b}$. This conclusion is apparently in conflict with what follows in the paper. The author specifically points out (under the heading "Intensity Formula Types") that the Meyer formulas of the type, $i = \frac{a}{t + b}$, give correct results over time intervals to about 200 min. They are intended for application only to time intervals up to 120 min. Fig. 1 shows that Mr. Bernard's parabolic type of formula can be used only for time intervals longer than 40 min. The writer has never suggested the application of his formulas to time intervals longer than 120 min.

At best, all formulas of rainfall intensity are empirical. Since they are derived from a given group of physical data, it follows as an elementary principle that they cannot be extended, with the slightest assurance of accuracy, more than a few per cent. beyond the limits of the data on which they are based. Discussions tending to show that certain formulas cannot be applied to data lying far outside the limits of the group of base data used in their derivation, are beside the mark. All too frequent attempts are being made to extend formulas and principles far beyond the scope of the base data. When such attempts lead to error, the formula or the principle often is blamed. The author, however, specifically points out the limitations of the several formulas.

Natural phenomena such as rainfall intensity and duration are virtually haphazard occurrences. The derived formulas are empirical, and since they do not embody a fundamental physical relationship, such formulas are necessarily limited to the base data from which they are derived.

The writer would like to see the author's conclusion respecting the limits of application of his charts added to the title of each chart lest these charts be reprinted and used without the author's qualifying statement that they are intended for application to duration periods greater than two hours.

R. W. Powell,[17] Assoc. M. Am. Soc. C. E. (by letter).—The author's charts give in condensed form a mass of valuable information regarding the probable intensity of rainfall for periods of from 2 hours to 3 days for an important section of the United States. It is to be hoped that some one will develop similar information for the remainder of the country. It is questionable, however, whether it is worth while to distinguish different values of *n* for different frequencies because, for most places, the values in Fig. 11 (for a frequency of once in twenty-five years) could be used for all frequencies without introducing errors larger than those which are probably already present in the data. For example, the values of *n* shown on the charts for Detroit, Mich., vary from 0.780 to 0.805, while Milton F. Wagnitz, M. Am. Soc. C. E., and Lewis C. Wilcoxen, Assoc. M. Am. Soc. C. E., from a study of Detroit data alone found a value of 0.855.[18] On the other hand, C is clearly a function of the frequency, but it seems probable that this relationship could be represented by an equation which would require the use of only one map. Charles W. Sherman,[19] M. Am. Soc. C. E., has suggested a formula for Boston, Mass., which can be expressed as:

---

[17] Asst. Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

$$C = k\,F^{0.27} \quad \text{(4)}$$

Equation (10) for Detroit[18] is practically the same formula. The writer has read values for Columbus, Ohio, from the author's charts and finds a relationship that can be expressed either by,

$$C = 24\ F^{0.23} \quad \text{(5)}$$

or

$$C = 13 + 27 \log_{10} F \quad \text{(6)}$$

Equation (6) gives the best fit, but Equation (5) is the more convenient for combining with other equations. Putting it in the general form,

$$C = k\ F^{x} \quad \text{(7)}$$

and substituting in the author's Equation (3):

$$i = \frac{k\,F^x}{t^n} \quad \text{(8)}$$

For long periods the total precipitation is more useful than the rate of precipitation. If P = total inches of precipitation in t min.,

$$P = \frac{t\,i}{60} = \frac{k\,t^{(1-n)}\,F^x}{60} = K\,t^{(1-n)}\,F^x \quad \text{(9)}$$

in which, $K = \frac{k}{60}$. For most points considered n seems to be approximately 0.75 and x, approximately 0.25, which leads to the interesting approximate formula,

$$P = K\ (t\ F)^{0.25} \quad \text{(10)}$$

This would require only one map giving values of K. For more accurate values Equation (9) would be used. This would require another map giving values of $(1 - n)$. The coefficient, x, would probably vary so little with the location that an average value could be used.

The question presents itself as to whether these formulas could be used for periods longer than three days. This was tested for Columbus, Ohio, by computing the values given for a period of one month and comparing them with observed values. Using $n = 0.77$, $k = 24$, and $x = 0.23$, Equation (9) becomes,

$$P = 0.40\ t^{0.23}\ F^{0.23} \quad \text{(11)}$$

The equality of the exponents in Equation (11) is probably only a coincidence. Taking the average month as 43 830 min., the probable maximum monthly precipitation occurring once in F years is computed in Table 4. Values in Column (3), Table 4, were taken from Fig. 16. These curves were plotted from records of the maximum recorded monthly rainfall at the Columbus Weather Bureau from 1878 to 1921, at Ohio State University from 1882 to 1921, and at Westerville (13 miles north of Columbus), from 1854 to 1902.[20] The data were combined to make one composite record of a total of 1 555 months which was considered as typical of the vicinity.

---

[18] *Transactions*, Am. Soc. C. E., Vol. 95 (1931), p. 964.

[19] *Loc. cit.*, p. 955.

TABLE 4.—Probable Maximum Monthly Precipitation at Columbus, Ohio

Frequency of occurrence once in F years (1)	Total precipitation, P, in inches, by Equation (11) (2)	From the curve of observed values, Fig. 16 (3)
5	6.77	7.7
10	7.94	8.4
15	8.71	9.0
25	9.80	9.8
50	11.49	10.9
100	13.48	12.1

The fact that these formulas give such reasonable values when extrapolated so far beyond the range for which they were derived, speaks well for the soundness of the author's method and indicates that his formulas could be used safely for periods of more than three days. It is interesting to note, however, that the formulas do not hold for periods as long as one year. Equation (11) gives a 1-year maximum of 12.0 in. once in 5 years, and 23.9 in. once in 100 years. The actual values from Fig. 16 are 42.0 and 53.3 in., respectively. These conclusions are based on Columbus, Ohio, only and need confirmation from other points.

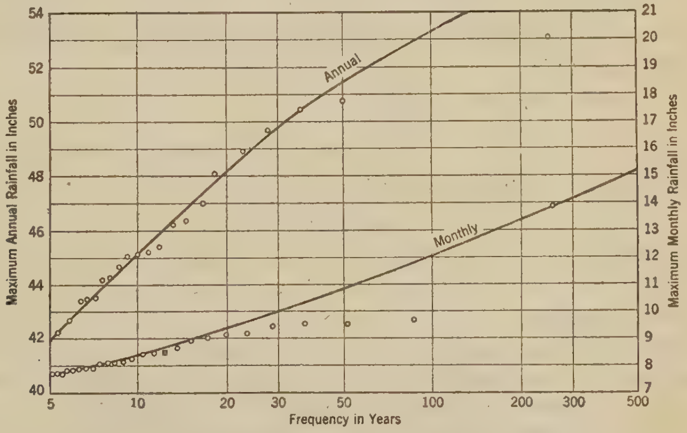

Fig. 16.—Maximum Rainfall at Columbus, Ohio.

---

[20] Data from "A Climatological History of Ohio," by W. H. Alexander, pub. by the Eng. Experiment Station, Ohio State Univ., 1923.

C. E. Grunsky,[21] Past-President, Am. Soc. C. E. (by letter).—As the outcome of long experience in the use of formulas for the approximation of probable maximum rain intensity during time periods not sufficiently covered by actual observation, the writer suggests the following formulas which differ from those heretofore in common use mainly in that the factor, time, is expressed in hours instead of in minutes.

This departure appears desirable because the rain intensity is commonly expressed in inches per hour and not in inches per minute. Furthermore, the coefficient which appears in the formula most frequently used, thus becomes equal to the maximum number of inches of rain in 1 hour, a fact which facilitates a first approximation thereof. The formulas herein suggested should commend themselves by reason of their simplicity.

The maximum rain intensity during t hours, can be expressed by Equations (12), (13), and (14):

For $t < 0.33$ hour (20 min.),

$$i = \frac{0.75\ C}{t^{0.75}} \quad \text{......................} (12)$$

For the range, $t > 0.33$ to $t < 64$,

$$i = \frac{C}{t^{0.50}} \quad \text{......................} (13)$$

For $t > 64$,

$$i = \frac{2\ C}{t^{0.67}} \quad \text{......................} (14)$$

The maximum rain intensity during t hours, can be expressed by Equations (15), (16), and (17):

For $t < 0.33$ hour (20 min.),

$$R_t = 0.75\ Ct^{0.25} \quad \text{......................} (15)$$

For the range, $t > 0.33$ to $t < 64$,

$$R_t = Ct^{0.50} \quad \text{......................} (16)$$

For $t > 64$,

$$R_t = 2\ Ct^{0.33} \quad \text{......................} (17)$$

In these equations,

R = the maximum rainfall, in inches per hour;
R_t = the total rainfall from the beginning of a rain of maximum intensity during the t hours of its duration;
i_t = maximum rain intensity, in inches per hour, being the maximum average rate of rainfall during t hours;
t = the time, in hours, for which maximum rain intensity or the maximum total rainfall is to be determined; and
C = a coefficient which is to be ascertained for any locality from records of measured maximum rainfall.

These formulas for maximum rain intensity as well as for the maximum quantity of rain, if plotted, will be found to represent continuous lines with slight changes in direction at the 0.33-hour and 64-hour points. Fig. 17 shows these lines on logarithmic paper for values of t, ranging from 0.01 hour (0.60 min.) to periods far beyond any that ordinarily come under consideration.

---

[21] Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

The formulas are to be adapted to any place by the selection of a proper value of C. In each case this will be based, of course, on the best information relating to measured heavy rainfall at, or near, or in the general region of, the place in question. They should be found satisfactory in all cases in which the probable maximum rain is to be determined at any place for short or long time periods, from records which have already established the probable maxima for other comparable short or long periods, as the case may be. A computation sheet, as shown in Table 5, will be found convenient.

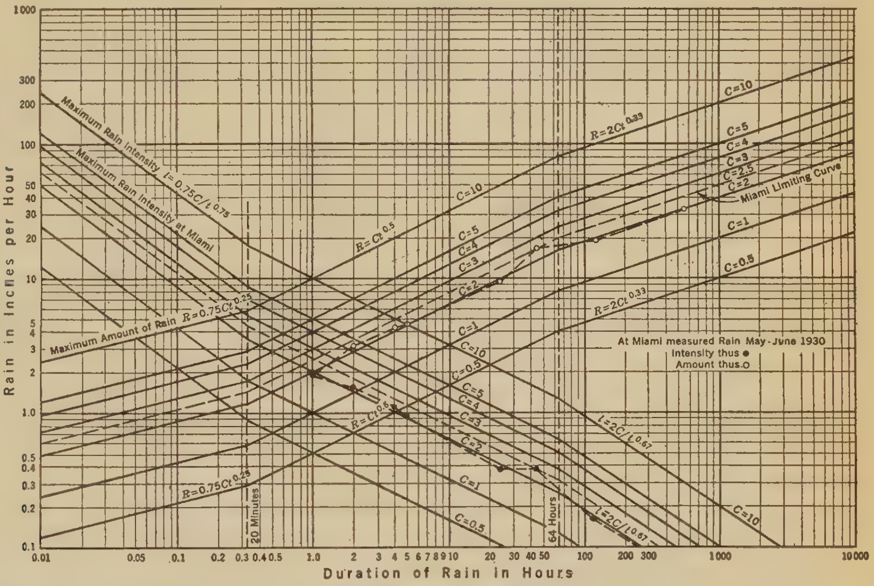

FIG. 17.—PROBABLE RAINFALL MAXIMA IN VARIOUS TIME PERIODS AND CURVES OF MAXIMUM RAIN INTENSITY.

These formulas are intended to replace formulas of the types (Equations (2) and (3)) referred to by the author. The coefficients a, b, and C, and the exponent, n, in Mr. Bernard's formulas, all depend for value on locality. The time, t, in these formulas is expressed in minutes while i is expressed in inches per hour.

The simplified Equations (12) to (17) are intended to obviate the inconvenience and limited application of the older types.

The following examples of exceptionally heavy rainfall are illustrative:

Example 1.—At Campo, Calif., on August 12, 1891, 11.5 in. of rain fell in 1.33 hours (80 min.). What was the probable maximum rainfall in 1 min. during this storm?

TABLE 5.—FORMULAS FOR MAXIMUM RAIN INTENSITY, COMPUTATION SHEET

Time, in hours, t	$t^{0.25}$	$t^{0.50}$	$t^{0.33}$	$\frac{1}{t^{0.75}}$	$\frac{1}{t^{0.50}}$	$\frac{1}{t^{0.67}}$	MAXIMUM RAIN INTENSITY, IN INCHES PER HOUR			MAXIMUM QUANTITY OF RAIN, IN INCHES		
							$\frac{0.75\ C}{t^{0.75}}$	$\frac{C}{t^{0.50}}$	$\frac{2\ C}{t^{0.67}}$	$0.75\ C\ t^{0.25}$	$C\ t^{0.50}$	$2\ C\ t^{0.33}$
0.0167	0.36			21.5			16.1 C			0.27 C		
0.083	0.54			6.5			4.7 C			0.40 C		
0.167	0.64			3.8			2.9 C			0.48 C		
0.333	0.76			2.28			1.71 C			0.57 C		
0.50		0.71			1.41			1.41 C			0.71 C	
1		1.00			1.00			1.00 C			1.00 C	
2		1.41			0.71			0.71 C			1.41 C	
3		1.73			0.58			0.58 C			1.73 C	
4		2.00			0.50			0.50 C			2.00 C	
5		2.24			0.447			0.45 C			2.24 C	
6		2.45			0.408			0.41 C			2.45 C	
12		3.46			0.289			0.29 C			3.46 C	
24		4.90			0.204			0.20 C			4.90 C	
48		6.94			0.144			0.14 C			6.94 C	
64		8.00			0.125			0.125 C			8.00 C	
72			4.13			0.0585			0.117 C			8.26 C
96			4.58			0.0475			0.095 C			9.16 C
120			4.94			0.0410			0.082 C			9.88 C
240			6.21			0.0259			0.052 C			12.42 C
720			8.97			0.0124			0.025 C			17.94 C

In this case, because $t > 0.33$ and < 64, Equation (13) applies: $i_t = \frac{11.5}{1.33} = 8.65 = \frac{C}{1.33}$; $C = 8.65 \times 1.33 = 10.0$ (in round numbers); and for $t = 1$ min. $= 0.0167$ hour (by Equation (16)), $R_{0.0167} = 0.75 \times 10 \times 0.0167^{0.25} = 7.5 \times 0.36 = 2.7$ in., the probable maximum in 1 min.

Example 2.—At Orpid's Camp, about 20 miles northeasterly from Los Angeles, Calif., observations with two recording rain gauges, about 4 ft. apart, showed rainfall in 1 min. (from 4:43 to 4:44 A. M.) of 1.03 in. in one gauge and 0.92 in. in the other. What coefficient does this indicate for the formulas of maximum rainfall?

Taking the maximum rainfall of this storm at 1.00 in. per min. (0.0167 hour), $i_{0.0167} = 1.00$ in. per min. $= 60$ in. per hour. By Equation (15), $R_{0.0167} = 1 = 0.75\ C\ (0.0167^{0.25})$; from which, $C = 4.2$ and $R = 4.2$ in., the probable maximum for any storm at this place during 1 hour.

The storm produced 1.17 in. of rain in 10 min. and 2.20 in. in 1 hour. For the 10-min. period (0.167 hour) Equation (15) would give, $R_{0.167} = 4.2 \times 0.167^{25} = 2.7$ in., the probable maximum, to be compared with the 1.17 in. as measured.

Example 3.—In a letter to the writer, Mr. J. F. Voorhees, Associate Meteorologist of the U. S. Weather Bureau, has stated that:

> "On November 18, 1930, an automatic recorder belonging to the U. S. Geological Survey and situated in Moanalua Valley, Honolulu, measured 15.2 in. in 3 hours and 5.6 in. in 1 hour."

In this case, $C = 5.6$, and the probable maximum fall of rain during any single minute was $5.6\ \sqrt[3]{0.0167} = 1.4$ in.

Example 4.—At Miami, Fla., there was an unusually heavy rain from May 29 to June 2, 1930.[22] This storm established a near record for the periods of 1 hour, 2 hours, 4 hours, and a full day, as well as for the longer period of 44 hours. A comparison of the measured rain, during this storm, with the limiting curve deduced therefrom, is presented in Table 6. In this table, R_{44} (43.93 hours), equals 16.49 in. Then, by Equation (16), $R_{44} = C \sqrt{43.93} = 16.49$; from which, $C = 2.48$. Similarly, $R_4 = C \sqrt{4} = 4.39$; from which, $C = 2.20$.

These results indicate that at Miami the value of C should be taken at 2.50. It is with this value that the comparisons shown in Table 6 have been made.

TABLE 6.—RAIN AT MIAMI, FLORIDA, MAY 27 TO JUNE 19, 1930, COMPARED WITH COMPUTED MAXIMA

1 440	.....	......	0.0395	57.	....
8 640	.....	......	0.0119	108.	1 year.

*This period from May 27 to June 19, includes 49 consecutive hours on May 27, 28, and 29, after the beginning of the storm in which no rain fell.

It appears from the foregoing that while the greatest measured rainfall in 1 min. may well be credited to Orpid's Camp, there have, no doubt, been many other rainstorms with short-time rainfall of still greater intensity, as indicated by Examples 1 and 3.

More is known of the maximum rate of precipitation to be expected at single stations than of the maximum average rate in any selected period of time over extensive water-sheds. Thus, for example, during the entire storm at Campo in which 11.5 in. of rain fell in 80 min., the rainfall at another point only 1.25 miles distant, was only 3 in. What correction factors should be used for area and for location and orographic features? There is still ample field for study and such contributions as that of Mr. Bernard are valuable additions to the literature on this subject.

---

[22] See *Monthly Weather Review*, June, 1930.

CHARLES W. SHERMAN,[23] M. AM. SOC. C. E. (by letter).—In utilizing the Miami Conservancy District records of 1-day, 2-day, 3-day storms, etc., allowance ought to be made for the fact that few if any of these storms lasted exactly 24, 48, or 72 hours. Nearly all the figures are based on records of ordinary (not recording) rain-gauges, observed once daily. All the rain accumulated between two such readings is assumed to have fallen in 24 hours. There is nothing in the records themselves to show that a 1-day precipitation may not have fallen in a single hour or even less, a 2-day collection in, say, 2 hours, one preceding and one following the time of observation, and a 3-day collection within about 25 or 26 hours. It is unlikely that maximum rainfalls can occur in such short periods, but it is not improbable that some of the high 1-day rainfalls actually occurred in periods not exceeding 20 hours; the 2-day rainfalls in 40 to 42 hours, etc.

The writer believes, therefore, that Mr. Bernard was not justified in using 1 440 min., 2 880 min., etc., as representing the durations of such storms. In no case could the durations exceed those assumed, and in an appreciable number of cases they must have been considerably shorter. Would it not have been more correct to assume that the actual durations were at least 10% shorter than the number of minutes corresponding to the length of the storm in days? Actually, the storms must have varied in duration, so that curves based upon the assumption that all 1-day storms lasted exactly 1 440 min., or any other definite number, can be at best only approximate.

Another inaccuracy is in the treatment of all rainfall records within an arbitrary quadrangle, as though they represented observations at a single station, with a length of record equal to the sum of the periods of observation at the several stations. In the first place, the quadrangles are so large that wide variations in storm-producing conditions are likely to exist at various points in many of them; and, second, the combination of a number of short records obtained during a period when either an excess or a deficiency in rainfall is generally prevalent, cannot possibly be equivalent even to one long-term record covering a wide range of climatological conditions. In the major part of the United States, such a wide range is experienced when the term of years is great enough. The writer does not mean to imply that no advantage results from the combination of records, but rather to call attention to the fact that implicit confidence should not be placed in the formulas derived.

Examination of the charts, for values of the exponent, n (Figs. 5, 7, 9, 11, 13, and 15) shows a comparatively small range in these values—roughly from 0.72 to 0.83. In view of the inaccuracies inherent in the records, and the method of combining them, it appears to the writer that a single value, and that a convenient fraction, such as $\frac{3}{4}$ or $\frac{4}{5}$, might have been assumed for n, which would leave only one factor varying with location, namely, the coefficient, C.

---

[23] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

The writer has shown elsewhere[13] that at least for some localities an intensity-duration equation of the form,

$$i = \frac{a}{(t + b)^n} \dots\dots\dots\dots\dots\dots\dots\dots (18)$$

is much better for storms of short duration when the exponent approximates 0.7 than the Meyer form in which the exponent is 1.0. If b is less than 10, as seems probable from such data as have been studied, this does not differ materially in the case of long storms from,

$$i = \frac{a}{t^n} \dots\dots\dots\dots\dots\dots\dots\dots (19)$$

As a matter of fact, the writer found a single formula applicable to Boston storms of both long and short durations, at least up to about 30 hours. With longer storms, especially those of rare occurrence, the formula was not as good a representation of the observed intensities as might be desired.

These criticisms are intended primarily as warnings against putting too great faith in the formulas derived by Mr. Bernard. They are not intended to throw discredit upon the results for practical use in drainage problems. The immense amount of detailed work which the author has devoted to the study is obvious, and the writer believes that, for the section of the country to which the figures are applicable, the available data have been arranged in such shape that the designer of drainage works can make use of them with much greater confidence than has been possible heretofore.

MERRILL M. BERNARD,[24] M. AM. SOC. C. E. (by letter).—The closing discussion will be confined to the several important points raised and to a number of interesting facts which developed in consolidating, extending, and checking the rainfall intensity charts.

Agricultural drainage and stream-flow analysis have opened a comparatively new field of use for the "rational" method, and have created the need for formulas expressing the relationship between rainfall intensity, duration, and frequency for time intervals longer than 120 min. The time of concentration for a system of storm sewers is seldom more than 180 min.; concentration time at the upper end of an agricultural drain is never less than 60 min. The two fields will seldom overlap in the same problem, and there would be little advantage in covering all duration periods in one expression. The Meyer formulas, which may be safely extended to durations of 200 min., adequately meet the needs for design in the field of storm sewers. The writer's formulas, with values of t ranging from 60 min. to several days, may be used in the design of extensive drainage systems and in the analysis of stream flow of considerable magnitude.

Factor b was not introduced into the intensity formula for the following reasons:

(1) Its influence on intensity rapidly diminishes for duration periods beyond 100 min.

(2) The refinement gained in introducing this factor is not warranted when many greater discrepancies are accepted in the course of design.

---

[24] Cons. Civ. Engr., Crowley, La.

(3) The study, so extensive as to embrace one hundred and seven 2°-quadrangles, could only be undertaken by utilizing the facility of logarithmic plotting, which permitted the rapid and accurate adjustment of the curves, as straight lines, to the plotted points.

In extending the limits of the charted area, the writer has followed the suggestion that n need not vary with frequency, but may be considered to be constant and need only vary with geographical location, as may the exponent, x, in the formula,

$$i = \frac{K F^x}{t^n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

in which,

i = average rainfall intensity, in inches per hour.
F = frequency, in years.
t = duration of rainfall, exceeding 1 hour, in minutes.
K = a coefficient, depending for value on locality.
x and n = exponents, depending for value on locality.

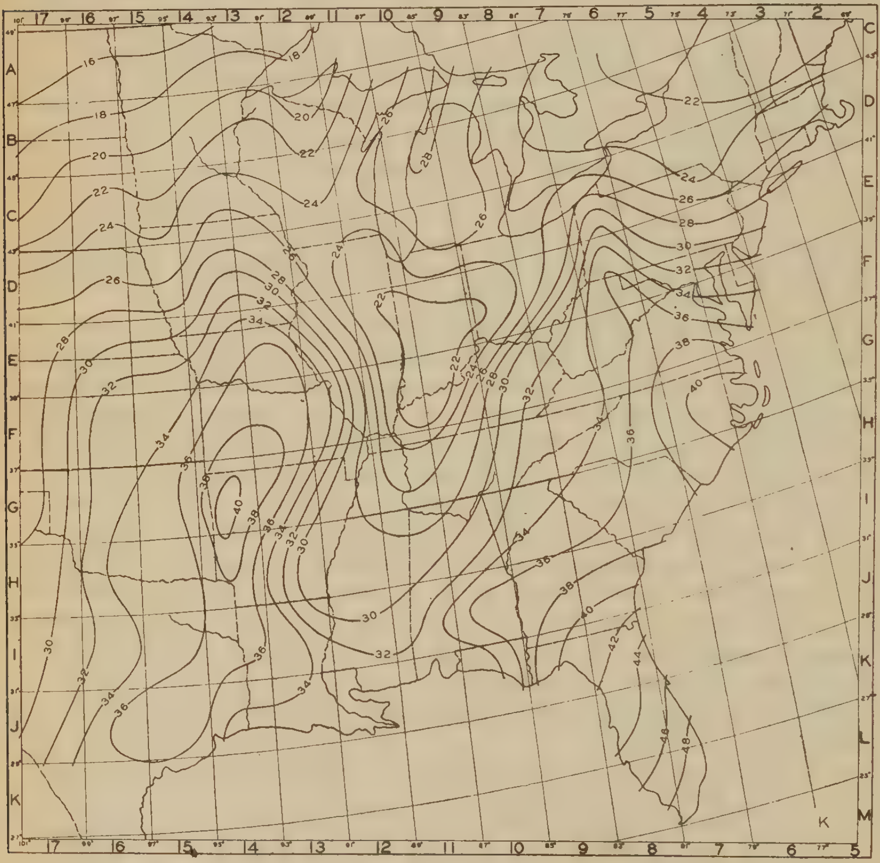

FIG. 18.—VALUES OF COEFFICIENT, K, IN EQUATION (20)

The range in value of both the exponents is too great to permit further generalization by the use of average values. The formula may easily be modified if it becomes necessary to express time in hours. Rainfall depth is obtained by multiplying the computed average rainfall intensity by duration in hours.

Figs. 18, 19, and 20 have been constructed similar to Figs. 4 to 15, inclusive. Their limits have been extended to embrace all that part of the United States east of the 101st Meridian, completing the area covered by the Meyer and Morgan studies. Fig. 18 gives values for the coefficient, K; Fig. 19, values for the exponent, n; and Fig. 20, values for the exponent, x, in Equation (20).

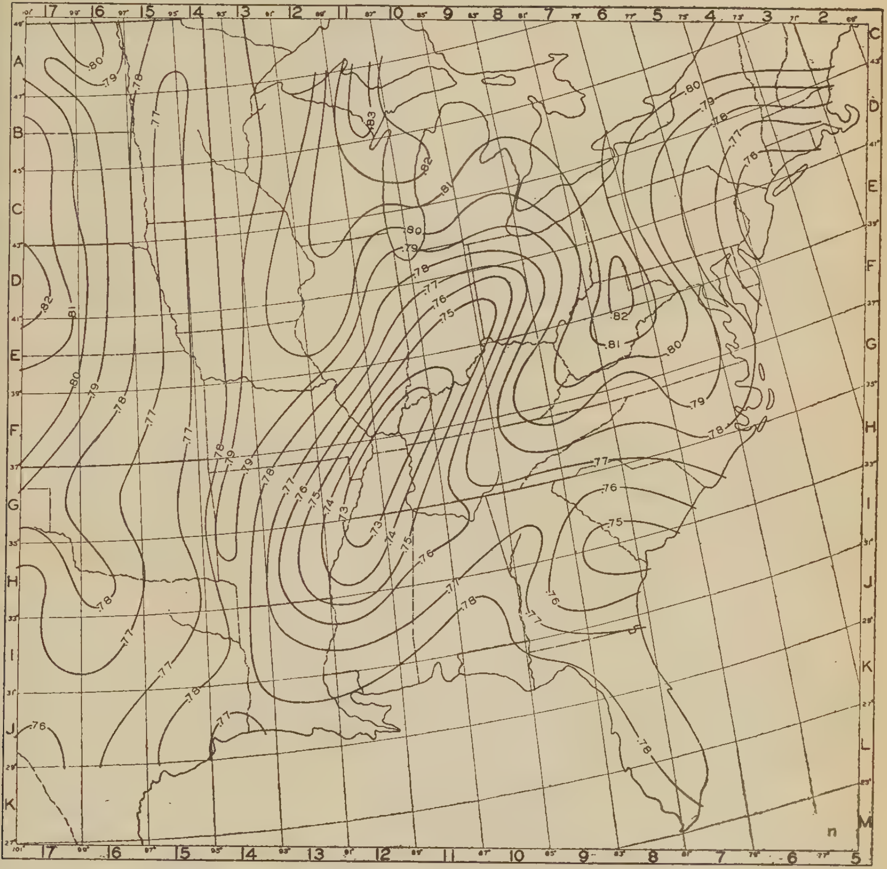

FIG. 19.—VALUES OF EXPONENT, n IN EQUATION (20)

Mr. Powell has shown that, at Columbus, the 30-day rainfall depths, as computed from the charts, agree quite accurately with the observed values taken from a composite record for the locality. The writer has followed the suggestion that this be verified at other points. The results are shown in Table 7, in which thirteen well-distributed points are listed according to

the magnitude of the coefficient, *K,* in their intensity formulas. These are followed by the computed and observed 30-day rainfall depths, the deviation of the computed from the observed being expressed as a percentage of the observed. The study has a threefold interest:

First.—It has submitted the charts to a rather extensive check.

Second.—It indicates that the intensity and depth curves taken from the charts may be extrapolated to durations considerably beyond four days.

Third.—Considering monthly rainfall depth as a rate-duration relationship, it presents the opportunity to compare single station records of nearly 100 years, with composite records of equal or greater length.

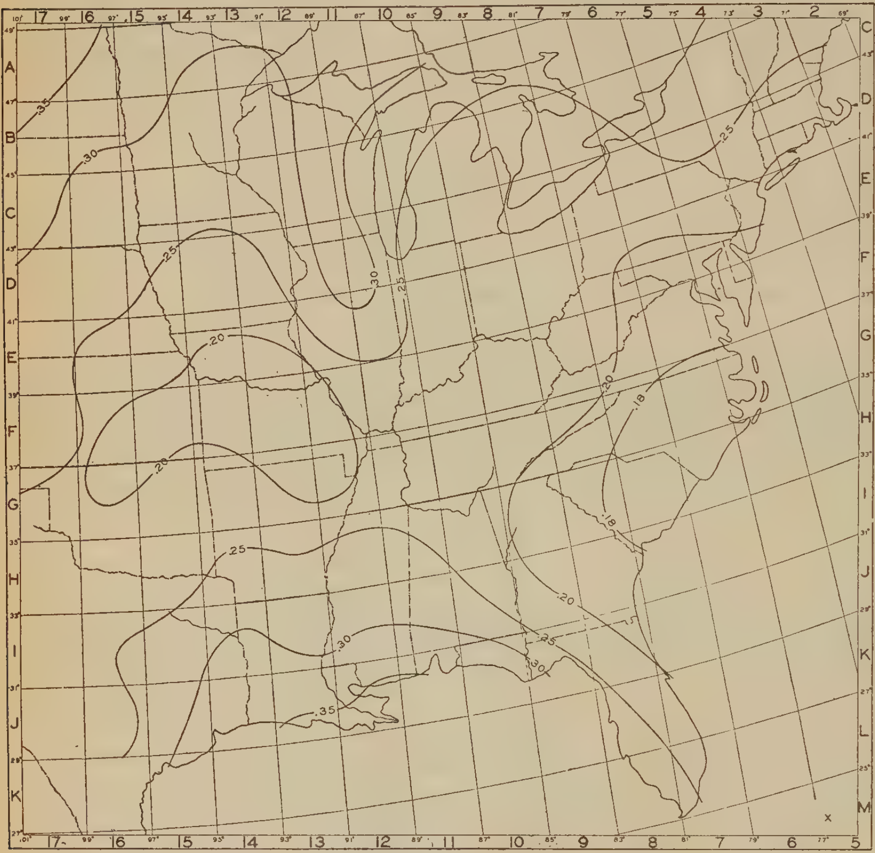

FIG. 20.—VALUES OF EXPONENT, x, IN EQUATION (20)

Because of meager intensity-duration data the theory of the composite record has not been fully established or explained, although it is rapidly being accepted as the basis for design. Composite records, varying in length, number of stations, distribution of recorded years, and arrangement of stations within the area represented, are compared with single station records

at Charleston, S. C., Austin, Tex., Washington, D. C., and Columbus, Ohio, the latter being compared with the single station record at Cincinnati, Ohio. It should be noted that Table 7 compares computed values, by formulas based on composite records and duration periods to four days, with observed values from single station records for a duration period of thirty days. For this reason it is thought fair to show the algebraic averages of the deviations.

U. S. Weather Bureau data giving accumulated daily and monthly rainfall depths must be accepted as representing the time interval observations and the calendar month, respectively. Maximum 24-hour and 30-day values would be slightly higher.

The writer's formulas are shown in Table 8, with those published by Charles W. Sherman, M. Am. Soc. C. E., for Boston, Mass.,[19] and by M. F. Wagnitz, M. Am. Soc. C. E., and Lewis C. Wilcoxen, Assoc. M. Am. Soc. C. E., for Detroit, Mich.[18] respectively. They are in practical agreement for the lower frequencies and shorter durations, but the writer believes the comparatively short records, upon which they are based, have given them exponential values which are too high and which will result in intensity rates for the longer durations that will prove to be excessive when their individual records have extended to 100 years.

ECONOMICAL DESIGN OF HYDRAULIC PIPE-LINE DREDGE[1]

BY JOHN FRANCIS CUSHING,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. R. L. VAUGHN, ARTHUR L. COLLINS, AND JOHN FRANCIS CUSHING.

SYNOPSIS

The hydraulic pipe-line dredge described in this paper[3] is possibly the largest and most powerful built to date (1930) and embodies some new and novel equipment and construction features. It was designed for the Great Lakes and ocean service as well as for river work. The steel hull is made exceptionally heavy and rigid not only to withstand the machinery vibrations, but to support the dredge without failure if it sinks on an uneven bottom. The curved ends of the hull are the result of experiments to determine that shape which would require the minimum power for towing.

The cutter drive is of unusual flexibility and power, with a specially designed cutter, digging to a depth of 50 ft. The method of control is entirely new.

In order to excavate in a definite area at all times, even in a heavy fog when fixed sights could not be used, a gyroscopic compass is installed which insures accurate and positive operation, as well as an assured return to the site, if the dredge is compelled to seek harbor because of a storm.

The dredge is designed for the maximum economy of capital, labor, and power, and the extensive and thorough investigations by the writer and Mr. R. V. Hoopes to determine the economy of these three elements developed the following conclusions:

(1) That a dredge with a discharge pipe 30 in. in diameter is more economical than any smaller size;
(2) That for this size a Diesel-electric installation results in lower production costs than a direct Diesel engine drive; and,
(3) That a single-stage dredge pump driven by the maximum power applicable is most desirable.

---

[1] Published in November, 1930, *Proceedings*.

[2] Pres., Great Lakes Dredge & Dock Co., Chicago, Ill.

[3] The Diesel-electric dredge, *New Jersey*, constructed for, and under the specifications of, the Great Lakes Dredge and Dock Company.

INTRODUCTION

There has been considerable development in the design and manufacture of dredges of the hydraulic pipe-line type in the last few years. Until about twenty years ago (1910) the use of this type of dredge was limited to the transportation of sand or other loose material through comparatively short distances, after mixing the material in a stream of water through a centrifugal pump. By the adoption of cutting machinery, the field was gradually widened to include more refractory materials, such as clay.

At the same time, the effective range of transportation was extended by improvements in pump design and by an increase in power applied to the pump. This increase was limited for a time to the capacity of reciprocating steam engines with speed characteristics suitable for this class of work.

The application of steam turbines followed the reciprocating engine with very beneficial results.

The more recent improvements of the Diesel type of oil engine has opened a new field of development in the design of dredging equipment, and some installations of Diesel-driven pumps have been made.

The first installation of any considerable size, with Diesel-electric power applied to this service, was made in 1925 by the Port of Portland Commission, Portland, Ore., when the dredge, *Clackamas,* was constructed. It has a pump with a 30-in. discharge, driven by a 2 700-h.p. direct-current motor, the power being developed by four Diesel engines, connected to direct-current generators.

This design and installation had some very special features. The conditions under which the dredge was to operate were not as widely variable as to the nature of material, elevations, distances, exposure, etc., as would be encountered in the field of contracting. The dredge was designed primarily for river operation and it was not necessary to design for lake or ocean conditions.

In general, the design of a dredge of this type for contractors' use involves numerous other considerations which are of vital importance and are not included in a special design for rather fixed conditions. The installation described hereafter, covers a dredge for contractors' use and represents the result of many years of experience, combined with the best engineering and manufacturing skill.

NOTATION

The following notation has been adopted consistently throughout this paper:

A = cross-sectional area of the discharge pipe, in square feet.

$b = \frac{700\,e}{n\,w\,f\,d^{(2-p)}}$, a variable coefficient of the ratio of the cost of labor to the cost of power.

B = a variable coefficient $= \frac{700\,e}{n\,w\,f}$.

c = unit cost of labor and power, in dollars per effective pumping hour; c_l = unit cost of labor; and c_p = unit cost of power used by the main pump.

C = unit cost of labor and power, in dollars per cubic yard.

d = diameter of discharge pipe, in feet.

D = a variable coefficient $= \frac{c_l}{c_p}$.

e = efficiency of pump.

f = coefficient of friction in the pipe.

H = hydraulic head, in feet; H_s = suction head; H_e = elevation head; and H_f = friction head.

L = length of discharge line, in feet.

n = exponent of V in the formula for friction head.

O = output, in cubic yards, per effective pumping hour.

p = exponent of d used in the formula for friction head.

P = horse-power; P_m = water horse-power of the main pump; and P_s = shaft horse-power of the main pump driver $= \frac{P_m}{e}$.

R = rate of discharge, in cubic feet per second.

S = fraction by volume of solid material.

V = velocity of discharge, in feet per second; V_e = economic velocity.

w = weight of the mixture of water and solids, in pounds per cubic foot $= (S\ W + U - S)\ 62.5$.

W = weight of dredged material, in pounds per cubic foot.

ECONOMIES OF CAPITAL, LABOR, AND POWER

Reduced to its fundamentals, the basis for designing a dredge for commercial use must be one of economy—economy of capital, economy of labor, and economy of power. The results of investigation in these three fields will determine the type, size, and capacity of the tool.

Each of these elements is made up of inversely varying factors. The greater the size and capacity, the more refined the type, the greater is the initial investment and, of consequence, the attendant interest and depreciation charges. Against these must be set the decrease in cost of dredging. These items which may be called "fixed charges", are converted into the unit cost of output by dividing the annual fixed charges by the annual capacity. This item of cost varies, therefore, in direct proportion to the initial investment.

The cost of labor required is likewise proportional to the size and refinement of type, and the unit cost of labor is inversely proportional to the capacity. In the same manner, the cost of power varies with the size and type and the unit cost of power is inversely proportional to the capacity.

The hydraulic dredging method is unique as compared to that involving the use of other excavating machines. The dredge excavates its material and immediately transports it to comparatively great distances and there distributes it. The operation is continuous and direct, without the need of intermediate storage of the excavated material common in most other methods of dry or wet excavation. Because of this feature of directness, a fine co-ordination of all the parts or units is essential. Continuous functioning of all the elements or parts is also essential because when one part is out of commission or impaired, the entire dredge is in the same measure out of commission and its ability to do work is impaired. If the cutter is idle, the transportation system, namely, the discharge line, is likewise out of service. If the main pump is out of service, the cutting unit and the transportation unit are likewise out of service. If either the suction line or the discharge line is plugged, broken, or otherwise idle, the remainder of the dredge is out of commission, etc., each one of the units or parts being highly dependent on all the others.

The total power of the dredge is used largely in cutting or dislodging the material, sucking it up to the pump with a high percentage of water, and there energizing the burdened stream with velocity and pressure to sustain the transportation of the dredged material at a velocity of 10 to 25 ft. per sec. through pipe lines of from 1 000 to 12 000 ft. in length. More than three-fourths of the power is used in overcoming the friction in the pipe line, and this friction varies inversely as about the square of the diameter. Consequently, it is economical to use as large a pipe line as practicable, because the greater the diameter, the less is the friction, and also the range of the dredge. The distance it will transport the dredged material economically increases with the diameter of the pipe line. For the same reason, the use of straight, smooth pipes as far as practicable is desirable.

A diameter of 30 in. for the discharge is not necessarily the limit in economy from the standpoint of power consumption per unit of output or from the standpoint of the labor involved in operating the dredge alone. Practically, however, the shore discharge pipe can be handled satisfactorily in diameters up to this size.

The waste water from the enclosed spoil-bank areas can well be taken care of, and the annual capacity of such a dredge is more in keeping with the average demand of a hydraulic dredge than one of a larger size.

THE POWER PLANT

As the power plant of the hydraulic dredge, *New Jersey,* represented upward of 25% of the total cost of the dredge, it was a matter given most thorough consideration.

Four two-cycle, air-injection, cross-head type of Diesel engines, each direct-connected to a generator, was the final selection of power plant to fill the many requirements for this dredge in the best way. Among the principal considerations in this design are: (1) The fuel economy of the Diesel engine selected; (2) its convenient and balanced installation in the dredge hull; and (3) the comparatively light weight of the two-cycle engine per unit of power developed in this large size of engine. A four-cycle engine weighing 70 to 80% more would require much higher mean effective cylinder pressures. The cross-head type and comparatively low-speed engines were favorably considered because of their longer life and more reliable service as compared to the trunk type or other high-speed engine.

The range and flexibility of the power were developed by using any combination of the four units, by the convenient pooling of the power, and by its wide-ranged distribution to the different motors on the dredge to meet the almost momentarily changing demands. Particularly is this true in clay work, now quite common, where a wide range of quality of material is encountered frequently in a single swing of the dredge. These alluvial clay deposits, bordering and on the bottoms of rivers and lakes, are mixtures of solid material and water. The solid material is similar to that of shale and slate, which have developed from the clay and mud particles in geological times.

Physical Characteristics of Clay and Shales

Shales probably are produced from the soft clays and mud. They weigh from 160 to 175 lb. per cu. ft., and slates, which have a certain small percentage of porosity, weigh 175 lb. per cu. ft. Considering the influence of heat, and also that the hardest clay particles contain some water, 165 lb. per cu. ft. seems the most probable weight of the solid particles in very soft clay and mud, and this is equal to the weight of most stones. The specific gravity of these solid clay particles is 2.64, assuming the specific gravity of water as 1, and its weight as 62½ lb. per cu. ft. If v is the volume of water in a cubic foot of clay or mud then $(1 - v)$ is the volume of solids, and the weight of the clay per cubic foot will be, $w = 62.5\,v + (1 - v)\,165$. If, for example, the clay is 10% water by volume then the weight would be 156 lb. per cu. ft. If the clay contains 80% of water, the weight, w, equals 83 lb. This shows the wide range of 73 lb., or about 90% variation in the weights of clays commonly encountered in reclamation work.

These values illustrate why clays and muds are more difficult to predetermine and classify and also why they are relatively so costly to handle. Sands or other similar materials do not retain permanently this high content of water and hence are more uniform in weight and other characteristics. In the hydraulic dredging operation, the water content of clays may be changed or it may not be changed substantially, depending on the character of the clay. If it is changed, it will probably return to its original condition after it has been placed in the fill area. In pumping clay the liquid mixture of the suspended particles encountered does not weigh 160 to 175 lb. per cu. ft. as in the case of sands, gravels, and other similar materials; but while these particles rather weigh less, depending on the normal, natural content of water in the clay, nevertheless the weight per cubic foot of clay is greater and the work required to move it from the cut to the fill is greater. This accounts for some of the difficulties of retaining clay fills within the confines of the filled area, because it is manifest that, for higher water contents, the clay is lighter and more fluid. Furthermore, if the fill is a deep one the problem of the compression of clay is involved. When clay is compressed so that the water oozes out, the solid particles remain the same; but the height or depth of the fill is decreased, and it is important to note that the subsidence in the clay fill is not exactly in a direct proportion to the decrease in water content. The subsidence is at an increasing rate. For example, if a clay with 50% of water is compressed to 40% water, the subsidence or decrease in h, the height, would be $\frac{(0.50 - 0.40)}{1 - 0.40}\,h = \frac{1}{6}\,h$. Therefore, it will be seen that if the water content in the fill is to be reduced 10% from that found in the cut, 17% more cubic yards of clay must be pumped from the borrow area than will be paid for in the filled area as commonly measured.

In 1924 and 1925, the writer had an experience with a clay fill on the lake front at Chicago, Ill., in which the loss was in excess of 10% in the pay units of output for the dredge. This resulted largely from such compression of clay. The reclaimed or filled area was approximately 3 000 000 sq. ft., quite regular in shape, and would correspond to a circular area about 1 960 ft. in diameter, requiring about 110 000 cu. yd. for each vertical foot of fill over the area. The average depth of water before the fill was deposited was about 16 ft. The fill was of the same material as that of the ground below, and when hydraulically deposited, it could be considered as of the same quality after its natural compression. The clay was soft, with a natural slope of between 4 on 1 and 5 on 1 near the surface of the bed of the lake in the cut and in the fill, the lower strata in the cut naturally becoming a little firmer. The dredging was done during two years, settlement in each case continuing over the winter periods when the dredging operation could not be continued because of the exposure to lake storms and ice conditions. Successive surveys were taken over the cut and fill areas.

TABLE 1.—COMPRESSION IN CLAY FILL.

Year.	Average height of fill, in feet.	Quantities, in Cubic Yards.			Percentage of compression
		Cut.	Fill.	Discrepancy.	
1924......	18.2	2 030 750	2 002 590	28 160	1.39
1925......	9.9	1 459 250	1 086 403	372 847	25.5
Total....	28.1	3 490 000	3 088 993	401 007	11.5

Table 1 shows the progress by years. In the placing of the first two-thirds or approximately 18 vertical ft. of the fill, a compression of only 1.39% was produced; however, during the second year in the placing of the remaining one-third (corresponding to a layer about 13 ft. over the previously placed fill) an average of less than 10 vertical ft. was actually found by survey, which constitutes an apparent compression of about 25 per cent. The height of this fill is only about 1½% of the width, which is a comparatively thin layer. It is conclusive, of course, that much of the compression took place in the lake bed and the first 18 ft. of fill above it.

The average apparent settlement on the fill was 3.65 ft. The water content of the clay was approximately 45%, and its weight was 119. lb. per cu. ft., producing an average pressure on the lake bottom of about 1.7 tons per sq. ft. By quite an extensive and careful analysis of this lake-bed clay and by computing the compression, it was possible to account for 266 000 cu. yd., or about 66% of the total discrepancy between the cut and fill measurements given in Table 1.

The subsidence that would result in a compression of 66% is equal to 2.32 ft. in vertical height. This corresponds to a 4% reduction in the water content, so that if clay with 49% water is compressed to 45%, the subsidence would be, $31.75\left(\frac{0.49 - 0.45}{1 - 0.45}\right) = 2.31.$

The additional power required to handle medium or hard clays is cumulative and places a comparatively great demand on the power plant of the dredge.

More power is required for cutting, much more power for transporting the larger pieces of solids through the pipe, and considerably more power is required for handling throughout this denser and heavier material. More man-power is required on the fill for the distribution of the material. The high velocity required in the pipe line to transport these larger pieces of clay is quickly lost at the end of the discharge pipe. The clay lumps are immediately dropped and pile up near the end of the pipe, and this requires much additional pipe laying for distributing the fill, but, more important, it causes delays and lost working time of the dredge while the pipe is extended or the discharge is switched to another line.

To reduce delays to the dredge, due to these shore operations, a Y-valve that was developed by the writer is being used in the shore line for shifting the discharge from one line to another, without interrupting the operation of the dredge. This valve is a simple device, consisting of a spoon-shaped blade revolving on the axis of the pipe that enters the Y from the dredge so that material is deflected from one branch of the Y to the other. The sealing edges are built so that they will clear themselves, and will not jam, due to the heterogeneous burden in the stream. While the valve is in operation the cross-sectional area (and, therefore, the velocity of the discharge through it) is constant while the discharge is being shifted.

If the fill area is large, the natural slope may vary with the water ratio, and it is very expensive, if not impractical, to place the fill so that it differs much from its natural slope, which varies with the softness or water-ratio in the clay or mud. Clay with 40% of water (weight, 124 lb. per cu. ft.) is considered soft. This water-ratio, or porosity, is like that of average sand (35 to 45%) and the material is nearly of the same weight per cubic foot as sand and water. The natural slope of sand in water is about 25°, but the more fatty clay particles, lacking the sharpness of sand, will only have a natural slope of about 20 degrees. Only the best clays, when thoroughly wet, will reach a slope of 25 degrees. Mud or silt containing 60% of water (104 lb. per cu. ft.), of old formation in lakes, has a natural slope of about 4°, and in newly formed river mud the slope is probably even less. Clays of different solid matter may vary a little with the same water-ratio, but in clays of the same composition, the slope could be considered as decreasing approximately in a ratio that varies directly as the increase of water percentage.

Such alluvial clays range from very soft to very hard, and frequently contain boulders. Some clays are easy to pump, and others are difficult, developing a high friction coefficient. Some of these clays are broken up into small pieces by the pump, and others are tough and pass through the entire discharge line unbroken or in approximately the same sizes as sliced from the bank by the cutter. It is highly desirable to feed excavated material or burden into the pump and the line stream uniformly so as to reduce the shock to the machinery; and it is more important to reduce the delay due to "slugging" or plugging the suction, pump, or discharge line; but under the conditions described it is very difficult to approach uniformity in cutting or feeding the material into the dredge. In operation a practical limit is reached by working to a margin so that a momentary overload of burden can be passed through without slugging. The ability to shift power and speed quickly between the swinging motor, cutter motor, ladder hoist motor, and main pump motor is of great advantage. It permits giving to the temporarily overloaded unit a "shot" of power and to the overloading unit a reduction at the propitious moment.

In order to study the problem of designing a dredge it is necessary to have an understanding of the physical properties of materials encountered and of the field operating conditions on the dredge and on the fill. Furthermore, it is necessary to know something of the effect of storms, winds, tides, low temperatures, and slides in the cuts and fills.

Preliminary Considerations

In any undertaking, the development of a plan or program for a short period of a few days is simple; such a program for a year is more involved; and for a 5-year period it is much more difficult, as many new problems are thereby brought forward for consideration, to be weighed and fitted into the program in a fashion that will make the entire project feasible and most desirable. These longer programs are necessarily subject to modification from time to time and this must be provided for, but it will be found that the practice of looking many years ahead will result in much more stable and economic progress than otherwise could have been possible. The plans and specifications for a dredge of the character described in this paper must cover a program for a period of 30 to 35 years, or the anticipated life of the dredge.

The application and distribution of power in the Diesel-electric installation are so flexible that the increased fixed charges on the additional electrical equipment and the loss of power in the double conversion are more than offset by the reduction in cost of output.

In a direct Diesel-engine installation it is necessary to provide maximum power capacity for both the main pump and the cutter and other auxiliaries independently. When the full cutter power, however, is not required, the engine supplying this power is at part load and any surplus is not available for other purposes. Similarly, when the full power is not required on the main pump, its engine is operating at part load and the surplus from this source is also not available for other purposes.

Practically, this means that when handling refractory materials, such as hard clay, the power requirement for the cutter is at a maximum while that of the main pump may be reduced, due to a decrease in the percentage of solids in the outflow and possibly to the fact that there may be a lower friction coefficient than with more pliable material. In this case, a proper and efficient distribution of power can be made by motors to all units while drawing current from a common pool of power.

Both the main pump and cutter requirements call for maximum horsepower over a considerable variation of speed. This cannot be accomplished except to a limited extent, with either a reciprocating engine or a turbine; but it can be taken care of almost automatically with motor drive. For instance, in this design, the main pump motor will deliver full-rated horse-power from 250 to 360 rev. per min., without over-heating; the cutter motor will deliver full-rated horse-power from 250 to 500 rev. per min. at full load with armatures in parallel, and from 125 to 250 rev. per min., at full load with armatures in series. The slow-speed range of the cutter is required only in very soft material so that power supply is ample for that condition.

The operating economy as between labor and power depends, in general, upon the velocity of discharge; that is, between the limits of a minimum velocity required to transport the dredged material and the maximum which can be provided by the pump.

Assuming any fixed set of conditions as to length of line, elevation, total head, percentage of working time, and percentage of solids in the stream, the daily output will be directly proportional to the velocity of the discharge. The power required for pumping will be proportional to the velocity and the total head. The total head consists of the suction head, the static or elevation head, the friction head, and the velocity head—the last being of such a low order as to be negligible in the computation.

For comparison, the suction head and the static head may be assumed as constant for any comparable condition. The friction head is an exponential function of the velocity and the diameter of the pipe. It may be demonstrated mathematically that there is a point of maximum economy between labor and power, a velocity at which the combined cost of labor and power is a minimum. By definition, the total cost for labor and power will be,

$$C = \frac{c_1 + c_p\, P_s}{O} \quad \text{.......................} (1)$$

The horse-power required to move a given quantity of liquid against a given head is equal to $\frac{w\ R\ H}{550}$, in which, w is the weight of the liquid per cubic foot; R, the rate of discharge, in cubic feet per second; and H, the head, in feet. The shaft horse-power of the driver is this value divided by the efficiency of the pump, or $\frac{w\ R\ H}{550\ e}$. Furthermore, R is a function of V, such that $R = A\ V$, or,

$$P_s = \frac{w\ A\ V\ H}{550e} \quad \text{.........................} (2)$$

The total head, H, is made up of the static head, the suction head, and the friction head. Equation (2) may then be written,

$$P_s = \frac{w\ A\ V\ (H_s + H_e + H_f)}{550\ e} \quad \text{......................} (3)$$

The friction head is an exponential function of the velocity and is also a function of the length of line through which the mixture is pumped. Therefore,

$$H_f = \frac{L\ f\ V^n}{d^p} \quad \text{..........................} (4)$$

Substituting this value in Equation (3),

$$P_s = \frac{w\ A\ V \left(H_s + H_e + \frac{L\ f\ V^n}{d^p} \right)}{550e} \quad \text{.................} (5)$$

The output is also a function of the velocity, since it is proportionate to the rate, R, which is equal to $A\ V$. Therefore,

$$O = 133.3\ S\ A\ V \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Substituting Equations (5) and (6) in Equation (1):

$$C = \frac{c_l}{133.3\ S\ A\ V} + \frac{c_p\ w\ (H_s + H_e)}{133.3\ S \times 550\ e} + \frac{c_p\ w\ (L\ f\ V^n)}{133.3\ S \times 550\ e\ d^p} \ldots\ldots (7)$$

Differentiating Equation (7),

$$\frac{d\,C}{d\ V} = \frac{-\,c_l\ V^{-2}}{133.3\ S\ A} + \frac{n\ c_p\ w\ f\ L\ V^{n-1}}{550\ e \times 133.3\ S\ d^p} \ldots\ldots\ldots\ldots (8)$$

in which, $A = 0.7854\,d^2$. This value is zero for a minimum, and,

$$V_e = \sqrt[n+1]{\frac{c_l}{c_p}\left(\frac{700\ e}{n\ w\ f\ L\ d^{2-p}}\right)} = \sqrt[n+1]{\frac{b\ c_l}{L\ c_p}} \ldots\ldots\ldots\ldots (9)$$

Equation (9) can be written in a more convenient form, as follows:

$$\log\ V = \frac{\log\,(b\,c_l) - \log c_p}{n+1} - \frac{\log\ L}{n+1} \ldots\ldots\ldots\ldots (10)$$

Therefore, V_e varies directly as the $(n+1)$ root of c_l and inversely as the $(n+1)$ root of c_p.

The practical use of Equation (10) is to determine the horse-power of the main pump driver that will produce at least the economic velocity for the existing costs of labor and power on any length of line which may be met in ordinary operation.

Economic Velocity Under Typical Service Conditions

In the Great Lakes region labor is highly organized and, consequently, is costly, and the power developed by Diesel engines is relatively cheap. Consequently, the economic velocity for dredging under those conditions is high, and it is important to supply the dredge with sufficient power to attain it.

In Table 2, Items 1, 2, and 3 give the economic velocity when the dredge is handling medium clay and the horse-power required for a 30-in. Diesel-electric dredge based on the labor and power costs which obtained in 1925 when the design was first considered.

TABLE 2.—Economic Velocities Under Various Conditions of Dredging.

Item	L, in feet.	V_e.	P_e.	P.
1.	2 000	22.5	2 599	3 000
2.	6 000	15.3	2 427	3 000
3.	11 000	12.4	2 397	3 000
4.	2 000	24.0	3 057	3 000
5.	6 000	16.3	2 858	3 000
6.	11 000	13.3	2 808	3 000
7.	2 000	24.3	2 683	3 000
8.	6 000	16.5	2 463	3 000
9.	11 000	12.7	2 145	3 000

These values were determined by means of Equation (9) and (5), in which, $\frac{c_l}{c_p} = 3.940$; $b = 373$; $e = 0.70$; $n = 1.86$; $w = 68$; $f = 0.523$; $d = 2.5$; $p = 1.25$; $S = 0.067$; $H_s = 16$; and $H_c = 10$.

Anticipating an increase in labor cost, a 3 000-h.p. motor was installed. Under the conditions obtaining in 1930 the corresponding values of V and P_s are as given in Table 2, Items 4, 5, and 6. The actual velocity was checked at times in the field by injecting a salt solution at the dredge pump and observing the time required for it to travel through the pipe line, its passage at the discharge end of the shore pipe being detected by a galvanometer.

From the general Equation (10) developed for finding the economic velocity, it is possible to study the effects on the cost and shaft horse-power requirements, etc., for different values of the other factors involved. No effort has been here made to catalog partial unit costs of hydraulic dredging work as frequently printed, but rather to make a valuable contribution to the extension of the field of knowledge itself. A very careful and comprehensive estimate of the entire situation surrounding each piece of hydraulic dredging work is necessary in order to arrive at a worth-while unit cost. In the absence of such estimate, unit costs are generally misunderstood and misleading, because frequently, knowing the unit cost on one piece of work, a futile attempt is made to correct for the difference in conditions and the situation on another job by mere interpolation without fully recognizing the principles and fundamental conditions partly set out in this paper.

In developing Equation (10) only the costs of labor and power are included. To these must be added the maintenance and depreciation on the plant and the interest on the investment; the cost of shore labor for distributing the fill material; the cost of the attendant plant; wear of the shore discharge line; and the overhead. This cost of labor and power may vary from 30 to 70% of the total, depending on the nature of the material handled, local conditions of disposal, and weather hazards. It depends also on the cost of moving the equipment on and off the work, the cost of marine insurance, the cost for work done outside the section, and effects of shrinkage and of settlement. The miscellaneous items of cost are practically independent of the velocity and the power and may be considered either as current or fixed annual charges, depending on the annual output only.

Table 2 shows that the velocity and the horse-power required for economic operation is greater on short lines than on long lines, although the head is less. It is a characteristic of a centrifugal pump that the peripheral velocity of the impeller, and hence the revolutions per minute, is a function of the square root of the total head. For values of L from 2 000 to 11 000 ft. at the economic velocity of discharge, the head will increase in each case from about 130 ft. to about 220 ft. or, the square root of the head changes from about 11.4 to 14.8, a variation of about 23% using the upper value as a base. Table 2 shows that, in order to maintain the economic velocity the pump driver must deliver about 7% more power at this reduced speed on short lines than at rated full-load speed; on long lines, the pump must deliver 23% more power under the same conditions. In the case of a steam engine this can only be done by putting in an over-sized engine and using it at less than full load on long lines, or by using a smaller sized impeller, or by doing both. The disadvantage of this is that there is a lack of flexibility. This is also true in case of direct Diesel-engine drive. In either case the horse-power is proportional directly to the revolutions per minute and the revolutions per minute cannot be varied independently of the horse-power without considerable loss. This condition can be met with an electric motor of proper design. Computations indicated that the value of this flexibility more than offset the loss of energy in the Diesel-electric conversion.

Effect of Decreasing the Unit Weight of Excavated Material

The weight, W, of dredged material may be determined from the formula, $w = S\ W + (1 - S)\ 62.5$, or,

$$S' = \frac{w - 62.5}{W - 62.5} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

For example, if $w = 68$ lb. per cu. ft. and $S = 0.067$, by Equation (11) $W = 144.5$ lb. per cu. ft. This corresponds to a hard heavy clay. If $W = 124$ lb. per cu. ft., corresponding to a medium sand, then, by Equation (11), $S = 0.0894$.

In Equation (6), the output, $O = S\ A\ V = \left(\frac{w - 62.5}{W - 62.5}\right) A\ V$, varies directly as S, but inversely as W. Therefore, a decrease of 14% in the specific weight of the material corresponds to an increase of about 34% in the carrying capacity of the discharge, assuming that f remains constant. That is, for $W = 144.5$, $V = 22.5$, and $S = 0.067$, $O = 14\,700\ S = 14\,700 \times 0.067 = 985$ cu. yd. per hour, and for $W = 124$, $V = 22.5$, and $S = 0.0894$, $O = 14\,700 \times 0.0894 = 1\,315$ cu. yd. per hour.

Effect of Variation in f Upon V_e and P_s

Under typical service conditions for which the *New Jersey* was constructed, the value of f has been previously given as 0.523. If this value is changed to 0.420, the value of $b = \frac{700\ e}{n\ w\ f\ d^{0.75}}$, will change proportionately, and the economic velocities for Items 7, 8, and 9 of Table 2 are found by Equation (9).

These data show that for a decrease in f of 20%, when $L = 2\,000$ ft., V is increased 8% and P_s is increased 2%; and for a decrease in f of 20%, when $L = 11\,000$ ft., V is increased $2\frac{1}{2}$% and P_s is decreased $12\frac{1}{2}$ per cent.

Approximate Effect on V_e and O of Decrease or Increase in Diameter of Pipe Line

From Equation (9),

$$V_e^{\,n+1} = \frac{c_l}{c_p}\left(\frac{700\ e}{n\ w\ f\ L\ d^{(2-p)}}\right) = \frac{700\ D\ e}{n\ w\ f\ L} \div d^{(2-p)} \quad \ldots\ldots\ldots (12)$$

and,

$$V_e = \left(\frac{700\ D\ e}{n\ w\ f\ L}\right)^{\frac{1}{n+1}} \div d^{\left(\frac{2-p}{n+1}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

For typical service conditions, previously described, the exponent, $\left(\frac{2 - p}{n + 1}\right) = \left(\frac{2 - 1.25}{1 + 1.86}\right) = 0.262$; therefore, V_e varies approximately as $\frac{1}{d^{0.262}}$, and, for

$d = 2.5$, $L = 2$, and $V = 22.5$. If d is reduced from 2.5 to 2.0, then $V_e = \dfrac{22.5}{\left(\dfrac{2}{2.5}\right)^{0.262}} = 23.8$ for $d = 2.0$; that is, a 20% decrease in d corresponds to a 5.8% increase in V_e.

From Equation (6), $O = (133.3 \times 0.067)AV = 8.9AV$. For $d = 2.5$, $A = 4.90$, and $V = 22.5$. Consequently, $O = 8.9 \times 4.9 \times 22.5 = 985$ cu. yd. per hour; and for $d = 2.0$, $A = 3.14$, and $V = 23.8$, and, therefore, $O = 8.9 \times 3.14 \times 23.8 = 665$ cu. yd. per hour. This illustrates that, for a decrease of 20% in d, O is reduced 320 cu. yd. per hour, or 32½ per cent.

EFFECT ON C OF DECREASING THE DIAMETER OF DISCHARGE LINE

In Equation (9), $V = \left[\dfrac{b\ c_l}{L\ c_p}\right]^{\frac{1}{n+1}}$; and $b = \dfrac{700\ e}{n\ w\ f\ d^{(2-p)}} = \dfrac{B}{d^{0.75}}$. Therefore,

$$V_e = \left[\frac{c_l{}^{B}}{c_p\ L\ d^{0.75}}\right]^{\frac{1}{2.86}} = c_l^{\frac{1}{2.86}}\ B^{\frac{1}{2.86}}\ c_p^{-\frac{1}{2.86}}\ L^{-\frac{1}{2.86}}\ d^{-\frac{0.75}{2.86}} \ldots\ldots. (14)$$

From Equation (7),

$$C = \frac{c_l}{133.3 \times 0.7854 \times 0.067\ d^2\ v} + \frac{c_p \times 68 \times 0.523\ L\ V^{1.86}}{133.3 \times 550 \times 0.7 \times 0.067\ d^{1.25}} + \frac{c_p \times 68 \times 26}{133.3 \times 550 \times 0.7 \times 0.067}$$

or,

$$C = \frac{c_l}{7.014\ d^2\ v} + \frac{0.01034\ c_p\ L\ V^{1.86}}{d^{1.25}} + 0.5142\ c_p \ldots\ldots\ldots (15)$$

Substituting the value of V_e in Equation (14) for V in Equation (15), and simplifying:

$$C = \frac{c_l{}^{0.65}\ [c_p L]^{\frac{1}{2.86}}}{d^{1.737}} \left[\frac{1}{7.014\ B^{\frac{1}{2.86}}} + 0.01034\ B^{0.65}\right] + 0.5142\ c_p \ldots..(16)$$

The value of C for any economic velocity varies inversely as the 1.737 power of the diameter. The unit cost of labor, c_l, is also some function of the diameter; it is larger for large diameters. However, c_l may be considered constant for values of d between 2.0 and 2.5 ft. and a constant smaller value for diameters less than 2.0 ft. The unit cost, c_l, does not decrease proportionately with d, and even if it did, it appears in the numerator to a fractional power, while d appears in the denominator as a power greater than 1. Hence, the unit cost may be decreased by increasing the diameter of the discharge of the dredging pump.

EFFECT OF OPERATING AT VELOCITIES HIGHER AND LOWER THAN V_e

The value of V for minimum cost is given by Equation (9) assuming $n = 1.86$; thus,

$$V_e^{2.86} = \frac{c_l\ b}{c_p\ L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

Under the typical service conditions previously described, the shaft horse-power, P_s, is determined from the relation:

$$P_s = 22.54\,V + 0.1442\,V^{2.86}\,L \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

The value of P_s corresponding to a minimum value of C occurs when $V = \sqrt[2.86]{\frac{c_l\,b}{c_p L}}$.

Substituting this latter quantity in Equation (18) and writing D for $\frac{c_l}{c_p}$,

$$P_s = 22.54 \sqrt[2.86]{\frac{D\,b}{L}} + 0.1442\,D\,b \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

The economical shaft horse-power varies directly with D and b and inversely with L. For all values of V greater than, or less than, $\sqrt[2.86]{\frac{D\,b}{L}}$, C will increase. Since P_s varies directly with V, the application of any shaft horse-power greater than that corresponding to $V = \sqrt[2.86]{\frac{D\,b}{L}}$ will increase the unit cost instead of reducing it. Fig. 1 shows the effect on C of a change in V and P_s for a particular instance, with L equal to 6 000 ft. It illustrates most clearly how definite Points V_e and P_{se} are, and how sharply the value of C rises with the application of power either less or greater than P_{se}, the economic power.

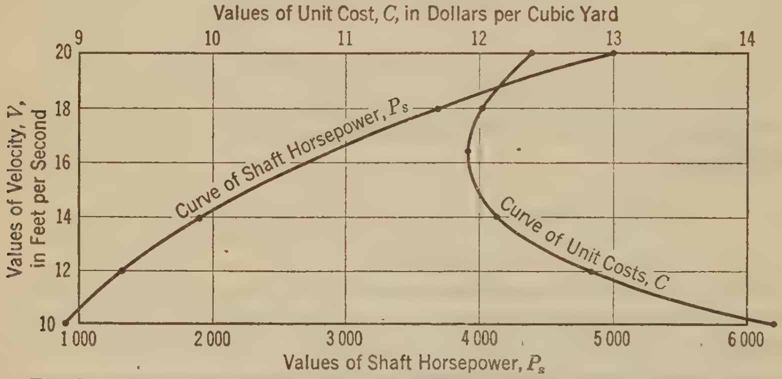

FIG. 1.—CURVES SHOWING THE RELATIVE EFFECTS OF VARYING THE VELOCITY OF DISCHARGE AND THE SHAFT HORSE-POWER.

EFFECT OF BOULDERS IN HYDRAULIC DREDGING

The unpleasant consideration of this element of the dredgeman's work was left to the last so that the foregoing engineering principles and finer analysis might be given calm and deliberate thought. Boulders are frequently mixed with clay and sand in natural deposits. Many times they are promiscuously distributed; sometimes they are more or less uniformly scattered; and at other times they are found in nests as if to make a concentrated attack on the dredge for disturbing their peaceful seclusion of millions of years. A relatively small percentage of boulders by volume in the proposed cut eliminates it for the hydraulic dredging method of excavation. In fact, the only sufficient reason for considering the hydraulic dredging of ground containing boulders is to secure that part of the work not involving the handling of them.

All boulders are highly objectionable in this method of excavation, but the size most detrimental is that critical one which will pass through the opening in the cutter and will not pass through the opening in the pump flyer. It becomes lodged and sometimes tightly jammed, thus badly unbalancing the flyer and making it necessary to shut down the dredge for the removal of the boulder. These are expensive delays and, in terms of unit of excavation, may cost as much as $200 to $500 per cu. yd. for the boulders encountered. Boulders that are too large to enter the cutter, or become jammed in it, or smaller boulders that will pass through the pump and discharge line, are not so objectionable; but they are highly undesirable, and their presence seriously upsets all the calculated economies set forth in this paper.

There is, of course, a relation between the size of opening in the cutter and that in the pump flyer. The cutter designed for maximum efficiency in clay will have a maximum opening or clearance between blades of approximately six-tenths the diameter of the pipe line. For low-speed dredge pumps the minimum opening or clearance through the flyer vanes would be approximately five-tenths the diameter of the discharge pipe, and for high-speed pumps somewhat less, because of the flatter or less radial shape of the vanes. As the efficiency of the main dredge pump is so important, an efficient design of the impeller cannot well be compromised for this boulder condition. Similarly, the efficient design of the cutter is very important and, therefore, these clearance dimensions for both cutter and pump are more or less fixed. The particular size of boulder that will become lodged in the cutter or in the pump is the critical size and, of course, this varies with the size of the dredge.

The frequency of delays to the dredge caused by the removal of boulders is, of course, in proportion to the percentage of the critical size of boulders in the area to be excavated, and also to the output of the dredge. While the presence of boulders has a great effect on the cost of the work, there is no formula, either theoretical or empirical, that is applicable for determining the effect. Only by careful analysis and long experience can this element of the cost be even roughly estimated for any job.

The critical size of boulder for the *New Jersey* is 3 to 5 cu. ft., or 400 to 700 lb.; but, at times, and on short-line work, much larger ones are taken from the pump. For example, a granite boulder weighing 1 050 lb. was taken from this pump at Toledo, Ohio, on July 5, 1929, while dredging heavy hard clay mixed with sharp gravel. This combination of material is somewhat unusual and difficult to handle. Mysteriously, the minimum dimension of this large boulder (19 in.) was more than an inch greater than the maximum distance between the cutter blades, and if this is accounted for by springing these heavy short blades, it furnishes a new measure of the forces to be resisted and the sturdy design required.

The Design Elements

Having determined, from the preceding analysis, the relation between the different factors involved and their relative importance for economic operation, the conclusions, tempered with experience, have been applied in the design and construction of the *New Jersey*. Another factor considered of great importance, of course, is the general time efficiency of the entire dredge. Such dredges are usually operated 24 hours per day, and the time efficiency is the ratio of the number of working hours to the 24 hours, and for obvious reasons too numerous to mention, this has been kept in mind in the design of every unit of the dredge.

Having determined that a dredge with a 30-in. discharge, with Diesel-electric drive, is the most economical within practical limits and the best commercial type of the available sizes or types of power installations, the problem remains to design the component parts necessary for the successful operation of the entire installation.

Hull.—The first consideration in design, of course, is the hull, which must be constructed so as to provide buoyancy for the weight of machinery, fuel, supplies, etc. It was necessary that it be sufficiently rigid to withstand the vibrations set up by the Diesel engines, as well as the stresses incident to dredging operations, and that it be able to support the dredge without failure if stranded on an uneven bottom.

The limitations were that the hull should not draw too much water which would eliminate it from working on shallow projects, and that its length and breadth should not exceed the capacity of locks in canals between the Great Lakes and the Atlantic Coast. It was found impossible to keep within the required beam, so the hull was constructed with a detachable side section to bring it within the required width. The dimensions finally decided on were: Length, 245 ft.; beam, 50 ft.; depth (moulded), 14 ft. 4 in.; and draft (working condition), 9 ft. 3 in.

The hull proper is divided into compartments by a system of water-tight bulkheads. This affords maximum protection against sinking from collision or other mishap as well as protection against damage to the electrical equipment should any part of the hull be flooded. The side compartments are used for the storage of oil, water, and supplies; the larger center compartments are used for the machinery. The main pump and main pump motor are in separate compartments to avoid damage to the motor in case the pump should be broken by a boulder, or from some other cause. These bulkheads add considerable strength and rigidity to the hull structure.

In addition, there are two longitudinal trusses, at 23-ft. centers, the full length of the hull. They are extended at the bow to form the gantry for supporting the dredging ladder, and at the rear they support the stern spud anchors. The depth of these trusses is less than that ordinarily found in bridge practice. It was desired to keep down the height of structures above water to reduce wind resistance and maintain low bridge clearance. To have given the truss greater depth would have necessitated running it through the roof of the lower house which would have made it unsightly and left opportunity for leaks. In addition, it would have projected into the living quarters which would have made that part of the layout quite complicated. The additional weight due to the reduced depth is not great and adds to the rigidity of the entire structure.

Another novel feature is the shaping of the ends of the hull. This is done to reduce towing resistance. As early as 1914 the writer's Company had tests made at Rensselaer Polytechnic Institute, Troy, N. Y., to determine the relative resistance of square hulls with ends varying in shape. The models had square ends with differently shaped rakes. It was found at that time that a section of compound curvature increasing at the bottom had the least resistance. Later tests made by W. C. Sadler, M. Am. Soc. C. E., at the University of Michigan, developed the fact that a rounding of the deck section still further reduced the resistance. The results of both these series of tests have been included in this design.

Another feature of the hull design is the recess placed at the after starboard corner to accommodate the stern ball connection in the discharge line. Two methods are ordinarily used for this connection, either (1) to bring the discharge pipe through the hull near the water-line and support the connection by an A-frame, or gantry; or (2) to bring the pipe above deck and use a swinging elbow in a gooseneck. Both methods have serious faults. The first has the disadvantage of a connection that is more or less inaccessible due to its being in or near the water; the second involves short-radius elbows, and brings the discharge too high above the water. The new method meets the objections to both, eliminating the elbows and putting the discharge pipe at the proper level for joining to the pontoon line.

Deck House and Crew Quarters.—The main deck house is of steel and provides a complete enclosure for the machinery, leaving a deck space of approximately 9 ft. on each side. This space has guarded bulwarks 30 in. high around the ends and extended about 6 ft. along each side, with chains supported by removable steel stanchions between the bulwarks. The roof is supported by the longitudinal trusses. The doors in the lower house are of steel, and the windows are fitted with wire glass in steel sash.

The upper house rests on the steel roof of the lower house. It is of wood construction throughout and is divided into 39 rooms, comprising 18 staterooms, 3 toilets, 3 baths, 2 washrooms, 2 dining-rooms, 2 storerooms, wireless room, office, galley, pantry, room for ice machine, refrigerator room, officers' lounge, crews' "social hall", and laundry.

It has been found that comfortable quarters for the crew on a machine of this kind where the men spend most of their time on board, is a great asset; it keeps them satisfied and more inclined to stay with their job. The provision of an officers' lounge and a social hall for the crew may appear extravagant at first, but it must be realized that it is only necessary to take a very little from each of the staterooms to make this space available, and that the common social halls afford opportunities for recreation which could not be made possible in individual quarters.

All the rooms are heated, lighted, and well ventilated, and open into a common corridor in the middle of the house. Over this corridor for its full length is a monitor with ventilators. The galley is fitted with sink, tables, lockers, shelves, and an oil-burning range. Complete culinary equipment is provided for a crew of fifty men.

Cutter and Ladder.—A heavy plate-girder ladder of sufficient length for a digging depth of 50 ft. is hinged to brackets in the bow well, with its outer end suspended through wire-rope tackle blocks from the bow gantry extension of the main trusses. The lower end of the ladder is formed by the steel casting suction head made in two pieces with two bearings for the cutter shaft about 10 ft. apart. The outer bearing extends well inside the cutter head and consists of a sealed and water-lubricated cutless bearing. The suction head has a pressure-water chamber with jets directed into the suction inlet to assist in freeing a clogged pipe. Lugs are provided for the purpose of anchoring the ladder suspension tackle and the swinging sheaves. Heavy flanges serve to tie the suction head thoroughly to the structural part of the ladder. The upper ladder end has three heavy annealed steel castings which form the ladder hinges and foundations for the cutter motor and gear box.

The cutter head (Fig. 2) was designed and built by the writer's Company. It is an integral alloy steel casting with eight spiral arms connecting the hub and back ring. Replaceable chrome vanadium blades are riveted to the arms. The hub is taper-bored and keyed to a 13½-in. cutter shaft which is supported by two bearings in the suction head, two in the gear box, and four intermediate bearings mounted on transverse ladder girders. The lower bearing is designed to transmit the axial thrust of the shaft to the ladder.

The 600-h.p. cutter-drive motor is mounted on the ladder and drives the cutter shaft through a flexible coupling in combination with a slipping friction. The first set of reduction gears is of the herring-bone type; the second set, consisting of the cutter shaft gear and its pinion, is of the single helical type. Both sets are encased and run in oil, with all gears and pinions mounted between two bearings built into the gear casing. The cutter shaft is made in six sections held together with bolted and keyed couplings.

Suction and Discharge Pipe.—The suction pipe has an inside diameter of 34 in., and enters the hull through a packed and water-sealed ball joint which is bracketed to the end of the well plating and the deck concentric with the ladder trunnions. A readily removable manhole section next to the pump has a hydraulically-operated hinged cover, the mount of which permits it to function as a suction line relief valve.

The discharge pipe has an inside diameter of 30 in., and is located immediately outside the house on the starboard deck. It is connected to the discharge line with a rubber-packed, quick-opening ball joint mounted in a gimbal ring, the deck being tapered off to the stern to receive the bracket and ring. The joint is provided with compression spring bumpers which contact with a structural frame to limit its transverse angular movement. A gate-valve section is placed in the line immediately forward of the ball joint, and there are two manhole sections adjacent to the pump discharge. Replaceable plate liners are spot-welded in the lower half of each straight pipe section. All cast-pipe fittings on the dredge have cast alloy steel liners. The discharge pipe sections are held together by special rubber-sealed pressure joints.

Pump.—The pump (Fig. 3) is somewhat unusual; a number of novel features have been introduced in its design. It is of the square-casing lined type recommended by J. H. Polhemus, M. Am. Soc. C. E., who has had a

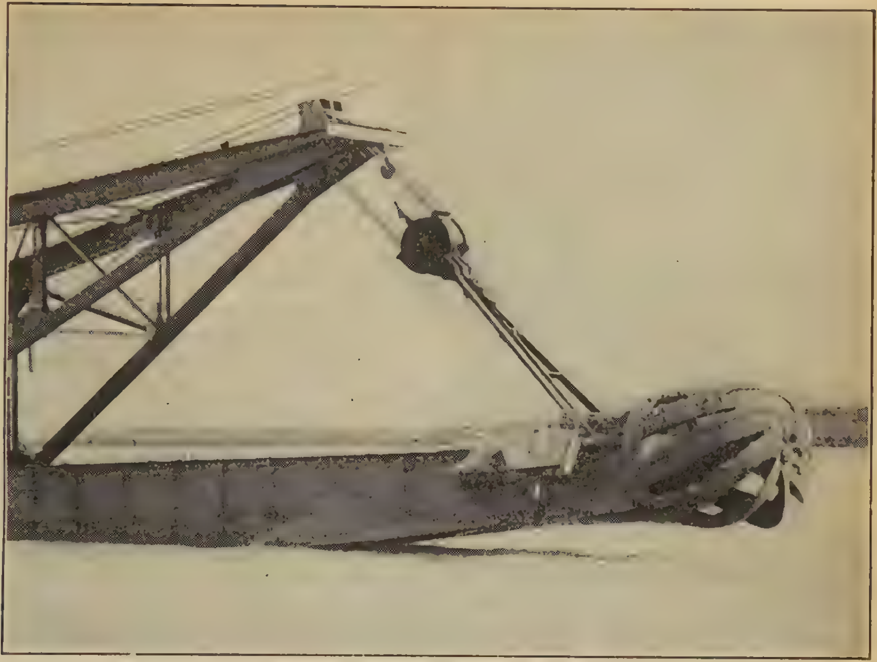

FIG. 2.—VIEW OF CUTTER HEAD.

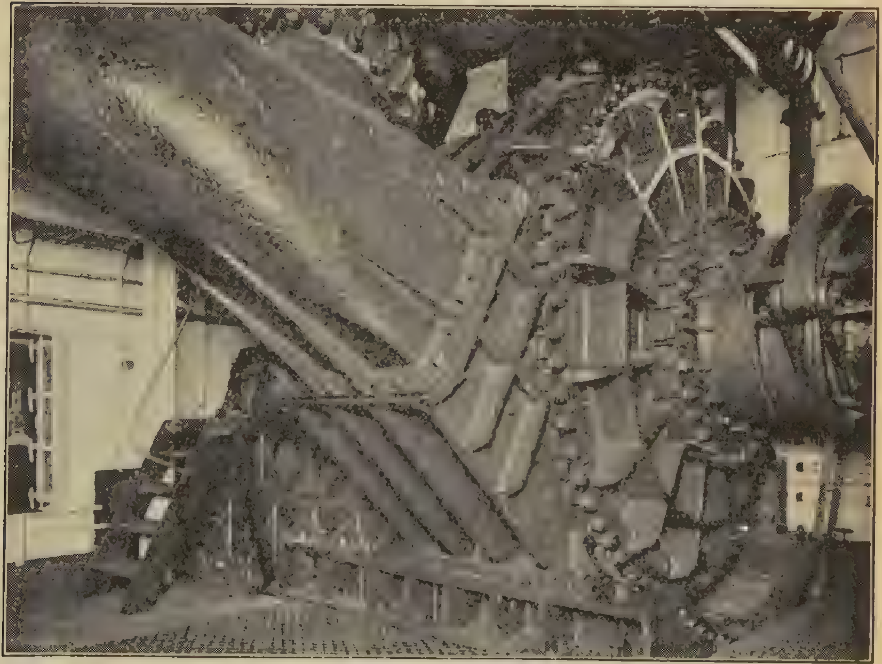

FIG. 3.—THIRTY-INCH DREDGE PUMP.

marked degree of success with that type of pump on the Port of Portland (Ore.) dredges. The casing is made of alloy steel and consists of an outer ring with the discharge outlet cast in one piece. It is about 9 ft. in diameter. The inner face being flat, it is stiffened circumferentially and cross-wise over the 3½-in. thick metal with rail-shaped ribs. The side flanges have slotted holes for bolting to the front and back ends. The periphery of the casing is lined with plate sections held with countersunk bolts. The front and back heads are well-ribbed alloy-steel castings with double liners held to them with countersunk bolts. The liners which contact with the material, are made in a number of pieces to permit obtaining maximum wear on all sections. The liners adjacent to the casing are somewhat heavier than the disk liners and are alloy-steel castings made in sections. The disk liners are plates. The suction-mouth liners are heavy iron castings held in place with studs. A rubber-faced adjusting ring may be set up from outside the suction mouth to limit the clearance between it and the runner. This tends to prevent a circulation from the discharge pressure chamber to the suction inlet, thereby maintaining the pump efficiency and eliminating wear.

For experimental purposes, there are two runners; one with a square, and the other with a long-sweep, throat. Both are alloy-steel castings of the shrouded type with four vanes and threaded to receive the runner shaft. A nut serves to lock the runner in place on the shaft. The runner and thrust shafts are 14⅝ in. in diameter and are made in three sections bolted together through flanges forged with the shafts. The intermediate or short section is removable to permit of readily withdrawing the runner shaft through the back head. The shaft has a replaceable sleeve where it passes through the water-sealed stuffing-box in the back head. A motor-operated turning device consisting of a worm and wheel which may be readily thrown in or out of engagement, serves to assist in backing the runner off the shaft or to lock the shaft against turning. The thrust shaft has one collar which transmits the thrust to the base through an over-sized two-way, oil-lubricated, water-cooled thrust bearing in combination with a radial bearing. The radial bearing next to the pump back head is of the same type.

Three heavy cast-iron bases are securely bolted together to form a rigid foundation for the motor, pump casing, and bearings.

Bow Winch.—The bow winch consists of five drums loosely mounted on a single shaft. The middle drum hoists the ladder and is driven from a 110-h. p. motor with control for dynamic lowering. The two drums next to the ladder hoist drum are used for swinging the dredge in normal operation, and the two outer drums may be used for side-breasting or for crane service. A 125-h. p. motor drives the swinging and the auxiliary drums. The motor pinions are mounted on stub shafts. Each set of first-reduction gears are of the herring-bone type encased and running in oil. The second set of intermediate gears and the pinions which mesh with the drum gears, together with an independent friction and brake, for each drum, are mounted on a single intermediate shaft which has a winch head on each side of the house. The intermediate shaft is made in coupled sections for alignment purposes. The hoisting drum is grooved for its rope; all other drums have plain barrels. All spur gears have cut teeth.

The frictions, which are of the internal expanding, reversible driven type, are air-operated. The machinery with the driving motors is mounted as a unit on a substantial, structural steel base.

Stern Winch.—The stern winch is mounted on the deck aft of the main engine hatch and forward of the spuds. It consists of two drum shafts upon each of which is loosely mounted a grooved spud drum and a plain barrel auxiliary drum. Each drum has an independent friction and brake which, together with the drum gear pinions and intermediate gears, are mounted on an intermediate shaft, coupled in three sections, with a winch head on the port side. The first reduction gears are of the herring-bone type encased and running in oil. The auxiliary drums may be used with the forward auxiliary drums for breasting the dredge, for warping the pontoon line, or for auxiliary crane service. The gears, frictions, and other winch details are similar to those of the forward winch. The machinery and motor are mounted as a self-contained unit on a substantial, structural base.

All clutches and brakes for the bow and stern winches are controlled from the pilot-house which is located above the crews' quarters at the forward end. Each lever line is distinctly marked. If desired, the stern winch (including the motor) may be controlled from the stern as well as from the pilot-house. The pilot-house is the full width of the deck-house and has windows on all sides. It houses the controls for the cutter, ladder hoist, forward and stern winch motors, a push-button cut-out for the main pump motor, as well as all meters and gauges for the motor and main pump. The pilot-house is in communication with the engine-room and the other parts of the dredge through signal, telephone, and speaking-tube systems.

Spuds.—There are two spuds mounted in lined steel casting keepers in wells cut into the stern with a space of approximately 20 ft. between the upper and lower keepers. The upper keeper reactions are taken directly into the hull trusses. The stern of each keeper has a pin-connected gate which may be opened to unship the spuds. The spuds are 48 in. square, made with corner angles and side-plates, and two internal latticed trusses in the fore and aft direction. The lower spud end is of novel design; it consists of a heavy cylindrical steel casting, the outer point of which is clamped to, and rotates about, an inner point to which the square structural spud is securely riveted. Bushings and washers which form the contacts between the inner and outer points, are made of special brass. The spud-hoisting sheave is mounted in the upper end of the inner casting and is thoroughly rope-guarded. The rotating-point feature relieves the spud of all torsional stresses which otherwise would have to be transmitted through the spud to the keepers when the dredge swings.

Another very unusual feature is the provision for pinning up on the spud as is done on the forward spuds of a dipper dredge. This assures a firm grip for the spud in any reasonable bottom. The point remains fixed while the spud rotates, thus tending to prevent loosening the grip by enlarging the hole which has been made by the spud point.

The design of the spud machinery is such as to utilize the weight of the idle spud for "pin-up" reactions on the digging spud. The "pin-up" sheave is mounted in a steel casting bracket riveted to the upper spud end.

Power Plant.—All main dredging units are driven from a 600-volt direct-current power line energized by four 800-kw. parallel-operated, direct-current generators. Each of the latter is driven by an 1 150 b. h. p. vertical, 6-cylinder, 180 rev. per min., Diesel engine of the 2-cycle, air-injection, cross-head type. The engines are mounted on heavy longitudinal girders which are tied into the deep transverse floor system with plate intercostals. The generators and outboard bearings are mounted on steel-casting bed-plates.

The main Diesel engines are right and left hand with the operating gear for each on the inside. The air compressor, scavenging pumps, lubricating oil pumps, and fuel-oil injection pumps are built integral with the engines. A fresh-water cooling system consisting of re-coolers, filters, sea and fresh-water pumps, and a tank into which the water is discharged from the engines and redrawn by the circulating pumps, maintains the engines at a proper temperature by circulating water through the cylinder jackets and pistons. If desired, sea water may be used for cooling purposes in which case a small pump preserves a constant level in the discharge tank by discharging the cooling water overboard.

The dredge is equipped with 53 motors having a total normal rating of about 4 600 h. p. The main motors are operated from the 600-volt main generator busses, and this includes all motors of 5 h. p., or more, except the 7½-h. p. bilge-pump motors. The other motors are for auxiliary service and are of units less than 5 h. p. They are operated from the 125-volt bus which is energized from a 75-h. p. motor generator set, or the 75-h. p. Diesel engine set.

The main pump motor is of the adjustable speed type and will normally develop 3 000 h. p. continuously. Resistance is used for starting duty only, which means a sufficient period of time to fill the pipe line. Push-buttons in the engine-room serve to regulate the speed of the main motor through a motor-operated field rheostat between the limits of 250 and 360 rev. per min. This range is sufficient to allow for all reasonable service variations due to the pumping of different grades of material or variable line lengths with the same runner. This type of motor and control permits of efficient operation at full-load rating at any speed within the range, thus using the entire output of the power plant for variable duty, which assures maximum output at all times. The motor may be stopped by a push-button in the operating room.

The cutter motor has a full-load continuous rating of 600 h. p., and will develop overloads for time intervals up to a maximum of 1 100 h. p., for 5 min. This is considerably more power than has ever been applied to a cutter and the method of control is entirely new. The motor is of the adjustable-speed, double-armature type with resistance for only heavy-duty starting. The normal speed range with armatures in parallel is from 250 to 500 rev. per min. for full loads or overloads. With the armatures in series, the speed range is from 125 to 250 rev. per min. with about 50% of the normal load or overload ratings. This arrangement with the 4:1 speed range gives efficient and flexible control. The power developed by the motor at slow speeds is ample to satisfy the service condition, as the slow cutter speeds are required for easy digging only. The cutter and swinging motor controls are interlocked, which automatically slows down the swinging speed when the cutter is overloaded and restores it after the cutter motor has pulled through the overload condition.

The swinging motor has a continuous rating of 125 h. p., and is operated from the variable voltage motor-generator set with a Ward-Leonard system of control for starting, stopping, and regulating the speed from zero to 700 rev. per min. This system is used on the swing motor because of the necessity for a very wide speed variation and more reliable protection for the cutter motor through the interlocking control than could be obtained by a resistance control. A solenoid brake is provided on the swinging motor to prevent the dredge from drifting through wind or current action.

The ladder and spud-hoist motors are of the series-wound type with magnetic control and dynamic lowering. Solenoid brakes are provided, which set on the neutral position of the control lever. Both motors are controlled through the pilot-house, but the spud-hoist motor may be controlled from the stern if unlocked through the pilot-house controller. Both motors have a 75°, half-hour, 110-h. p. rating.

Miscellaneous Equipment.—There are two 10-ton, hand-operated traveling cranes, of 21 ft. span, mounted on overhead runways and supported by the truss posts. The runways extend over the upper end of the ladder to the bow gantry. For making heavy lifts, both cranes may be used together at any point in the length of the runway. There are six 5-ton, deck-mounted, cargo cranes, three forward and three aft. Blocks, lead sheaves, and anchorages are provided for operating these cranes by hand, from the winch head, the auxiliary drums of the bow, or the stern winches. A jib crane is pin-connected to the suction head at the lower end of the digging ladder, and is designed to fold back so as to be held by the ladder suspension bars when not in use.

A 3-ton, stockless anchor with 150 fathoms of stud-link chain, operated from a 30-h. p., worm-driven anchor hoist, with a locking gear and hand-operated brake, is located between the spuds on the deck, with a chain locker below the deck. A 30-h. p. capstan, with hand-operating mechanism, is located on the deck at the stern.

Application of the Gyro-Compass to Dredging Work

Under numerous circumstances, especially when working in the lake at some distance from shore and at times when weather conditions prevent the use of ordinary ranges placed on shore, it is desirable and often essential that a means be provided on the dredge both for determining its location with reference to fixed points on shore and the width and direction of the cut being made by the dredge.

A partial solution of this problem was suggested in the use of the compass. To be of value in this respect the compass would have to be under the constant view of the operator and, because of the many cables carrying heavy electric currents which pass through and about the operating room, the magnetic compass proved to be of little value as it could not be adjusted to maintain true readings.

The next suggestion was the use of a gyro-compass which is not affected by the presence of electric currents and which has an additional value in that its readings are always given in true azimuth. In this manner the compass readings can be adapted to a survey based on co-ordinates the axes of which are parallel to and perpendicular to the true azimuth without correction.

The installation consists of a master compass which contains the gyroscope and all its mechanism, together with one or more repeaters, which has the advantage of providing a relatively small instrument in the repeater which can be placed in a convenient location. These repeaters are provided either with fixed horizontal compass cards or are mounted in gimbal rings for tilting in the plane most convenient for reading. An azimuth circle attachment is also provided by use of which the position of the dredge may be determined by triangulation, with fixed points on shore, the co-ordinates of which are known. More exactly, this process gives the location of the compass from which, by reading the heading of the dredge, the exact location can be determined by means of a small template of the same scale as the survey map.

The installation of this instrument proved a complete solution of this problem, and it was found that the dredge could be located within reasonably accurate limits by this means. Likewise, having established the location of the dredge, the cut can be maintained in any predetermined direction and of any predetermined width by controlling the swing of the dredge an equal distance either side from a predetermined average heading or direction of the cut.

After this installation was made and found to be satisfactory, a further addition was made to the installation which consisted of a recording repeater. The record of this repeating instrument was made on a paper strip, 7 in. wide, which gave the azimuth readings across the sheet, passed under the recording pen at a rate of about ¼ in. for each 10 min. of time. The clock mechanism was operated by an 8-day movement, and the record roll was of sufficient length to last a month.

In ordinary use on board ship this record is almost a straight line, showing only variations from the established course of the vessel due to windage, wave action, or other disturbing forces which alternate with the corrections applied to these deviations either by the wheelsman or by the automatic steering mechanism which is often applied to it. The curve produced by this recording and dredging operation, however, is quite different. It consists of a series of diagonal lines which record each swing of the dredge, indicating the azimuth reading at the end of each swing. Delays are recorded by a straight line in the direction of the chart so that a complete record of the operation of the dredge is maintained, indicating the exact number of minutes occupied in actual dredging, during which time the dredge is swung either in one direction or the other, and the actual delay time.

In addition, the operation of moving the dredge ahead in the cut by walking it on the two stern spuds leaves a characteristic record. The swing of the dredge is interrupted on the chart by a delay of about 1 min. or 2 min., during which time one spud is lowered and the other raised. This is followed by a continuation of the swing line through a certain number of degrees, and followed again by a delay of from 1 min. to 2 min., during which time the spuds are reversed. From the distance between the centers of the spuds and the angle moved through in the walking operation, the number of feet which the dredge will be advanced, can be determined. Checking the computed advance of the dredge over a considerable period of time by location from fixed points on shore, it was found that this method was especially accurate. This compass record gives an accurate determination of the width of the cut and the advance of the dredge so that, knowing the elevation of the bottom before and after dredging from soundings, the quantity of material moved can be checked with fair accuracy from day to day and from hour to hour.

As an essential part of the dredge operation, especially designed pontoons lashed together support the discharge pipe, and a special derrick boat at the discharge end permits of a wide range of free flow from the end of the pipe when discharging over a breakwater, or otherwise.

Acknowledgments

This entire problem has been worked out by the organization of the Great Lakes Dredge and Dock Company, of which the writer is President, by R. V. Hoopes, Vice-President, and A. Neveling, Chief Mechanical Engineer, with the assistance of James H. Polhemus, M. Am. Soc. C. E., Chief Engineer of the Port of Portland Commission, as Consulting Engineer, together with the Engineering Staffs of the Bucyrus-Erie Company, of South Milwaukee, Wis., the Manitowoc Shipbuilding Corporation, at Manitowoc, Wis., the Busch-Sulzer Brothers Diesel Engine Company, of St. Louis, Mo., and the General Electric Company, of Schenectady, N. Y.

DISCUSSION

R. L. VAUGHN,[4] M. AM. SOC. C. E. (by letter).—This paper, the most valuable which the writer has seen on the subject, is, perhaps, unique. It points the way to what has seemed a hopeless task, the application of scientific reasoning to that exceedingly complicated affair—a pipe-line dredger.

The writer has made several attempts to apply hydraulic theory to the dredger pump, and invariably has come to an abrupt stopping place at Equation (2). This is the customary formula given by many authorities on pump design, but the writer always has doubted whether it was even approximately true when applied to the pump on a pipe-line dredger. If the material passing through the pump were a uniform one, such as water or mercury, the formula would be unquestionable, but the mechanical mixture generally handled may present an entirely different set of problems.

The reason for introducing the factor, w, is to convert the fundamental relation, "power equals force times distance divided by time", into a form which can be applied readily to the conditions of a centrifugal pump. If the pump is handling a mechanical mixture the weight of which may (and often does) vary widely from moment to moment, the question arises as to what value should be assigned to w. In the ordinary texts, w is used as if it were the weight of material actually passing through the pump, although several observations indicate that this may not be correct.

Indicating watt-meters have frequently been observed while connected to pump motors of constant speed working on long pipe lines. When the digging was stopped and clear water pumped, there was no observed change in power, except such as could be accounted for by change in weight lifted to the pump, until such time as the line began to clear. If the ordinary equations are correct, there should have been a marked change in power as soon as clear water reached the pump.

Not infrequently some inspired enthusiast, with a background of theory on the design of centrifugal pumps, comes forth with a proposal to revolutionize the dredging business by arranging to introduce the material into the water after it has passed the pump. Mechanical details vary with the originality of the inventor, but the basic idea is that the pump will be handling clear water and can be designed to give much higher efficiency than an ordinary dredger pump will show. Then too, of course, the added advantage of greatly decreased wear on the pump is stressed.

If any advantage were to be gained by keeping the value of w low, that is, if the weight of the material actually passing through the pump were related to the question, there would be a great possible saving in power by keeping it low in the equation for power, and the idea might not seem so far-fetched.

A number of hopper dredgers have been built with arrangements for pumping the load ashore. The general arrangement has been a long suction line passing under the hoppers, with valves in each hopper discharging into the pipe. The material was dumped into the suction because this was the obvious and simple way to do it. If any real advantage existed in keeping the value of w low while the mixture passed the pump, it would be comparatively easy, and not too expensive, to insert the material into the discharge line instead of into the suction. No one seems to have discovered any such advantage.

---

[4] Cons. Engr., San Francisco, Calif.

Designers have assured the writer that, if a pump were handling clean water and a boulder were introduced into the line, there would be a momentary fluctuation in the watt-meter, corresponding to the change in weight of the mixture, while the boulder passed through the pump. The absurdity of this contention will become evident if two extremes are considered. Suppose that a pump is pumping water against a considerable lift and friction head. Imagine that the liquid (in the pump only) is replaced momentarily by mercury. According to the theory the power input should increase at once about eightfold. Again, suppose the water is replaced by some incompressible but weightless liquid. Then the power should drop to zero. Evidently, in either hypothetical case, the total work being done on the system would remain unchanged, except for internal pump losses.

For these reasons, when considering a dredger pump, the writer has always felt reluctant to accord to Equation (2) that veneration and respect which the authoritative elements of a subject are supposed to merit. Furthermore, the texts then proceed to develop the equations for the pump by inserting a large number of constants, for which a value is never given, consequently the writer's opinion of the texts with which he is familiar, is not high. Evidently, the power consumed by a dredger pump is not wholly independent of the weight actually passing through it; but it seems probable that the relation is a complicated one, involving, among other things, perhaps, the characteristics of the actual pump in each case. It will be appreciated if the author will offer any explanation which will make this question clearer.

If it is understood that w, as used in the paper, is the average weight of mixture handled, and that this average remains sensibly constant, then the foregoing objections do not apply to the mathematical treatment given. The assumption is not true in practice because as a rule a dredger does not dig on the return swing, and never digs when setting ahead; in fact, it often happens that the line is entirely cleared of material while "fleeting ahead".

Equation (4) expresses the condition that the friction head varies directly as the first power of the length of pipe line. This, for some kinds of clay, is far from true. If clay is pumped 3 000 or 4 000 ft., the greater portion of it will be discharged on to the fill in the form of lumps and balls, while if it is pumped 10 000 or 12 000 ft. (even without a booster), in many cases a large portion will come out as mud. Therefore, to state that the friction head is a linear function of the length of line is to state that, for a mixture of a given weight, the friction is the same whether the mix is a thin mud or a combination of water and balls. Manifestly, this is not true, and yet Equation (4) is part of the basis for Equation (10).

There appears to be some confusion in the meaning of C. From the notation, and in the text under the heading "Economic Velocity under Typical

Service Conditions", it would appear that C is the unit cost for labor plus the unit cost for all power consumed on the dredger. In Equations (1) to (10), it appears that only the unit cost of power consumed by the main pump is included. Experience indicates that, generally, when digging clay, at least one-quarter as much power will be required by the cutter as is used by the pump, and the ratio is often higher. This would seem to be too large a factor to be neglected, even in an approximate solution.

Nothing is more certain than that w will vary with the velocity in the pipe line, and yet it seems to be treated as a constant when the equation is differentiated. Thus, the writer looks upon the mathematical treatment resulting in Equation (10) with some misgivings and would like much more explanation of it. However, it is interesting, and worthy of careful study, as it may indicate correctly the effect of varying certain factors in the general problem.

Moreover, it must be confessed that the results which the author gets by using Equation (9) are in line with the writer's experience. A decrease in weight of material gives a relatively great increase in output. A considerable variation in pipe-line diameter does not produce much change in desirable pipe-line velocity. Again, on the average, large pipe lines, with suitable increases in power, make for reduced unit costs, and many contractors are obtaining larger machines.

In general, the paper describes a fine dredger which affords little to criticize or question in regard to its mechanical features. The need for strength and rigidity in the hull is illustrated by the experience of the dredger, *Houston*, which sank in a depth of 30 ft. of water in Galveston Bay during the hurricane in 1915. At the time she sank both spuds and the ladder were down and the hull came to rest nearly level longitudinally, upside down, with the bottom making an angle of 55° with the horizontal. The hull was of wood and was exceptionally well designed and well built. It was 165 ft. long, 44 ft. beam, and 14 ft. deep, with no trusses extending above the deck. The stresses which this hull underwent in rolling over as it sank, then being rolled back and raised, can be imagined. (In explanation of how a hull 44 ft. wide could roll over in 30 ft. of water, it may be well to state that the hurricane had raised the water to a depth of about 44 ft.) Rolling the hull back again after the storm, when there was only 30 ft. of water, was difficult. Extensive re-caulking and some repairs around the ladder and spud-wells put the dredger back in service, and, with some additional repairs, the hull is in good condition to-day (1931).

The installation of a gyroscope compass is a refinement not hitherto considered justified on a dredger, although as early as 1913 a device was proposed, consisting of a recording mechanism actuated by a gyroscope and also connected to the ladder, so that the device would draw a cross-section of the cut at each set-up. This proposal was rejected on the ground of expense, and for the further reason that it required the best energies of the organization to keep the dredgers running, without adding further complications.

Some mechanically successful Diesel-electric dredgers have been built. They are not without advantages. Practical Diesel speeds do not correspond to suitable dredger-pump speeds, and if direct-connected, it is necessary to use gears. The advantages of flexibility to be had with direct current are recognized, while the shocks which a Diesel engine gets when directly geared to a cutter are not conducive to trouble-free operations. However, when the added capital cost, the additional skilled labor required, and the additional complications are all considered, the writer has never been fully convinced that the Diesel-electric is the best design. On a large machine it probably is the best, due to the possibility of using several moderate sized duplicate main engines. Up to a size of at least 1 000 h.p. on the pump, the direct Diesel design seems to be satisfactory.

No information is at hand concerning the power distribution conditions throughout the territory in which this dredger is to be used. On the Pacific Coast power is abundant, cheap, and available nearly everywhere at 11 000 volts, alternating current. As a result, most successful dredgers there are electric ones. These are simple, relatively cheap to build, and inexpensive to operate. Power is brought to the dredger on pole lines (often built over the water) and by 1 000 ft. or so of armored cable; it is then reduced to 2 200 volts, the transformers being located on the dredger or on a scow moored alongside. All the principal motors are usually 2 200-volt alternating-current machines. Any other voltage is readily available through small auxiliary transformers.

Rotary converters could be installed and the power converted to direct current on the dredger, but this has never been done. Direct current has advantages as to flexibility, but these have not been considered sufficient to warrant the additional investment, complications, and power loss. The main motors are of the phase-wound induction type. Some variation in speed is obtained by means of variable resistances in the rotor circuits (external). However, variable pumping conditions are usually met by changing the diameter of the pump runner.

A recently developed device will give these motors a range of speed from 25% below to 25% above the rated speed, maintaining constant torque, with little loss of energy. The device has not yet been applied to a dredger as far as the writer knows, but it is being considered for that purpose.

The first turbine dredger to be built had a turbo-generating unit producing alternating current at 2 200 volts, and was otherwise arranged as an ordinary electric machine. It was a simple matter to install transformers on a scow, bring power from shore when available, and dispense with the steam plant. It was found that operating costs could be much reduced in this way, and the dredger is still so operated. At present (1931), larger motors have been installed and the steam plant could not begin to give the output which can be had by taking power from shore.

On paper, it is easily possible to show that power can be generated on board more cheaply than it can be bought ashore. These calculations, when applied to a dredger, usually prove to be "a delusion and a snare". Dredging contractors find it advantageous to abstain from the power business whenever possible.

It is understood that the anticipated conditions were such that the *New Jersey* must have her own power plant, and that, when considering the design, the advantages of direct current were attractive; but it would be interesting to know whether the possibility of obtaining power from shore, occasionally, was fully considered when selecting the type of electrical equipment which was installed.

The author's statement that the largest practical diameter of pipe is the most economical, may be misleading. It is true as regards power expenditure per unit of material transported. It is far from being true as regards a dredger of stated power. For a given machine, when pumping mud, the largest line within reason will be the best, but in pumping any mixture that will segregate, there will be a minimum velocity which must be maintained. This velocity will vary with the size of the particles in the mixture, and with the percentage of dilution. If the line is too large, a much diluted mixture must be pumped, and there is no economy in that. In fact, most dredgers do not have power enough for the size of the line; very few of them can pump all the clay they can dig for a distance of 6 000 ft. It is often a question of whether or not more power should be added. More power means more pressure, which causes trouble. The ball joints freeze; there is more trouble in holding the line together; and heavier pipes are required. Often, it is better to put in a booster.

Selecting an economical size of dredger for a contractor involves so many practical considerations, that a mathematical analysis can only be used as a guide to the judgment on a few factors. The tendency is toward larger sizes, undoubtedly. The author has selected a 30-in. machine. For jobs of some magnitude this is probably not too large, although for a series of scattered jobs, each of, say, from 100 000 to 500 000 cu. yd., coming up from time to time, some contractor with a well-designed 22-in. machine, having a 500-h.p. cutter and a 1 500-h.p. pump, could furnish plenty of competition.

Be that as it may, the 30-in. diameter having been decided upon, the next step is the question of how much pump power is suitable for this size of line. This may be approximated by remembering how much power the designer wishes he had had on some previous dredger which worked fairly well, and estimating that the powers should vary, roughly, as the squares of the respective pipe-line diameters. The next step is to estimate how much digging power is needed to keep this pumping outfit busy on a reasonably short line. Experience indicates that at least one-quarter the pump power should be available for the cutter, and more may be needed. The *New Jersey* has a nominal ratio of one-fifth which may be found ample, particularly as this is an intermittent service and the drive will stand a generous overload.

The writer fully shares Mr. Cushing's opinion concerning clay with boulders in it. Any dredger which will perform, even passably well, in such material is a good machine. During the early days of the dredging business it was considered necessary to install a "stone box" in the suction line just ahead of the pump. This device was provided with grate bars intended to prevent the entrance into the pump of anything that could not pass through. Eventually, it was found that the trouble with the stone box was that it worked too well;

the delays caused by cleaning it were intolerable. Runners were obtained which would pass anything that could come up the suction line; the gain in running time far more than made up for any loss in pumping efficiency. Present practice is to have a suction larger than the discharge, in which case it is not necessary to have a runner which will pass larger objects than can pass down the line. With a cutter having a maximum opening of only six-tenths the diameter of the pipe, no rocks should stick in the pump, although trash may. Other cutters are used, having larger openings. In such cases, where necessary, the condition is met by inserting intermediate rings in the cutter, or by placing a bar across the mouth of the suction pipe.

An extended experience with trash, buried forests, saw-mill slabs, pile stubs, etc., might modify the author's opinion concerning the relative value of high efficiency in a dredger pump. Large rocks can be excluded from the suction, but these other things can not, and the manner in which they can plug up a runner is truly remarkable. Ordinarily, if the runner can pass anything which can go through the line, there will not be much trouble from this source. Runners with smaller openings can often be used, and are better. A few years ago a two-vane runner was developed at New Orleans, La., for pumping sewage. Built somewhat after the fashion of a weedless propeller, it would pass just about anything, and when adapted to a dredger it did yeoman service in the swamps. The output of the dredger increased from 1 600 to 10 000 cu. yd. per day, and the operators spent little time in vain regrets over the sacrifice in mechanical efficiency.

The author uses an efficiency of 70% for his pump, which is to perform against heads ranging from 125 to 220 ft., with no alteration other than a variation in speed. Few centrifugal pump designers would undertake to design a water-pump to maintain such an efficiency over this range. When it is remembered that in a dredger pump the disk friction is much higher, that the turbulence is necessarily far greater, that the passages through the pump must be much larger than is desirable, that the surfaces of these passages are anything but smooth and highly polished, and that wear is constantly changing the theoretical lines, it is very doubtful whether any dredger pump even approaches this efficiency. If the author has any data to sustain such an efficiency, such information would be interesting.

Table 2 has been computed using one set of values for w, f, b, and p, and variable values of L. It is certain that w will vary with the length of line and with the velocity, while, for some materials, f will vary with the length of line independently of any variation in w. When this last factor varies, then f, b, and p are all variables. It would be a contribution of the greatest value if Mr. Cushing could give any experimentally determined values for e, f, n, and p.

The author states that the volume of a clay will be a linear function of the water content, and, of course, if this is true, then the statement follows, as given, that in a fill where the change in dimension is all in one direction the settlement will be in greater ratio than the change in water content. If there are any observations to substantiate this relation between water content and volume they would be of value. Experiments on the bulking of sand give different results. Anything approaching accuracy in estimating the volume of a cut, in clay or mud, required to make a given fill, is very difficult, and contractors as a rule are reluctant to bid on fill measurements.

A combination of causes probably contribute to the great difference in shrinkage between the first and second fill shown in Table 1. For one thing, the description indicates that the first fill did not come much above the water level. Under such circumstances a comparatively light load is placed on the original bottom, and there is little chance for the newly deposited fill to dry out. Furthermore, with less than two-thirds of the fill placed, a large settling basin must have remained and, consequently, there was only a small loss through the spillway. When the second fill was placed, it was mostly above water where it could dry out and shrink; also, the superimposed load expelled water from the first fill and from the underlying bottom. Again, during the second season's work the settling basin was becoming filled, and there were greater losses through the spillway. Under some circumstances these losses become quite appreciable, and no computations of volume ratio are of much value unless they are taken into account.

The description of liners in the hull pipe and fittings brings to mind an experiment made by the writer, which may be of interest. During the World War the problem of supplies and repairs was especially difficult on the Pacific Coast and any desperate expedient was justified. One job on hand involved the moving of about 2 000 000 cu. yd. of mud and 750 000 cu. yd. of clay which was in a fairly level strata under a portion of the mud. The mud was a fine slippery bay silt, containing less than 1% of heavier particles, grains of sand, and small pieces of broken shell. The clay contained considerable small sharp gravel. This last combination works on the principle of the diamond drill bit and is guaranteed to wear out anything rapidly, but there was no reason to anticipate more than nominal abrasion from the mud. It was proposed to strip as much of the mud as possible and deposit it in one fill and then dredge the clay and deposit it in another, and closer, fill.

Pipe was scarce, exorbitant in price, and was only available in low carbon steel which wore out rapidly. Records were on file showing cases in which at least 2 000 000 cu. yd. of sand had been handled through a single installation of wooden stave pipe. Several manufacturers of this pipe were located in the the vicinity, and were in a position to fill orders promptly. If wooden pipe would handle 2 000 000 cu. yd. of sand, there was no reason to think it would not give equally good service with soft slippery mud. Of this pipe, 1 000 ft. was purchased and installed in the most permanent part of the line. It lasted just five days during which it carried about 50 000 cu. yd. of mud and then blew up. More steel pipe was coming through the shops but there was none to spare on hand, and the experience was aggravating to say the least. No clay at all had been pumped.

What had happened was that the coarser particles settled to the bottom of the pipe where they were dragged along by the stream of mud and did a maximum amount of cutting. A width of about 6 in. on the bottom of the pipe was practically all cut away while the remainder of the pipe showed no wear at all. This circumstance suggested another experiment. Another 500 ft. of wooden pipe was purchased and sent to the pipe shop where the bottom third was lined with soft steel plates $\frac{1}{8}$ in. thick. All the liners were punched to template and held in place with small bolts, the purpose being that when the plates wore out they could be easily replaced. This experimental pipe was installed in the line and it never did wear out. It carried about 1 000 000 cu. yd. of mud and 750 000 cu. yd. of clay, and outlasted two sets of steel pipe.

The method used by the author to determine velocity in the pipe line is interesting, but can be used only in fresh water. Permanganate and several different dyes have been used with satisfaction in salt water. The coloring matter is easily introduced into the suction. A rough rule which is nearly correct is as follows: The velocity in the line, in feet per second, is equal to four times the horizontal distance, in feet, traveled by the stream while it falls the first foot after leaving the end of the pipe. That the rule may be correct, it is necessary that the pipe be full at the end, that it be discharging horizontally, and that the stream be falling freely.

A swivel joint near the lower end of a steel spud has often been discussed, but this is the first time the writer has heard of its actual use. While it is true that there is comparatively small stress on a spud near its point, still this sounds like an additional complication which may give trouble. Unless they have a round section of some length at the lower end, square spuds are subject to considerable torsion. Round spuds are free from this trouble. On the other hand, it is much easier to build a square steel spud than a round one. One steel spud was built 24 in. square from 1-in. plates and 8 by 8 by 1-in. angles. This spud was lagged to a round shape with hard wood; it was used in a 36-in. round spud well, and gave complete satisfaction.

The use of two steel spuds is open to one objection. Sooner or later the leverman will get careless and swing with both spuds down. When this happens it is preferable to have one wooden spud to replace rather than to have to deal with two bent steel ones. Even if the leverman never makes a mistake, a swinging wire has been known to carry away when the dredger was in a cross-current with both spuds down. One spud is used only to "fleet ahead", and there is no necessity for having this one as strong as the digging spud.

ARTHUR L. COLLINS,[5] ASSOC. M. AM. SOC. C. E. (by letter).—In changing from the steam-operated pipe-line dredge to the motor-driven units, it is well to bear in mind the peculiar characteristics of the centrifugal pump.

In present-day steam-dredge operation the efficiency of the pump is given little consideration. It is noted that in determining the power requirements for the dredge, *New Jersey,* the pump efficiency was assumed to be 70 per cent. While pumps with an efficiency as high as 90% can now be obtained for clear water, it would appear to the uninitiated that 70% could be depended upon for the dredge. However, when the dredge pump is properly tested, it is generally found that the efficiency is somewhere between 55 and 65 per cent.

---

[5] Cons. Engr., Berkeley, Calif.

This is about the minimum at which a centrifugal pump can be expected to operate.

In passing from the steam-driven to the motor-driven pump, whether the latter receives its electrical energy from a power station or from Diesel engines, it is of great importance that the temperamental operating characteristics of the pump be thoroughly understood.

Fig. 4 represents the characteristics of a typical dredge pump driven by electric motor. Only the fundamental information regarding the test is shown. In the motor-driven pump it is assumed that the speed is practically constant. This is the point that accounts for the condition of undesired instability, as indicated by the test. For example, the curve of total lift and capacity is very flat. At 24 000 gal. per min., the head is 131 ft. At 18 000 gal. per min., the head is 138 ft. In other words, the pump capacity falls 25% in a change of 7 ft. The power input to the motor falls from 1 060 to 880, or 180 kw. In normal operation the suction lift on the pump will fluctuate more than the specified 7 ft. from minute to minute, depending upon the material which is picked up by the pump. The fluctuation is 7 ft., more or less, and, consequently, the pump is in a continuous unstable condition, regarding capacity and power.

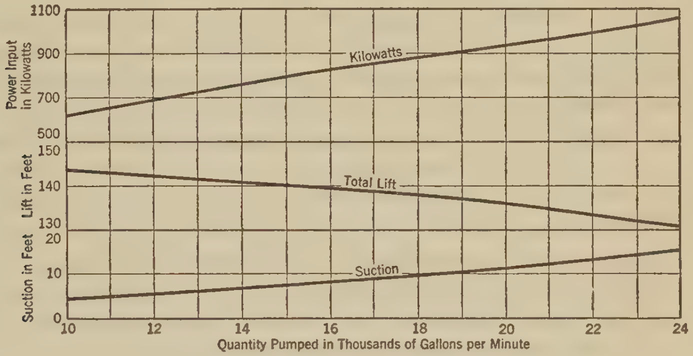

Fig. 4.—Characteristics of a Dredge Pump.

Ordinarily, there is a recording suction gauge installed on the pump. This gauge should show considerable variation, but this effect should not be instantly transmitted to the pressure gauge in a well-designed pump. A widely fluctuating pressure gauge is an indication of the sensitive pump.

A steam-operated pump, with its more or less flexible control, has a tendency to ease the characteristics of the pump. There is a balance between power and speed, as well as between head and capacity. The electrically-driven pump cannot slow down, but must maintain a nearly constant speed. The motor-driven pump is likely to be noisy, due, in part, to the constantly changing internal flow velocities.

The variable-speed motor does not eliminate the objectionable features of the constant-speed motor. The motor is operating at reduced efficiency when on any contact less than full speed. While on this contact, it is not far from being a constant-speed motor, the same as when operating at full speed.

In passing from the steam-engine drive to the electric drive, the engineer must take into consideration the difference between a constant-speed and the variable-speed, steam engine. Of course, the steam engine will be controlled within certain limits by the governor, but the governor can be set at any desired speed.

There are centrifugal pumps now in various parts of the United States which were installed in the late Seventies, and afterward, and which were operated by steam. Strange to say, some of these pumps have a very good efficiency. They are efficient because they can be driven at a selected speed. Try to drive them electrically with a constant speed, and it will be found that they cannot be satisfactorily operated, due to the conditions shown in Fig. 4.

It can be said that probably the pump given as an example did have an efficiency of 70% when it was first installed. Once a dredge pump is in operation, it undergoes a series of alterations. Parts of the pump interior are chipped intentionally or worn by service. Patterns for new parts are altered and the pump finally emerges as a highly temperamental piece of equipment. In this case it has lost its stability and is running wild as to power and capacity, and is only kept within bounds by reason of motor speed. It will be merely a coincidence if the pump will test 70% at any period after it has started operation.

More attention must be given to the design of the dredge pump, not only to save money in power consumption, but to eliminate wear and repairs. During the past few years much attention has been given to the design of the sewage pump. The pump companies have had to design the pumps for motor drives and they have developed pumps with characteristics that should be copied by the dredge designer. By making use of the similarity of the sewage pump, it is possible to build the larger sizes as used on dredges, and anticipate the desired characteristics. The electric drive will require a properly designed pump.

The writer does not consider the injection of salt or color into a line as the best method for obtaining data which will enable one properly to analyze the operations of the pump. The most satisfactory method is first to test the pump with clean water. The curve similar to that in Fig. 4 is obtained by pumping against a partly closed valve, and noting the action of suction and pressure gauge. The Pitot tube is used in the suction pipe for the capacity measurements. This method provides the true operating characteristics of the pump which are comparable from time to time.

From the viewpoint of the engineer endeavoring to check the characteristics, the color or salt-water injection method is not to be preferred. Its only justification would be to check or calibrate the gauges under load conditions after the fundamental information is obtained. The fundamental information is important, because one can check the condition of the pump within, say, 2%, from time to time, and can do this in a few minutes and with no loss of dredge time.

No doubt there are many dredge owners with steam-driven pumps who have their eye on the motor drive. It would be disastrous to assume the pump efficiency as 70 per cent. In view of the uncertainty of the operating characteristics of the pump unit, it is advisable to base the power requirements on a pump of low efficiency.

Too much stress cannot be placed upon the importance of knowing the exact performance of the pump. In operating a pump direct by a Diesel engine, the owner is very likely to be gravely disappointed, if the pump efficiency is rated too high. To begin with, the gas engine or Diesel engine is not generally given an overload rating. An electric motor with plenty of reserve power from the line can readily provide an overload of 25 per cent. The Diesel engine must be liberally rated, otherwise the centrifugal pump may be found to require more power than was anticipated by the assumed efficiency.

Generally speaking, little or no attention is paid to the matter of efficiency in the dredge pump after it is once in operation. The characteristics of the pump can change within wide limits, and the pump under the new conditions will require more power and more repairs. Without a systematic plan for checking the condition of the pump every few weeks, there is no clue as to how it can be improved. There may have been some justification for the lack of incentive on the steam-driven dredge to make frequent tests, due to the flexibility in speed and power of the prime mover.

With the advent of the motor drive, generally little or no information of importance is available in the files of the engineering department of the dredge owner to enable him to anticipate accurately the performance of the same pump under the motor drive. To operate a motor-driven dredge which will show good efficiency over a long period of time, will require that a constant check be kept on the characteristics of the pump.

It will require the concentrated effort of a technical engineer who has a full working knowledge of the meaning of the characteristic curve of the pump. The dredge captain should not step from the steam dredge to the motor-driven dredge without recognizing the value of the technical engineer in analyzing the pump problem. The cost of handling the material is not only affected by an excess cost of power, but also by repairs, shut-downs, and improper pipe-line velocities, all contingent upon the design of the pump; and which design can be altered quite unintentionally.

John Francis Cushing,[6] M. Am. Soc. C. E. (by letter).—Referring to Mr. Vaughn's discussion, it is probably true that there is and always will be difficulty in applying hydraulic theory to a dredge pump, but Equation (2) does represent the principal factors (and their relation one to the other) necessary to obtain results of practical value in dredging. Some authorities, however, question the exactness of this equation when the pump is used for handling uniform material, such as water and mercury. The power consumed by a dredge pump is dependent on the weight actually passing through it. It is likewise dependent on many other factors, and their relation one to the other may be complicated, but in hydraulic dredging operations there is an average condition, the limits of which are within a range that makes this equation of practical value. Many data are available on the performance of centrifugal water pumps, and they are available, probably, because of the general use of such pumps and because it was a simpler and easier problem to make such observation than to determine similar data for a pump handling a liquid burdened with a miscellaneous quantity and character of solid material. Nevertheless, this burdened stream of water passing through the dredge pump is made to act as a liquid and, therefore, the theory and data available on centrifugal water pumps are, in a large measure, made applicable to the dredge pump by developing new and different values for some of the constants in the formula.

---

[6] Pres., Great Lakes Dredge & Dock Co., Chicago, Ill.

It is true, as stated by Mr. Vaughn, that Equation (4) assumes that the friction head is a linear function of the length of line for a mixture of given weight. Even in dredging a material, such as a uniform clay or a uniform sand, this weight of burden is not constant in the pipe line, but varies materially, principally because of the lack of control of the operation of the cutter at the intake under water. Consequently, such loading of burden into the line cannot be done uniformly, but only within such limits as may be determined by observing the vacuum and pressure gauges. However, in the usual dredging operations, these limits are promptly established by the experienced operator and hence an approximate average condition is maintained under any given set of conditions.

By means of constants, Equation (4) also takes into account the character of the material; soft or light material requires one value for f, and hard clay balls or gravel another. These must be determined by experience with the particular dredge being used; the constants for one dredge are not essentially applicable to another, but it is feasible and practicable to develop such constants for one dredge and re-use them for predetermining economic performance on future contracts and under similar conditions.

The constant, C, in Equation (7) is the unit cost for labor plus the unit cost of all power consumed on the dredge, and in this equation the unit cost of power used by the pump is considered as this total cost divided by the power consumed by the pump only.

It is understood that in clay work, a large part of the total power used on the dredge is consumed by the cutter. Furthermore, a large part of the total power is used to operate the other auxiliaries on the dredge. Nevertheless, the pump consumes the main part of the power, and it is considered that power for these auxiliaries, including the cutter, is properly included in the cost of that for the dredge and that the complication resulting from developing a formula segregating the cost for these different units that absorb so much less power, would not be warranted over and above the practical results obtained by treating it as part of a whole or in keeping with the character of the operation.

In addition, it is usually found that where refractory material is being dredged, such as hard clay, and where much cutter power is necessary, that the pump power required also increases in proportion in handling the larger pieces through the pump and for transportation through the line. Likewise, in soft clays, or in fine sand that is not sharp, little cutter power is necessary and less pump power is required due to the lesser friction in the pump and line. These differences are adequately covered in Equations (1) to (10), inclusive, by variation in the values determined for the constants therein. It is probable that future practice will develop more accurate formulas for dredge pumps, but Equation (7) has been found reliable for determining economic performance.

The effect of w varying with the velocity in the pipe line would be important for low velocities, or for velocities just high enough to transport the solid material or particles in the pipe line; but in commercial dredging operations much higher velocities must be provided to reach some of the necessary economies, and for the velocities usually maintained—particularly in the more modern and high-powered dredges—this effect of the variation of w is not of high order. It has been determined in practice repeatedly that w increases up to a certain velocity. From this point there is a certain practical range of velocity in which w is more or less constant; that is, w is not increased materially by an increase of velocity. Other conditions remaining constant, the dredge operator frequently finds this practical range of velocity by actual experimentation. The results of similar experimentations may be used to determine the constants in Equations (1) to (10).

When a new contract is being started, estimates and calculations are made from the best data available by Equations (1) to (10), in order to find the practical and economic method of operation, including the economic velocity to be used. From the output over a few hours it is easy to determine whether the economic velocity has actually been reached and when the dredge begins to exceed it. Much of the work that has been done by the *New Jersey* has been done with only three of its main engines, and these three not developing full power. On other work that it has performed the full power as developed by all four engines has been utilized. From this experimentation in a great volume of work, however, mostly clay to date (1931), the writer is convinced that the theory and practice experienced in the development of Equation (10) are thoroughly applicable to such hydraulic dredging.

The writer believes with Mr. Vaughn that when electric power is available it is more simple and economic to use it on dredging. However, this power supply varies widely in different communities, and for general utility it is better to have the power plant aboard the dredge. In special localities where electric power is readily available, the building of a straight electric dredge would be advisable.

In the pump of the *New Jersey,* efficiency was determined as follows: At a time when working conditions were uniform, arrangements were made for conducting a velocity test, as described in the paper under "Economic Velocity Under Typical Service Conditions," by injecting a salt solution at the dredge pump and noting the discharge of this solution at the end of the line by the use of a small galvanometer at that point. During the period between the injection of the solution and its discharge from the line, readings were taken simultaneously at short intervals of the vacuum in the suction line, pressure in the discharge line, motor input amperes, line voltage, and motor revolutions per minute. If conditions fluctuated very widely during this period, the test was disregarded. However, if these various readings remained fairly uniform over the period, sufficient data were at hand to compute the efficiency of the pump by reducing them to values of shaft horsepower input to the pump and water horse-power output for the pump.

In two typical tests the following conditions were observed: The observed velocity was 20.1 ft. per sec.; the motor speed, 300 rev. per min., the shaft horse-power input to the pump, 2 760; the total head, 165.4 ft.; and the percentage of solids in the stream, 9.2. The computed efficiency of the pump in this instance was 68.8 per cent. This test was made on the pump after it had been in service approximately five months.

In the second case, the observed velocity was 20.5 ft. per sec.; the motor speed, 327 rev. per min.; the shaft horse-power input to the pump, 3 091; the total head, 197.4 ft.; and the percentage of solids in the stream, 7.0. The computed efficiency in this test was 74.5 per cent. This test was made shortly after the pump had been relined and with an impeller of a slightly different design from that in use when the previous test was made. The material being handled in each instance was a hard and abrasive blue clay which required an average of practically the full 600 rated h. p. of the cutter motor to maintain the percentages of solid materials indicated in these tests. Likewise, the velocities indicated in the tests were required to move the material uniformly in the pipe line without undue precipitation of the solid material to the bottom of the pipe.

In view of these and other similar tests made under varying conditions, it is believed that an average pump efficiency for this installation of 70% was reasonably justified.

In Table 2, "Economic Velocities Under Various Conditions of Dredging," it is true as stated by Mr. Vaughn that one set of values was used for w, f, b, and p, and variable values of L. It is true that w will vary with the length of the line and the velocity, and, for some materials, f will vary with the length of the line independent of any variation in w, but the variation in all these factors is not great if the velocity is maintained approximately at the economic velocity. Further, Table 2 shows the results of handling medium clay only; for a variation of material of course other values of some of these constants in the formula are used. The value of e was determined experimentally as described previously; the value of f by the reading of pressure gauges at intervals along the discharge line; the value of n was taken at 1.86 and that of p at 1.25 from the Schroder and Dawson formula for friction head in pipes.

Referring to the discussion by Mr. Collins, the matter of justification for assuming a pump efficiency of 70% for the purposes of computation and comparison has been covered to a certain extent in the preceding remarks. However, there are several other details which may be discussed. It is quite true that the ordinary run of dredge pump carries with it an efficiency of 55 to 65 per cent. One reason for this appears to be that some of the possibilities for higher efficiencies have been sacrificed in the interest of cheaper manufacturing costs and simpler operating conditions. As explained in the paper under "The Design Elements," the pump for the *New Jersey* was a specially designed unit, aiming at higher efficiency than that of common practice. The fundamental assumptions were based on the accomplishments of another pump designed along the same lines in which the efficiency averaged about 70% over normal operating ranges. This increase in efficiency was obtained by several refinements of manufacture and operation, some of which are frequent inspection and renewal of liners and the adjustment of clearances to a practical operating minimum by rubber-faced rings in the pump.

By the use of renewable liners throughout the pump its characteristics are maintained in accordance with the original design within close limits and, differing very much from the ordinary plain cast shell and impeller, such characteristics are not altered materially by wearing or intentional chipping.

It is quite true and likewise quite justifiable that the design, not only of the pump, but of the driving motor, should be given exceptional attention and care in the size of a unit, such as is used in the dredge, *New Jersey*. In smaller installations such refinement in design is not ordinarily obtained. It is not proposed that a pump efficiency of 70% can be assumed for any size or type of installation, but in this case the assumption was justified, as proved by subsequent test conditions.

Preliminary tests on this installation were conducted by pumping clean water and establishing various values of head by attaching a series of conical nozzles to the discharge. In this way the characteristics of the pump and motor as a function of head or as a function of quantity of discharge were determined. However, it is possible that the conditions obtained in such preliminary test would not maintain under the varying conditions of actual dredging service. For this reason, velocity tests by means of salt solution were used under actual working conditions where there were momentary variations of suction and pressure as well as fluctuations in the quantity of solid material passing through the pump and through various points in the line. In this regard, it is considered that the use of the salt solution in the stream would have an integrating influence, so to speak, in covering the momentary variations.

THE BUTTRESSED DAM OF UNIFORM STRENGTH[1]

BY HERMAN SCHORER,[2] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JAMES GIRAND, FRED A. NOETZLI, B. F. JAKOBSEN, CALVIN V. DAVIS, A. A. EREMIN, EUGENE KALMAN, A. FLORIS, FREDRIK VOGT, A. C. SCHWAGER, PAUL BAUMAN, I. M. NELIDOV, AND HERMAN SCHORER.

SYNOPSIS

Any investigation of the principal stresses in buttressed dams, as designed at present, reveals the fact that the maximum compressive stress occurs only at one single point in each horizontal section. At the same time, the up-stream portion of the buttress may disclose considerable tension in the direction of the second principal stress.

The object of this paper is to present the general theory of a buttressed dam of definitely known and uniform strength—to discuss its dimensional and quantity laws and to make suggestions for incorporating the theoretical findings in practical designs.

The theory is based on the conception of elementary arched column units, which transmit the water pressure from their respective deck areas directly and in uniform compression to the ground, together with the accumulated dead load. The elementary column units can be combined to a monolithic buttress system, in which the first principal stress is uniform compression throughout and the second principal stress is zero.

Secondary stresses due to shrinkage, temperature changes, etc., are largely eliminated by dividing the buttress system into several arched column units of practical dimensions, which units, together with their monolithically connected decks, are completely separated from each other by continuous joints. Climatic influences are further reduced by designing the down-stream column units so as to enclose the structure completely.

The independent column units will also permit the construction of the dam to the ultimate height in independent steps at convenient time intervals. The dangerous and expensive necessity of anchoring new concrete to the older structure is thus successfully avoided.

A buttress system thus designed may be used in connection with any of the common deck types. The method is illustrated in a tentative example for

a dam 300 ft. in height, using a simple cantilever deck. Diagrams have been prepared, which will enable the designer to determine quickly the most important elements for any desired combination of the main design variables.

Considerable saving in cost can be realized for any height to which a gravity dam with the same apparent factor of safety may be built. With a design stress of 500 lb. per sq. in., the maximum possible height of the buttressed dam of uniform strength is about 800 ft.

INTRODUCTION

Hollow dams of the reinforced concrete type generally consist of three distinct members: First, the deck, forming a water-tight up-stream face; second, the buttress, or supporting system, transmitting the combined water and dead load to the foundation; and, third, the foundation, which transmits the total load to the ground.

The design of the foundation structure is governed entirely by local geological conditions which determine the permissible bearing pressures. The following analysis assumes that the dam is founded on solid rock, so that no special foundation structure will be required. The most common deck types are the simple beam slab of the Ambursen dam and the multiple-arch deck. The supporting system of both types generally consists of triangular buttresses with rectangular, horizontal sections.

Any analysis of the relative yardage in deck and buttress reveals the fact that with increasing height the volume of the buttress becomes by far the largest item. The cost of high hollow dams, therefore, is governed largely by an economical design of the supporting system.

The arbitrary, triangular buttress, which is commonly used, has been borrowed directly from the gravity dam. The same may be said of the ordinary buttress analysis, based on the stress determination in horizontal sections, when stability is assumed to be assured if the vertical stress components and the horizontal shearing stresses do not exceed safe limits.

Mr. B. F. Jakobsen first called attention[3] to the necessity of determining the principal stresses in the buttresses of multiple-arch dams, because the ordinary analysis may not reveal the existence of large tensile stresses. Later, Messrs. N. Kelen[4] and Carl Boegh[5] also gave solutions for the principal stresses in wedge-shaped buttresses. The older method of analysis, which considers horizontal sections only, must now be regarded as obsolete and unreliable.

Unfortunately, the principal stress determination does not simplify the design, because the analysis must begin with dimensions already known. For this reason all the present design methods are based on repeated trial analysis, a procedure which is well described[6] by Fred A. Noetzli, M. Am. Soc. C. E.

[6] "The Design and Construction of Dams," by Edward Wegmann, M. Am. Soc. C. E., Eighth Edition, 1927, p. 439.

For economic reasons, and for reasons of safety, the ideal design must always aim at a structure of uniform strength. It is evident that the arbitrary, triangular buttress shape, with rectangular horizontal sections, does not necessarily approach the structural ideal. The trial method also involves a large amount of labor, and the derivation of general dimensional and quantity laws, based on the arbitrary shapes, would lead to a waste of material in higher dams.

In order to eliminate the trial computations the following direct design method for the supporting system is proposed. The water pressure, acting on an elementary deck area, is transmitted to the foundation in the most direct way by elementary arched columns, dimensioned so that the compressive stress is constant throughout. These elementary columns can then be combined to a monolithic buttress of uniform strength. They may also be built as adjacent members, separated from each other by continuous joints, so that secondary stresses due to shrinkage, temperature changes, etc., can practically be eliminated.

The available space does not permit the full presentation of the analysis, and the mathematical expressions, therefore, must be limited to the fundamental results. For the detailed derivations the reader is referred to a more complete manuscript of the paper entitled, "The Hollow Dam of Uniform Strength," filed by the writer in the Engineering Societies Library, New York, N. Y.

NOTATION

The notation adopted for the discussion of this paper is as follows:

a = a ratio expressing the relation, $\frac{v}{c}$.

A = cross-section area of an elementary column; a subscript, 1, denotes the section at the point, P_1.

b = length of elementary deck area.

c = a ratio expressing the relation, $\frac{f_c}{\gamma_c}$; this unit is a length.

d = horizontal distance, top and bottom, of an arched column at the center line.

D = total height of buttress, identical with maximum depth of water.

e = base of Naperian system of logarithms.

f = unit stress; a subscript, c, denotes compression.

F = a sliding factor; F' is the sliding factor for the buttress of absolute minimum weight.

g = the gravity constant.

h = vertical distance from top of deck to the center of an elementary area of deck slab.

H = horizontal component of force; a subscript, 0, identifies this component with P_0 and a subscript, w identifies this component with R_w.

i = a ratio expressing the relation, $\frac{D}{c}$, called buttress ratio.

k = a factor signifying the relative deck weights.

m = a variable coefficient that expresses a relation, $\frac{v}{D}$.

P = axial thrust on an arched column; a subscript, 0, denotes water pressure; a subscript, k, denotes top thrust due to water and slab combined; and P'_k denotes top thrust due to water and normal slab component combined.

p = pressure at the top of an elementary arched column; a subscript, v, denotes the vertical component.

r = a coefficient expressing the ratio, $\frac{V'_w}{H_w}$.

R = resultant of all forces above the foundation; R_w is the resultant thrust on deck due to water.

S = a force that represents the weight of the elementary deck area; a subscript, B, indicates the component perpendicular to the deck; and a subscript, D, indicates the component transmitted through the slab to the base.

t = thickness of a catenary column; the subscript, 0, indicates a section at any point, N_0, and a subscript, 1, indicates thickness at Section N_1, etc.

v = vertical distance from the toe of the deck slab to the center of an elementary area in that slab; Δv = horizontal projection of w_0, the width of the elementary area, and $d\,v$ is the horizontal projection of a differential width of deck area.

V = vertical component of force; a subscript, 0, identifies this component with P_0; a subscript, w, identifies this component with R_w; and V'_w = total vertical component of water pressure of buttress of absolute minimum weight.

w = width of an arched column; a subscript, 0, identifies the width with that at N_0; and subscripts, 1, 2, etc., identify corresponding sections at N_1, N_2, etc.

W = weight of structure; a subscript, c, denotes the arched column; a subscript, D, denotes the total deck; and a subscript, B, denotes the total buttress.

x = horizontal distance from the toe of the slab to the center line of the arched column at its base; a subscript, 0, denotes horizontal distance from toe of slab to the center line of the arched column at its top; $d\,x$ is the vertical projection of a differential width of deck area; and Δx = small horizontal interval.

β = angle of R and V.

γ = unit weight; a subscript, c, refers to concrete; a subscript, w, denotes water; and γ'_w is an imaginary unit weight.

λ = weight factor: subscripts, D and B, are for deck and buttress, respectively; λ_0 = factor for buttress with zero deck weight; λ'_0 = factor for buttress of absolute minimum weight; and λ_g = factor for gravity section.

ϕ_0 = angle that deck slab makes with the vertical.

ϕ_1 = angle of column thrust with horizontal at N_1; ϕ_k = angle of combined top thrust, P_k, with horizontal, $\Delta\,\phi_k = \phi_k - \phi_0$; and $\Delta\,\phi$ = angular change of column axis corresponding to $\Delta\,x$.

ARCHED COLUMN UNIT

Referring to Fig. 1 consider an elementary deck area, $A\,B\,C\,D$, and the water pressure, P_0, acting on it. Assume for the present that the weight of the deck is zero. Similar to the thrust of an ordinary bridge arch the thrust, P_0, can be transmitted to the ground by direct compression by the arched column, $N_0\,N_1$. The crown of the arch may be imagined at O, and the right abutment at N_1. The water pressure, P_0, simply replaces the arch thrust at N_0.

If the cross-sectional area of the arch is varied so that the compressive stress is constant at any point, the arch axis will conform to a curve known as the catenary of uniform strength.[7] The elementary arch, $N_0 N_1$, then is defined as an arched column.

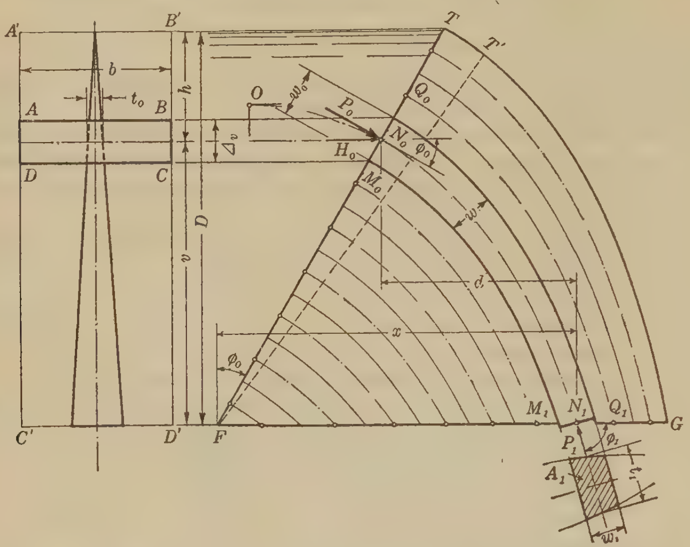

FIG. 1.—AN ELEMENTARY DECK AREA, *A B C D*, SUPPORTING A WATER LOAD.

Designating by f_c the unit compressive stress and by γ_c the unit weight of the arched column, the expression,

$$c = \frac{f_c}{\gamma_c} \dots\dots\dots\dots (1)$$

represents a parameter, the unit of which is a length. Furthermore, let the ratio, $\frac{v}{c}$, equal a. Designating by P_1 the resultant thrust of the arched column at N_1, and with reference to the dimensions of Fig. 1, the following relations can be derived,

$$\sec \phi_1 = \sec \phi_0 e^a \dots\dots\dots\dots (2)$$

or,

$$P_1 = P_0 e^a \dots\dots\dots\dots (3)$$

The horizontal distance, d, is given by the expression,

$$d = c\,(\phi_1 - \phi_0) \dots\dots\dots\dots (4)$$

in which, the angles, ϕ_1 and ϕ_0, are measured in radians.

Designating by W_c the weight of the arched column between N_0 and N_1, and by H_0 the horizontal component of P_0; then, also,

$$W_c = H_0\,(\tan \phi_1 - \tan \phi_0) \dots\dots\dots\dots (5)$$

---

[7] "Higher Mathematics," by Mansfield Merriman and Robert S. Woodward, Third Edition, p. 147, John Wiley & Sons, 1902.

The top thickness of the elementary column becomes,

$$t_0 = \frac{b\,\gamma_w\,(D - v)}{f_c} \qquad \text{(6)}$$

Equation (5) can now be written in the form,

$$W_c = b\,\gamma_w\,(D - v)\left[\sqrt{e^{2a}\sec^2\phi_0 - 1} - \tan\phi_0\right] \Delta v \qquad \text{(7)}$$

Multiple-Column Buttress of Uniform Strength

Assume that the whole deck strip, $A'\,B'\,C'\,D'$, is divided into a large number of elementary deck areas, and that the water pressure acting on each elementary area is transmitted by corresponding elementary arched columns, $Q_0\,Q_1$, $N_0\,N_1$, etc. If the cross-sectional area of the independent supporting units is shaped so that adjacent column faces just touch each other, the whole buttress can be conceived as built up of a large number of arched column units. Such a buttress is defined as a multiple-column buttress of uniform strength.

The cross-sectional area, A_1, of the elementary column at N_1 is found from Equation (3),

$$A_1 = \frac{P_1}{f_c} = \frac{P_0\,e^a}{f_c} \qquad \text{(8)}$$

If the width, w, of the column at any point is defined as the mean distance between the axis of adjacent column units, the column thickness at any point is definitely determined. Substituting,

$$v = m\,D \qquad \text{(9)}$$

and designating the column thickness at N_1 by t_1, and assuming that $\frac{D}{c} = i$, the following expression results,

$$\frac{t_1}{b} = \frac{D\,\gamma_w\,(1 - m)\,e^{2\,mi}\sec^2\phi_0}{c\,\gamma_c\left[\tan\phi_0\sqrt{e^{2\,mi}\sec^2\phi_0 - 1} + 1\right]} \qquad \text{(10)}$$

From Equation (4), the horizontal distance, $x = F\,N_1$, and,

$$\frac{x}{D} = m\tan\phi_0 + \frac{1}{i}(\phi_1 - \phi_0) \qquad \text{(11)}$$

The angle, ϕ_1, is found from Equation (2); ϕ_1 and ϕ_0 are expressed in radians.

By varying the factor, m, in Equations (10) and (11), the thickness of the buttress along the horizontal plane, $F\,G$ (Fig. 1), can be determined and by repeating the same process for other values of D it is possible to evaluate the shape of the entire buttress.

Equations (10) and (11) indicate that the shape of the buttress is mainly a function of the ratio, $\frac{D}{c}$ (or i), and the angle, ϕ_0. Considering ϕ_0 as a constant, buttresses with the same ratio, $\frac{D}{c}$, have a similar geometrical shape. From Equation (1),

$$\frac{D}{c} = \frac{D}{f_c}\,\gamma_c = i \qquad \text{(12)}$$

This important ratio is called the buttress ratio. Since γ_c is constant for a given case, the ratio, $\frac{D}{c}$, is simply a function of height and stress.

Fig. 2 gives an axonometric view of a monolithic buttress of uniform strength, with horizontal sections at different elevations computed by Equations (10) and (11). In this case, let $c = 200$ ft.; $f_c = 200$ lb. per sq. in.; $\gamma_c = 144$ lb. per. cu. ft.; and $\gamma_w = 62.4$ lb. per cu. ft. It will be noted that for $D = 80$ ft. the horizontal section approaches an isosceles triangle. As the height of the buttress increases the horizontal sections bulge out more and more, so that for $D = 320$ ft. and $D = 400$ ft., the maximum thickness, designated by $t_{\text{max.}}$, occurs at a considerable distance from the up-stream face. For $D = 400$ ft., $t_{\text{max.}}$ even exceeds the width of the deck strip.

Fig. 2 also shows the buttress ratio for the different values, D, computed by Equation (12) with the given values of γ_c and f_c. Since this ratio determines the shape of the buttress, Fig. 2 also represents the buttress shapes obtained with other unit stresses. Assuming, for instance, $f_c = 400$ lb. per sq. in., $D = 320$ ft., and $\gamma_c = 144$ lb. per sq. in., then the buttress ratio becomes 0.80. (See Equation (12).)

The corresponding buttress is, therefore, identical in shape with that of a buttress with $D = 160$ ft. and $f_c = 200$ lb. per sq. in., as shown.

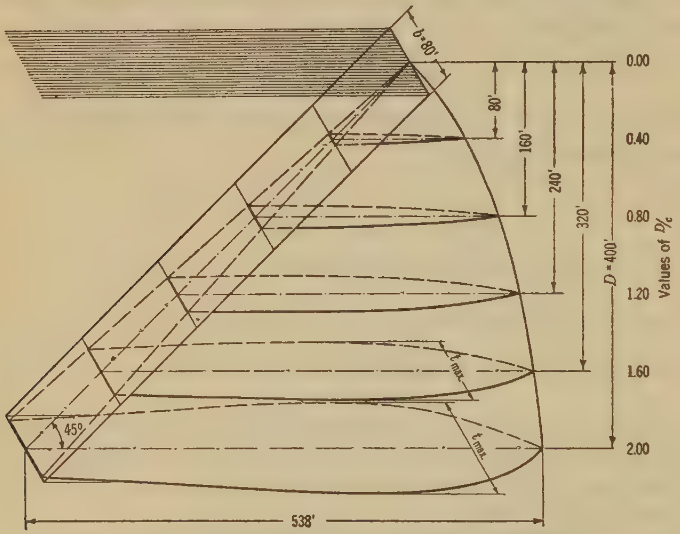

FIG. 2.—DIAGRAM SHOWING A MONOLITHIC BUTTRESS OF UNIFORM STRENGTH.

STRESSES IN THE MONOLITHIC BUTTRESS

The multiple-column buttress (Fig. 1) is built up of independent column units, which can deform freely under the applied load. Since the unit compressive stress is constant, each column will shorten in proportion to its length and the up-stream face moves into the deformed position, FT', which is almost a straight line. Opposite points along adjacent column faces, therefore, will closely retain their relative position after the deformation has taken place.

Neglecting the influence of Poisson's ratio, the same deformation of the buttress can evidently take place if adjacent column units are connected monolithically with each other, and no shearing forces along the imaginary column faces will be induced. Furthermore, in order to maintain equilibrium, no forces normal to the axis of the catenary columns are required.

Since the buttress is subject mainly to direct stresses in one direction the internal work must approach a possible minimum. From Castigliano's principle of least work it can then be concluded that the stress distribution in the monolithic buttress is very nearly the same as that in the multiple-column buttress composed of independent arched column units.

For practical purposes extreme accuracy is not required, because shrinkage and temperature stresses may easily destroy a theoretically refined stress analysis.

From these considerations the following conclusions are derived:

(1) The catenaries of uniform strength represent principal stress trajectories;
(2) The first principal stress, at any point of the buttress, is a constant compressive stress and equals the design stress, f_c; and,
(3) The second principal stress is zero throughout.

It should be kept in mind that such a stress condition applies only to a monolithic buttress with dimensions determined as for Fig. 2. Any other distribution of the buttress material must necessarily produce a different system of principal stresses. The larger the deviation from the ideal shape, the more distorted the resulting stress system must be.

A buttress, approaching more or less uniform strength, could also be designed by the trial analysis. After the principal stresses have been determined by any of the current methods, the shape of the buttress must be corrected until the final analysis gives a practically uniform first principal stress and a zero second principal stress.

Fig. 3 shows a reproduction of the Vöhrenbach buttress,[8] the heavy lines indicating the principal stress trajectories. The magnitude of the principal stresses along the trajectories is shown by light lines, the plus sign indicating compression.

The striking similarity between the first principal stress trajectories in Fig. 3 and the catenaries of uniform strength in Fig. 1 will be noted. The magnitude of the first principal stress in Fig. 3 also indicates that a more uniform stress distribution could be obtained by decreasing the thickness toward the down-stream face and increasing the thickness toward the lower elevations near the up-stream face. After several trial computations a shape similar to a multiple-column buttress of uniform strength would result. The trial computations would involve considerable labor; the advantage of the direct method is evident.

Influence of Deck Weight

In analyzing the influence of the deck weight on the shape and weight of the buttress, two extreme cases of deck support are considered.

Fig. 3.—The Vohrenbach Buttress.

Case 1.—Assume that the deck is completely separated from the buttress by a frictionless joint along the up-stream face of the buttress, as indicated in Fig. 4. In this case the initial top thrust of the catenary column, designated by P'_k, is composed of the water pressure, P_0, and the normal component, S_B, of the corresponding deck weight, S. The weight component, S_D,

Fig. 4.—Influence of Deck Weight if Deck and Buttress Are Separate.

is transmitted to the foundation through the deck itself. This type of deck support is found in the Ambursen slab deck, except for the uncertainties due to friction forces, but the assumption of a frictionless joint will be on the safe side.

The weight of the deck is dependent upon the type, working stresses in the deck, span, etc. The relative deck weight is expressed by a factor, *k,* defined as follows,

$$k = \frac{S}{P_0} \dots\dots\dots\dots\dots\dots\dots\dots (13)$$

For a triangular deck weight distribution, here considered, the factor, *k,* is constant for any elevation, *v*. Since its value is also practically independent of the inclination, ϕ_0, of the deck, the factor, *k,* is called the deck constant. The initial top thrust, P'_k, of the catenary column then becomes

$$P'_k = P_0 (1 + k \sin \phi_0) \dots\dots\dots\dots\dots\dots (14)$$

Equations (1) to (12) also apply to Case 1 if P'_k is substituted for R_0, or by replacing the unit weight, γ_w, by the unit weight γ'_w; thus,

$$\gamma'_w = \gamma_w (1 + k \sin \phi_0) \dots\dots\dots\dots\dots\dots (15)$$

Case 2.—Assume that the elementary deck strip is to be monolithically connected with the corresponding catenary column, as shown in Fig. 5. Adjacent column units are assumed to be completely separated from each other by continuous joints through deck and buttress.

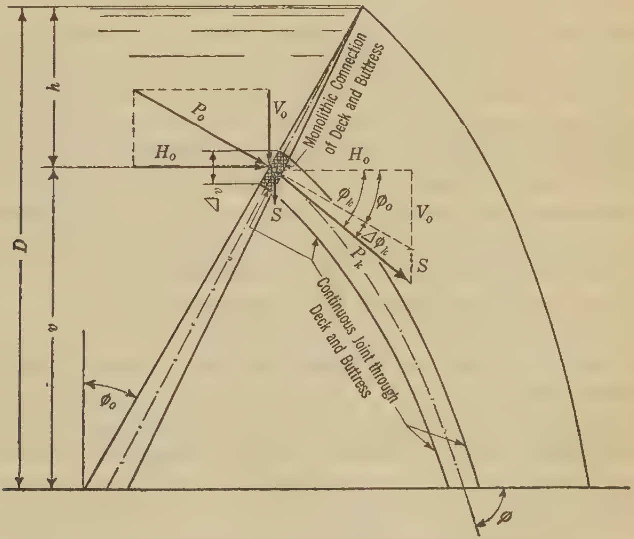

FIG. 5.—INFLUENCE OF DECK WEIGHT IF DECK AND BUTTRESS ARE MONOLITHIC.

In this case the full deck weight, *S*, is combined with the water pressure, P_0, and the resultant of these two forces, designated by P_k, is inclined at the angle, ϕ_k, to the horizontal. The angle, ϕ_k, is determined from the relation,

$$\tan \phi_k = \tan \phi_0 + k \sec \phi_0 \dots\dots\dots\dots\dots\dots (16)$$

For small values of ϕ_k the following approximate expression, measured in radians, can be derived,

$$\phi_k = \phi_0 + \frac{k \cos \phi_0}{1 + k \sin \phi_0} \quad \ldots\ldots (17)$$

The shape of the buttress, as modified by the deck weight, is given by the following equations, the derivations of which are similar to Equations (10) and (11);

$$\frac{t}{b} = \frac{D\,\gamma_w\,(1 - m)\, e^{2mi} \sec^2 \phi_k}{c\,\gamma_c \left(\tan \phi_0 \sqrt{e^{2mi} \sec^2 \phi_k - 1} + 1\right)} \quad \ldots\ldots (18)$$

and,

$$\frac{x}{D} = m \tan \phi_0 + \frac{1}{i}\,(\phi - \phi_k) \quad \ldots\ldots (19)$$

The angle, ϕ, is given by the relation,

$$\cos \phi = \frac{\cos \phi_k}{e^{mi}} \quad \ldots\ldots (20)$$

It may be noted that for $k = 0$, or $\phi_k = \phi_0$, Equations (18) and (19) become identical with Equations (10) and (11) derived under the assumption of a weightless deck.

The weight of the arched column unit is given by the following expression, which is similar to Equation (7),

$$W_c = b\,\gamma_w\,(D - v)\left[\sqrt{e^{2m} \sec^2 \phi_k - 1} - \tan \phi_k\right] \Delta v \quad \ldots\ldots (21)$$

Since the angle, ϕ_k, is always larger than ϕ_0, the effect of the deck weight has the tendency to shorten the length of the catenary column. For Case 1 the weight of the column will always be larger than under the assumption of a weightless deck, but this is not necessarily true for the monolithically connected deck. Although the increased top thrust tends to increase the weight of the catenary column, the shortening effect has a tendency to decrease its weight. For small angles, ϕ_0, that is, for steep decks, the shortening effect is very pronounced, whereas the increase of the initial top thrust is comparatively small. The resulting weight of the column then is actually less than that obtained for a weightless deck.

At some intermediate angle, ϕ_0, the two influences balance each other, and for larger angles, ϕ_0, that is, flat decks, the resulting weight of the column becomes greater than for $k = 0$.

In general, it may be stated that for Case 1 the influence of the deck always increases the weight of the buttress. The type described in Case 2 gives a more economical buttress in any case, and, for this reason, becomes of practical importance.

WEIGHT FACTOR AND SLIDING FACTOR DIAGRAMS

The total weight of the buttress is the sum of the weights of all the elementary, arched columns, and is found by integrating Equation (21), which contains the differential equation of the total buttress weight. Since it is not possible to present the integral in explicit form, Equation (21) has been integrated by Simpson's rule.

The main purpose of any dam consists in providing a structure which will resist the horizontal component of the total water pressure. The weight of the structure, therefore, may be expressed conveniently as a factor of the horizontal water pressure. With reference to Fig. 6, the deck constant, k, is then given by the ratio,

$$k = \frac{W_D}{R_w} \quad (22)$$

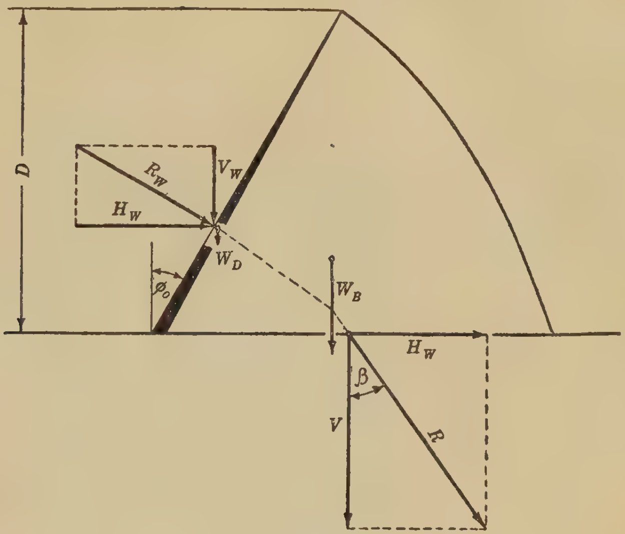

FIG. 6.

The weights of deck, buttress, and combined weights are defined by the following weight factors:

Deck weight factor:

$$\lambda_D = \frac{W_D}{H_w} = k \sec \phi_0 \quad (23)$$

Buttress weight factor:

$$\lambda_B = \frac{W_B}{H_w} \quad (24)$$

Combined weight factor:

$$\lambda_{BD} = \frac{W_D + W_B}{H_w} = \lambda_D + \lambda_B = k \sec \phi_0 + \lambda_B \quad (25)$$

In addition, the direction of the resultant, R, is given by the sliding factor, F,

$$F = \tan \beta = \frac{H_w}{V} = \frac{1}{\tan \phi_0 + \lambda_{BD}} \quad (26)$$

The deck weight factor, Equation (23), is a function of the deck constant, k, and the inclination, ϕ_0, of the deck. The buttress weight factor, Equation (24), is a function of k, ϕ_0, and the buttress ratio, i, defined by Equation (12).

The combined weight factor, Equation (25), is also a function of k, ϕ_0, and i, and the same is true for the sliding factor, F, Equation (26).

The weight and sliding factors can be presented in graphical form as functions of the variables, k, ϕ_0, and i, as shown in Figs. 7, 8, and 9.

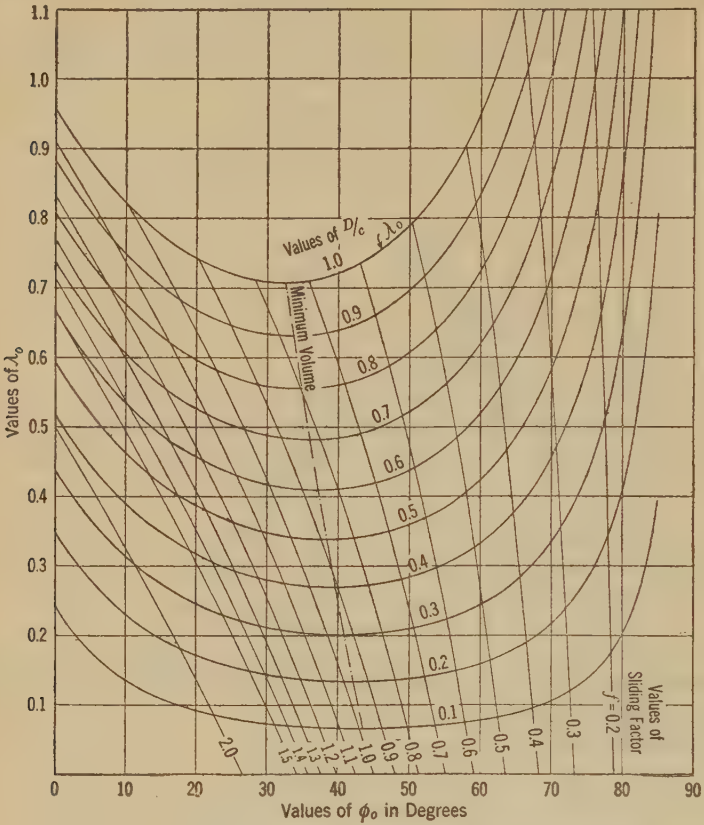

FIG. 7.—GRAPH FOR DETERMINING WEIGHT AND SLIDING FACTORS WHEN $k = 0$.

These diagrams illustrate the quantity laws of the buttressed dam of uniform strength for Case 2. It may be noted that the total volume becomes a minimum for deck inclinations ranging approximately from $\phi_0 = 20$ to $\phi_0 = 40$ degrees. However, the minimum quantities can only be realized in combination with excessively large sliding factors. The deck inclination, therefore, will be governed largely by the limiting sliding-factor values.

The buttress quantities for Case 1 can be obtained from Fig. 7, by computing the horizontal component of the water pressure from Equation (24), with an imaginary unit weight of water as obtained from Equation (15).

The diagrams can be used as guides in the design and for the purpose of preliminary estimates. They are equally applicable to any system of measurements, because the different factors represent pure ratios.

As an example, find the most economical deck inclination as well as the quantities in the deck and buttress of a hollow dam, with the following design data: $D = 200$ ft.; $b = 50$ ft.; $k = 0.10$; $f_c = 400$ lb. per sq. in.; $\gamma_c = 150$ lb. per cu. ft.; $\gamma_w = 62.5$ lb. per cu. ft.; and $F = 0.70$ (maximum permissible value).

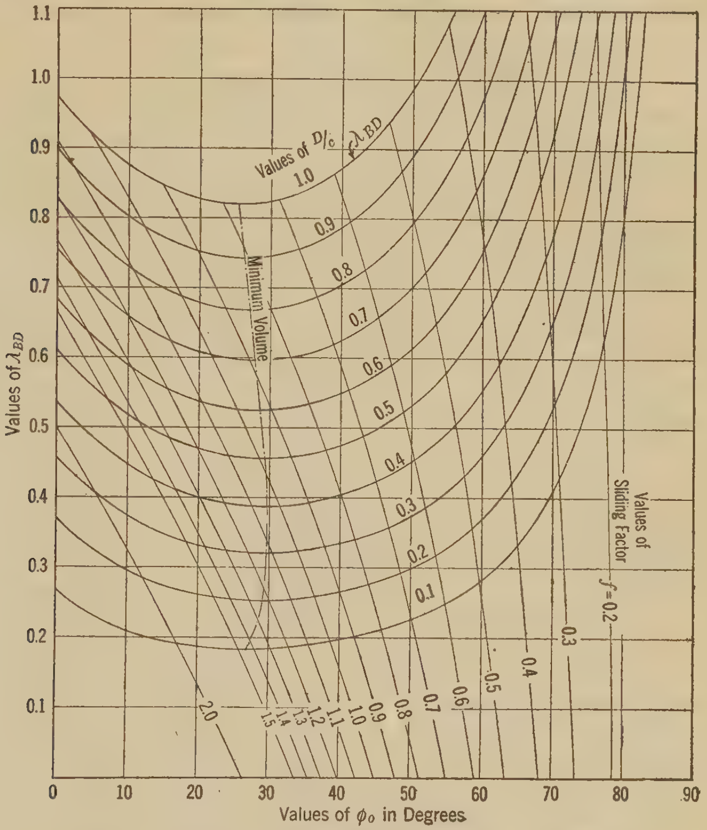

FIG. 8.—GRAPH FOR DETERMINING WEIGHT AND SLIDING FACTORS WHEN $k = 0.10$

By Equation (12) the buttress ratio is found to be 0.521. Entering Fig. 8, corresponding to the deck constant, $k = 0.10$, it will be noted that, for $\frac{D}{c} = 0.521$, the minimum quantities in the dam require a deck inclination, $\phi_0 = 29$ degrees. The combined weight factor, read at the intersection of $\frac{D}{c} = 0.521$ and $\phi_0 = 29°$, is $\lambda_{BD} = 0.47$. The same intersection gives a sliding factor, $F = 0.97$, which is too large.

In order not to exceed a value, $F = 0.70$, the deck inclination must be limited to $\phi_0 = 43°$; the corresponding combined weight factor is $\lambda_{BD} = 0.50$ which is only 6% larger than the possible minimum.

The total horizontal component of the water pressure, acting on the deck strip under consideration (in pounds), is,

$$H_w = \frac{50 \times 200^2 \times 62.5}{2} = 62\ 500\ 000$$

With $\lambda_{BD} = 0.50$, the combined weight of deck and buttress, from Equation (25), is, therefore, 50% of H_w. The combined volume, expressed in cubic yards, is,

$$\frac{0.50 \times 62\ 500\ 000}{150 \times 27} = 7\ 720$$

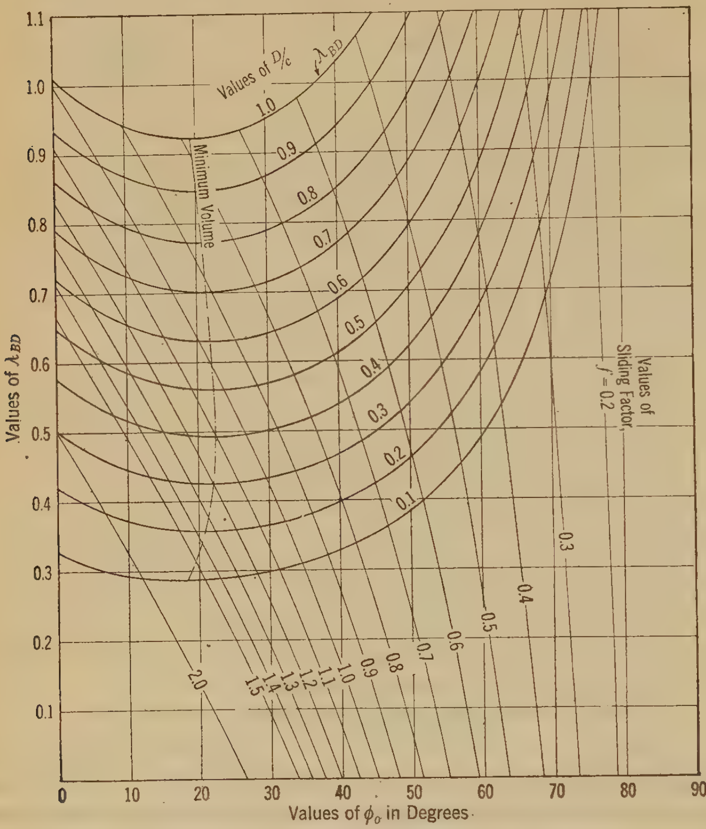

FIG. 9.—GRAPH FOR DETERMINING WEIGHT AND SLIDING FACTORS WHEN $k = 0.20$.

The quantities in the buttress alone are found from Equation (25), which gives the following percentage for the buttress volume,

$$\frac{\lambda_B}{\lambda_{BD}} = \left(1 - \frac{k \sec \phi_0}{\lambda_{BD}}\right) 100 = 72.6$$

These quantities represent the minimum possible volume that can be obtained with the given data. Because of the minimum practical wall thickness the actual quantities will be somewhat larger. If the buttress is provided with auxiliary stiffening structures, not designed as integral parts of the catenary columns, then the additional volume due to this cause must be added.

Generally, the larger the buttress ratio, $\frac{D}{c}$, the closer the agreement between the actual and the theoretical quantities.

Buttress of Absolute Minimum Weight

The previous deductions have been derived under the assumption that the buttress has a straight up-stream face. The weight factor diagrams (Figs. 7, 8, and 9) indicate that for certain deck inclinations the total quantities become a minimum. A straight up-stream face does not necessarily give the absolute minimum buttress quantities.

With reference to Fig. 10, consider the elementary catenary column, *A B C D,* which supports the water pressure acting over the vertical distance, *dv*. By varying the inclination of the elementary deck strip, *AB,* and by keeping *dv* constant, there will be one deck inclination, ϕ_0, which will require a minimum amount of column material.

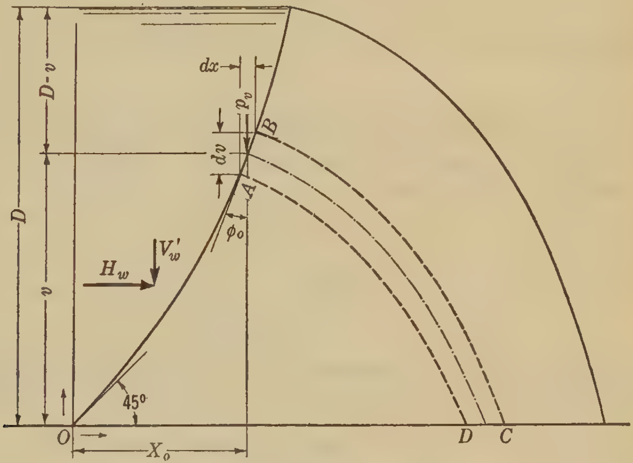

FIG. 10.

In case of a weightless deck this inclination can be determined by differentiating the column weight, W_c, Equation (7), with respect to ϕ_0, which leads to the following relation,

$$\tan \phi = \frac{1}{e^a} \qquad (27)$$

Equation (27) shows that the most economic deck slope is a function of the elevation, v, and the parameter, c $\left(\text{since } a = \frac{v}{c}\right)$. At the bottom, $v = 0$, the deck inclination is $\phi_0 = 45$ degrees. As v increases, the deck becomes steeper and steeper.

Equation (27) also represents the differential equation for the up-stream curve of the buttress, because $\tan \phi_0$ is identical with the first derivative of x_0 with respect to v. By integration the following relation is obtained:

$$x_0 = c\left(1 - \frac{1}{e^a}\right) \dotfill (28)$$

By substituting $v = mD$, from Equation (9), Equation (28) can be written in the form,

$$\frac{x_0}{D} = \frac{1}{i}\left(1 - \frac{1}{e^{mi}}\right) \dotfill (29)$$

Equation (29) shows that the buttress ratio, $\frac{D}{c} = i$, entirely determines the curvature of the up-stream face.

By substituting ϕ_0, from Equation (27), in Equation (7), the minimum weight of the elementary column is obtained. The total weight of the buttress, designated by W'_0, is found by integrating over the total height, D. Designating by λ'_0 the weight factor of the buttress of absolute minimum weight, then,

$$\lambda'_0 = \frac{W'_0}{H_w} = \frac{4}{i^2}(\sin h\, i - i) \dotfill (30)$$

The buttress weight factor is, therefore, a function of the buttress ratio, i, or $\frac{D}{c}$, only.

In order to find the sliding factor of the buttress of absolute minimum weight, the vertical component of the water pressure, designated by V'_w, must be first determined. By integration,

$$V'_w = r\, H_w \dotfill (31)$$

in which,

$$r = \frac{2\left(e^{\frac{1}{i}} + i - 1\right)}{i^2} \dotfill (32)$$

If the sliding factor of the buttress of absolute minimum weight is designated by F', then,

$$F' = \frac{1}{r + \lambda'_0} \dotfill (33)$$

A comparison with the straight-face buttress shows that the difference between the minimum quantities for $i < 1.0$ is less than 1 per cent. However, the buttress of absolute minimum weight has a sliding factor which is appreciably less than that of the straight-face buttress. The comparison becomes more favorable as the buttress ratio, $\frac{D}{c}$, increases. If the buttress is built with independent column units completely separated from each other by continuous joints along adjacent faces, then the individual bottom columns of Fig. 10 will have a maximum sliding factor value, $F = 1.0$.

With the same quantity of material, the stability of a buttress of absolute minimum weight is superior to that of a straight-face buttress under all conditions.

The influence of the deck, monolithically connected with the corresponding column head, is similar in effect to that derived for a straight up-stream face. The minimum weight of deck and catenary column unit combined is best determined by trial by varying the angle, ϕ_0. If the resulting sliding factor is too large, then the slope of the deck must be decreased until safe sliding-factor values are obtained.

In narrow V-shaped canyons, where the heights of adjacent buttresses change rapidly, the application of the foregoing principles may lead to practical difficulties. Under these conditions the deck of the dam would assume a warped surface, with lateral thrusts acting on the buttress heads.

In case of comparatively wide cross-sections the warping effect is small, so that the foregoing features may be advantageously incorporated in the design of the dam.

DESIGN EXAMPLE

Fig. 11 represents a tentative design for a buttressed dam of uniform strength, consisting of five catenary column units, completely separated from each other by continuous joints extending through deck and buttress system.

The deck consists of symmetrical cantilever beams or disks, monolithically connected with the column heads and similar in design with an ordinary wall footing. Columns No. 1 and No. 2 are treated as cellular sections, built up of rectangular plates to prevent buckling.

Preliminary computations by Equation (13) indicated an approximate deck weight factor value of from $k = 0.10$ to $k = 0.15$.

With a design stress, $f_c = 400$ lb. per sq. in., and a unit weight, $\gamma_c = 144$ lb. per sq. in., the buttress ratio, i, or $\frac{D}{c}$, becomes 0.75 by Equation (12). With a limiting sliding factor, $F = 0.70$, the inclination of the deck, ϕ_0, is found to be 38° from Fig. 8 ($k = 0.10$). From a similar set of curves, or by interpolation, for $k = 0.15$, the value of ϕ_0 is found to be 36 degrees. The mean value, $\phi_0 = 37°$, was adopted for the design.

The arched column units are designed as follows: First, the water pressure acting on the deck face, and (depending on drainage conditions) also the water pressure acting in the horizontal deck joints, are combined with the weight of the deck to obtain the initial top thrust of each column. For the present purpose the water pressure in the deck joints has been neglected.

The co-ordinates of the column axis and the sectional area at any point can then be computed by Equations (2), (3), and (4). In the present case (Fig. 11), a simple graphical method, based on the differential equation of the catenary of uniform strength, has been used. This method is illustrated in Fig. 12 in which P_0 represents the given top thrust, applied at N_0, and acting at the given angle, ϕ_0, to the horizontal. The horizontal through N_0 is divided into equal intervals, and the verticals, *AB, CD, EF,* etc., are drawn as shown.

The small angle, $\Delta\phi$, expressed in radians, is given by the equation,

$$\Delta\phi = \frac{\Delta x}{f_c}\gamma_c \quad \cdots\cdots\cdots\cdots (34)$$

Notes: All Forces in Thousand Lbs. for 30 Ft. Deck Width. Reinforcement, Joint and Drainage Details not Shown

FIG. 11.—DESIGN EXAMPLE OF BUTTRESSED DAM OF UNIFORM STRENGTH.

Assuming $\Delta x = 20$ ft., $f_c = 400$ lb. per sq. in., and $\gamma_c = 144$ lb. per sq. in., then $\Delta\phi = 0.05$.

Since P_0 is tangent at the point, N_0, the construction must begin with $\frac{\Delta\phi}{2}$, as indicated in Fig. 12, and N_1 then is the first point on the catenary of uniform strength. Additional points, N_2, N_3, N_4, etc., are found by equal deflections, $\Delta\phi$, as shown. A continuous curve drawn through N_0, N_1, N_2, N_3, etc., then represents the column axis. The thrust at any point is best determined from Equation (3) by means of a log log slide-rule. Its direction is found graphically by considering that the horizontal component is constant and equal to the horizontal component of P_0.

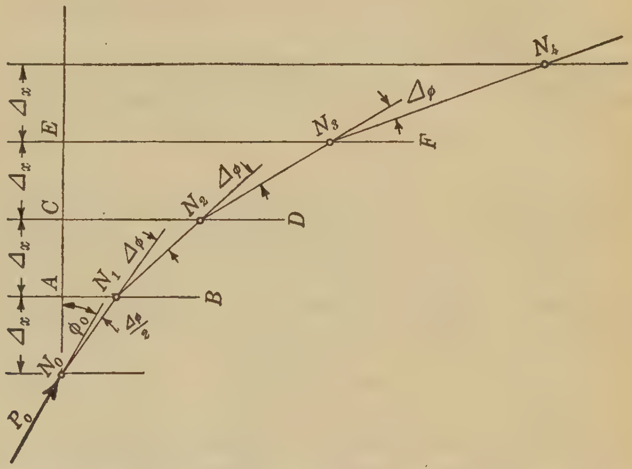

FIG. 12.—GRAPHICAL METHOD OF DETERMINING THE CO-ORDINATES OF THE COLUMN AXIS AND THE SECTIONAL AREA AT ANY POINT.

The resultant of all the column thrusts at the base and its direction are determined by a force and equilibrium polygon, as shown in Fig. 11(*b*) and Fig. 11(*c*).

For high dams the influence of secondary stresses due to shrinkage, temperature changes, yielding of the foundation, etc., deserves careful consideration in design and construction. In order to reduce the danger from this source, Mr. Jakobsen has advised[3] contraction joints in buttresses and arches of high multiple-arch dams.

The arched-column principle lends itself without difficulty to the elimination of secondary stresses because the logical location of such joints is given by the column outlines. In addition, the bottom joints, shown in Fig. 11, allow slight rotation of the individual columns, whereby the secondary stresses are further reduced. In certain cases temporary hinges, as used in arch bridges, may be provided near the foundation. Each column unit thus represents a statically determinate member, the action of which is definitely known under all conditions of loading.

Temperature changes in the interior of the dam are reduced to a minimum by the designing column, No. 1 (Fig. 11 (*d*)) so that complete enclosure of the structure is obtained. In severe climates this feature also effectively prevents freezing of the deck from the down-stream side, as reported[9] by F. W. Scheidenhelm, M. Am. Soc. C. E.

The down-stream face can also be designed as an overflow section, with most of the material acting as a column member. In locations subject to earthquake shocks, all the columns may be designed as adjacent cellular units, whereby it is possible to increase the lateral stability to any desired extent.

ECONOMIC CONSIDERATIONS

Buttressed dams are especially adapted for comparatively wide dam sites with solid rock foundations. For this reason the buttressed type is mainly a competitor of the gravity type of dam.

For moderate heights the economy of the Ambursen type has been recognized for some time, and the economic features of the multiple-arch type have been amply discussed by Mr. Noetzli,[10] V. H. Cochrane,[11] M. Am. Soc. C. E., and others.

In order to evaluate the economic possibilities of the buttressed dam of uniform strength, its maximum theoretical height must be considered. Fig. 2 shows that for the greater heights the thickness of the buttress assumes a maximum value (designated by $t_{\text{max.}}$) occurring at some distance from the up-stream face. Since two adjacent buttresses can not occupy the same space, the maximum height of the dam is reached when,

$$\frac{t_{\text{max.}}}{b} = 1.0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

Equation (10) shows that the ratio in Equation (35) is mainly a function of the buttress ratio, $\frac{D}{c}$. Designating the maximum height of the dam by $D_{\text{max.}}$, then by interpolation,

$$\frac{D_{\text{max.}}}{c} = 1.75 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

Assuming, for instance, a design stress of f_c = 500 lb. per sq. in., and a unit weight of γ_c = 144 lb. per cu. ft., the maximum theoretical height, in feet, becomes,

$$D_{\text{max.}} = 1.75 \times \frac{500 \times 144}{144} = 875$$

The maximum practical height is somewhat lower, due to the deck weight, but it may be concluded that the buttressed dam of uniform strength can be built to considerable heights with ordinary working stresses.

The relative volume of a buttressed dam and that of a gravity dam are best compared by means of the weight factors. The weight factor of a gravity section, designed for full uplift at the up-stream face, with uniform decrease to zero at the down-stream face, is designated by λ_g. Using the previous designations for the unit weight of water and concrete,

---

[9] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 772.

[10] *Loc. cit.*, Vol. LXXXVII (1924), p. 342.

[11] *Loc. cit.*, p. 370.

$$\lambda_g = \frac{\gamma_c}{\gamma_w} \sqrt{\frac{\gamma_w}{\gamma_c - \gamma_w}} \dots\dots\dots\dots\dots\dots\dots\dots (37)$$

With $\gamma_w = 62.5$ lb. per cu. ft. and $\gamma_c = 144$ lb. per cu. ft., $\lambda_g = 2.1$. The weight factor of the gravity section is practically constant for usual heights.

Figs. 7, 8, and 9 indicate that the combined weight factor of the buttressed dam increases about in direct proportion with the buttress ratio, $\frac{D}{c}$, but for usual sliding factors its value is only a fraction of λ_g. For the tentative design of Fig. 11 the combined weight factor value is, $\lambda_{BD} = 0.68$, or about one-third that of a gravity section. Therefore, even assuming that the unit cost of the buttressed dam is twice the unit cost of a gravity section, a saving of about one-third in the concrete cost is realized.

As the height increases the unit cost of the buttressed type decreases, because the cost of deck and formwork represents a smaller and smaller percentage, and the elimination of secondary stresses by means of expansion joints and complete enclosure results in considerable savings of reinforcing steel. Preliminary estimates indicate that the buttressed type of uniform strength will be superior in economy to the gravity dam in almost any case.

The independent column units permit construction to the ultimate height in convenient steps at long-time intervals, without the necessity of anchoring green concrete to the older concrete already in place. The uncertain action, due to different shrinkage and elastic behavior, is thus completely eliminated. At the same time spillway provisions for different construction steps may be conveniently incorporated in the column design.

Since the column units are statically determinate, their stress conditions and factors of safety are definitely known in advance for any contemplated height. To estimate the actual stress condition in the large masses of high gravity dams, even with the provision of vertical contraction planes, is not a simple problem, because successive layers are poured at comparatively slow rates, so that the lower portions may shrink and cool, while the upper portions expand due to chemical heat. It is also evident that the buttressed dam presents more favorable curing conditions because of the possibility of installing effective sprinkling systems, which will not only reduce the shrinkage, but also the setting temperatures.

Considering economy and safety combined it may be stated that the buttressed dam of uniform strength can be built to greater heights than the gravity dam.

CONCLUSIONS

From evidence presented in this paper, the writer has come to the following conclusions:

(1).—The arched column principle presents a simple and exact means for designing buttressed dams of uniform strength.

(2).—In case of monolithic buttresses designed by this method the first principal stress is constant compression and the second principal stress is zero.

(3).—Secondary stresses are practically eliminated by building the arched columns as independent, statically determinate units, separated from each other by continuous joints extending through deck and buttress system and complete enclosure of the dam.

(4).—The buttressed dam of uniform strength contains the minimum possible amount of material that can be obtained with a given design stress.

(5).—The exact quantities and design elements can be obtained from diagrams, in which the main variables are expressed as pure ratios.

(6).—The independent arched column units permit construction of the dam in economical steps at long-time intervals—no anchorage between the old and new concrete is required, and spillway facilities may be incorporated in each step with no waste of material for this purpose.

(7).—The buttressed dam of uniform strength is superior in safety and economy to the gravity type for any height to which a concrete dam can be built.

Acknowledgments

The writer deeply appreciates the encouraging assistance and valuable suggestions received during the preparation of the original manuscript from Mikael Juul Hvorslev, Assoc. M. Am. Soc. C. E., Walter Ruppel, Assoc. M. Am. Soc. C. E., and A. C. Schwager, Test Engineer, Pacific Electric Manufacturing Company, San Francisco, Calif.

DISCUSSION

James Girand,[12] Assoc. M. Am. Soc. C. E. (by letter).—The design of large massive structures has fallen short of the precision developed by the steel designers. There has been much groping for the fundamentals underlying the design of these monolithic masses, in which the weight of the structure is the sole resistance to the load. The author has presented a method, complete in every detail, which appears to be the solution so long sought. Difficulties of design and construction have pointed to a buttress of this shape. Other attempts have been made to approach this method of design, including a dam on the Choapa Project in Chile, in whch a graphical method was used instead of the analytic.

In discussion of this paper, two points may be emphasized. The first deals with the factor of safety of the structure, and the second, with the inclined open joints.

Factor of Safety.—It is apparent that in the author's development of the unit column theory and the use of $\gamma_c = 150$ lb. per cu. ft., that each unit column is in equilibrium with the water load balanced against its own weight. A decrease of load will allow part of the weight to rest on the underlying columns. An increase in load will overturn the entire column. In other words, the factor of safety of the structure against overturning is 1.0. This is due to the design, considering the full weight of the concrete as effective. Any desired safety factor can be secured by assuming the proper proportion of the concrete to be resisting the load. Various investigations by the writer on the trajectories of stress and the principle of least work have led to the conclusion that at the point of least work the stresses will distribute themselves so that about two-thirds of the weight of the structure will be useful in resisting the load. This gives a logical distribution of stress and a factor of safety of 1.5. This use of two-thirds of the unit weight of the concrete in the design will not materially increase the total quantity of concrete in the buttress; it will change the shape of the catenaries and slightly lengthen the buttress, but it will not increase the thickness. A high factor of safety against overturning is not essential, as the maximum load on a dam is well fixed. If an ample allowance is made for maximum high water, then the only additional load which could occur, would be an earthquake load which is generally accepted at 0.1 g.

Inclined Open Joints.—In his paper, the author indicates continuous joints between adjacent column units. This method of putting joints on the lines of first principal stress is being widely accepted, and the Coolidge Dam is an example of buttresses so constructed. This technique offers several inducements to the designer. It simplifies the units of design and permits more accurate use of the older methods. From the construction standpoint, it localizes shrinkage cracks and directs them so as to do the least harm to the structure. The latter is probably the principal excuse for introducing planes of weakness into a structure.

---

[12] Engr., Arizona Hydro-Elec. Syndicate, Phœnix, Ariz.

Why should designers intentionally remove some of the inherent strength of the structure? Many dams show considerable tension along the lines of second principal stress, and joints on the lines of first principal stress would seriously weaken the structure. This ability of the concrete to take tension is an additional factor of safety and should not be sacrificed. There are other reasons why the division into columns does not accomplish the best results:

(*a*) If the design is absolutely correct, the first principal stresses uniform, and the second principal stresses zero, it is immaterial whether or not, a joint is present, therefore, it may as well be omitted.

(*b*) The lines of stress will not conform to the shape of the column except at exactly the designed head. If the columns are totally free, this will lead to bending stresses and other undesirable conditions. If the columns are in contact with the adjacent ones, the stresses will be transmitted across the joint, in which case, it would be preferable to have no joint.

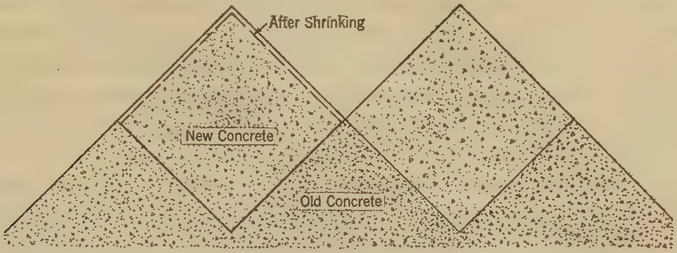
(*c*) In any case of a laminated body supporting a load, it is better to put the joints parallel to the lines of second principal stress rather than to the first. This might be exemplified by considering a foot cube of steel necessary to support a load. Such a cube would undoubtedly be made of plates lying flat and not standing on edge.

All these premises lead to the conclusion that no joints should be used; but how should one deal with the concrete as it is being placed to-day? Shrinkage undoubtedly occurs and even the finest structures with exceptionally high test concrete may have high initial tension due to it. Even if no cracks appear, the tension will radically affect the stresses and make futile the labors of the designer.

As the concrete must be placed in units, these units should be bounded by the lines of first and second principal stress.

The ideal way to place concrete would be in diamond-shaped units, as shown in Fig. 13. As the concrete sets and shrinkage takes place, the entire unit will settle down into the notch. This should relieve all tension in the unit and might actually cause a small initial compression. This method would not cause as many construction difficulties as would appear at first; the forms could be left open on the top edges until they were half full; strips nailed inside the forms would support short lengths of sheeting put in place as the pour rises. To bound the pour by the lines of first and second principal stress approaches this ideal method and allows the unit poured to free itself of some of the shrinkage stresses. If it is still considered desirable to introduce continuous joints to take up any movements and control cracks, the joints should be introduced along the lines of second principal stress instead of the first. In this location, they will cause the least weakening of the structure.

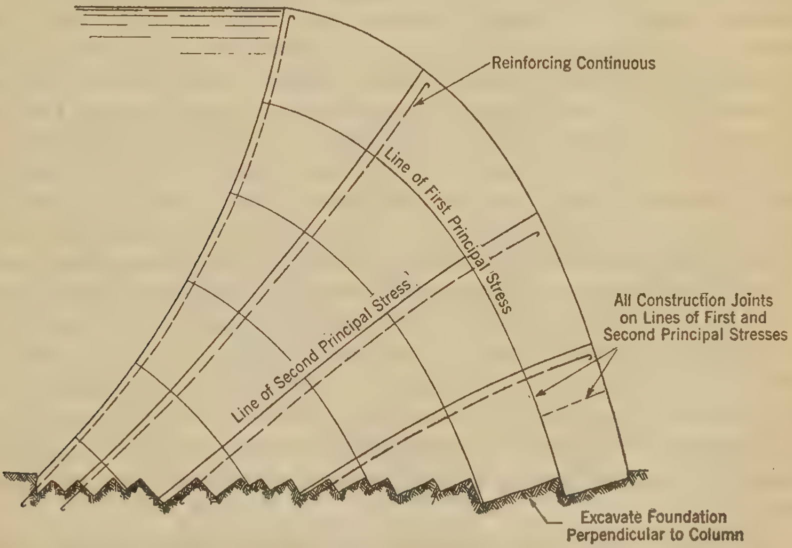
The idea of the horizontal construction joint with large form units, which may be sluiced full of concrete, is difficult to dispel. It is a fact, however, that at many dams the bed-rock has been stepped, cleaned, and treated in every manner to assure a good bond and to prevent sliding, while a few feet above it, there is a horizontal construction joint which does not have one-tenth the strength of the bed-rock joint.



After Shrinking
New Concrete
Old Concrete

FIG. 13.—AN IDEAL WAY TO PLACE CONCRETE.

The buttress of absolute minimum weight, as designed by the author, has many advantages. As pointed out, the sliding factor is less than that for a straight-faced buttress. The curved up-stream face is also advantageous if a multiple-arch deck is used, as the curve will cause the arches to be of constant intrados. The writer suggests modifications, as shown in Fig. 14. These



Reinforcing Continuous
Line of First Principal Stress
Line of Second Principal Stress
All Construction Joints on Lines of First and Second Principal Stresses
Excavate Foundation Perpendicular to Column

FIG. 14.

principally involve: (1) Using a unit weight of about two-thirds that of the concrete for γ_c; (2) the specification that the concrete units of pour shall be bounded by the lines of principal stress; and (3) the use of continuous reinforcement from the bed-rock through to the down-stream face of the buttress.

FRED A. NOETZLI,[18] M. AM. SOC. C. E. (by letter).—It is a well established fact that the highest degree of economy of material in a structure is obtained when this can be designed so that for full load the material is subjected at all points to the same maximum permissible unit stress. Such ideal conditions are feasible in relatively few engineering structures. The author has shown how they can be approached very closely in dams of the buttressed type.

In the type of dam described by Mr. Schorer a buttress is assumed to consist of a combination of elementary arched column units each of which transmits the portion of the water pressure acting on its up-stream deck, together with its own weight, by uniform axial compression to the foundation. By choosing any desired maximum unit stress of, say, 300, 400, or 500 lb. per sq. in., a designer is enabled with the aid of the author's formulas and diagrams to determine the theoretical dimensions of a buttress of minimum volume for any given height and spacing. Only the tallest buttress at a given dam site must be determined in this manner. The buttresses of lesser height are then merely portions of the tallest buttress cut off at the corresponding elevations.

The theoretical shape of a buttress of uniform strength, such as that shown in Fig. 2, requires some modification for practical applications, for instance, such as that incorporated in the author's design example shown in Fig. 11.

In buttresses of considerable length the shrinkage of the concrete is likely to produce cracks. The author proposes to provide inclined joints, thus eliminating the danger of irregular shrinkage cracks, such as otherwise might occur possibly in planes of high shearing stresses. Such joints have been used successfully in the buttresses of the Coolidge (multiple-dome) Dam, in Arizona, the Big Dalton (multiple-arch) Dam, in California, the Bananeiras (multiple-arch) Dam, in Brazil, and the Rodriguez (Ambursen) Dam, in Mexico. In some of these dams an investigation by the method of principal stresses showed tension stresses in the buttresses in planes perpendicular to the joints (second principal stresses). These tension stresses were taken care of by a proper amount of steel reinforcement. Whenever inclined joints are used in a buttressed dam it is desirable to investigate the stability of each individual inclined column. This may be done by combining all the weights and forces, including water pressure, which act upon one column, and then drawing the respective force and string polygons. In the author's type of dam this feature is already inherent in the design, because the axis of each elementary column has the shape of a catenary for the loads acting upon this column.

In buttressed dams of the usual type the joints are placed parallel to the direction of the first principal stresses because in these planes the shear stresses are zero. Each individual inclined column must be stable by itself. The safety against overturning can be increased materially at relatively small expense by placing reinforcing bars parallel to and immediately beneath the up-stream deck.

FIG. 15.

In Fig. 15 there are three inclined joints extending upward and forward from the base of the buttress to a short distance below the deck. For each individual column the funicular polygon was drawn for the forces involved, including water load and second principal stresses. Fig. 16 shows the stresses upon horizontal planes which were computed for the monolithic buttress (without joints), and for the individual columns, from the forces of the force polygons and the eccentricities of the string polygons relative to the column axes. The agreement between the stresses in the monolithic buttress and in the individual columns is reasonably good considering the almost unavoidable inaccuracies of the graphical construction of the force and string polygons.

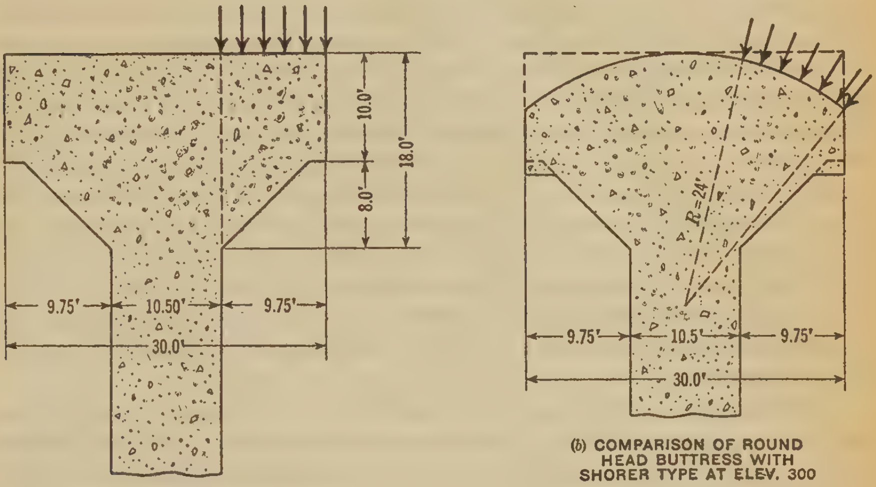
FIG. 16.

The buttress was analyzed further for partial water loads with the reservoir levels 30 ft. and 54.5 ft. below the crest of the dam. Also, for these load conditions, a reasonably good agreement was found to exist between the stresses in the monolithic buttress and in the individual columns.

In the design example shown in Fig. 11, Mr. Schorer proposes an up-stream deck consisting of a slab cantilevered out laterally for a length of 15 ft. on each side of the center line of the buttress. This cantilever slab is provided with large 45° haunches. The slab, haunches, and buttress wall are constructed integrally.

The normal sections of the deck slab at various elevations are shown by the author in Fig. 11(*h*). For instance, at the 300-ft. depth below the crest the normal section has the dimensions shown in Fig. 17(*a*). The bending moment per foot in slab and haunch on one side of the buttress wall has the value, $M = 62.5 \times 300 \times 9.75^2 \times \frac{1}{2} = 890\,000$ ft-lb. By the ordinary rules of reinforced concrete design the necessary reinforcement would be 3.5 sq. in. per ft. The maximum shear is about 80 lb. per sq. in., requiring bent-up bars or stirrups to take care of the diagonal tension stresses.



(*a*) SHORER TYPE AT ELEV. 300

(*b*) COMPARISON OF ROUND HEAD BUTTRESS WITH SHORER TYPE AT ELEV. 300

FIG. 17.

By way of comparison there is shown in Fig. 17(*b*) a round-head buttress for the same span of 30 ft. and the same thickness of the buttress used by the author. In such a case the water pressure is transmitted radially and by direct compression through the buttress head upon the buttress wall. Consequently, no bending moment occurs in the buttress head and no steel reinforcement is required. The quantity of concrete in the rounded head compares favorably with that of the cantilever type. Thus, by the simple arrangement of directing the water pressure toward the buttress wall by means of a rounded (or polygonal) up-stream face of the buttress head, plain concrete construction may be used instead of the reinforced cantilever type proposed by the author. At higher elevations of the dam where the water pressure is less, the cantilever type may require less material. On the other hand the principle of the round-head buttress may be applied economically to spans of 50 to 60 ft., with a minimum thickness of the buttress walls of 8 to 10 ft. This would enable the dam to be built of mass concrete instead of the thin reinforced concrete usually required for shorter spans.

Of course, the author's ingenious method of determining buttresses of uniform strength containing the minimum possible amount of material for a given design stress, may be used to advantage also for dams of the round-head buttress type.

B. F. Jakobsen,[14] Esq. (by letter).—The author presents a design method for a multiple-arch dam buttress, which should result in a structure of uniform strength. In general, at least, it should be possible to eliminate the possibility of buckling by providing counterforts, and since in Mr. Schorer's design two principal stresses are zero, the requirement of uniform strength is met when the third principal stress is constant throughout the buttress. As the author shows, this leads to a buttress having a horizontal section of variable width, as in Fig. 2, instead of a constant thickness, as has been customary in the past. The writer has calculated[15] the stresses in a buttress having a rectangular section in a horizontal plane. The section, for which the stresses were computed was an inclined, nearly normal section. The result shows, that the maximum principal stress (compression) was nearly constant, varying from about 260 to 286 lb. per sq. in. The intermediate principal stress, at right angles to the plane of the buttress, was zero, and the least principal stress (tension), varied from zero at the down-stream face to 84 lb. per sq. in. at the groin. This means that the factor of safety in compression is ten or more, while in tension it is three or less, unless steel is provided to take up the tension. This indicates the superiority of the author's design method.

The elimination of tension can presumably be accomplished by lengthening the buttress, but since stress calculations are complicated and time-consuming, it is difficult, if not practically impossible, to arrive at an economical design. Mr. Schorer's design method is therefore of great practical value.

In connection with the design of a fairly high multiple-arch dam the writer has had an opportunity to compare Mr. Schorer's method of design with the customary one. The consulting engineer, who prepared the design, first submitted one of the usual type having a constant thickness in a horizontal plane. This design had a small amount of tension, and it was decided to apply Mr. Schorer's method. The result was highly satisfactory to both parties, and a design with a tapered buttress in a horizontal section was adopted.

In a paper entitled "Stresses in Multiple-Arch Dams"[8] the writer treated the arch as monolithic with the buttress, as the author has done in Fig. 5. This treatment gives a shorter buttress than the assumption that the deck transmits load to the buttress only in a direction normal to the groin, as in Fig. 4. This latter involves the assumption of a frictionless joint between the deck and the buttress, and the writer questions whether such a joint is a practical possibility, considering that it must function for an almost unlimited time and under any conditions. These considerations would lead to the adoption of the arrangement shown in Fig. 4, as the safer design assumption, if it were not for the possibility of an upward thrust of the deck, due to water-soaking, combined with drying out of the buttress, and the consequent shrinkage. This tendency will be more pronounced when the temperature of the air is less than that of the water.

---

[14] Cons. Engr., Los Angeles, Calif.

[15] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 306.

Most multiple-arch dams, of which the writer has knowledge, show cracks in the buttresses which, near the groin, are normal to the direction of the groin.[16] These cracks may be due to shrinkage and swelling, as just outlined, or they may be due to tensile load stresses. In some of these dams the writer inclines to the opinion, that the cracks are due primarily to shrinkage and swelling. If the deck could be constructed of segments, say, 10 ft. high, which were provided with open joints above and below, so that these segments could not interact lengthwise, the condition illustrated by Fig. 5 would exist. This might involve difficulties for the multiple-arch type, but could easily be accomplished for the flat deck type of dam. As multiple-arch dams are generally built, it seems to the writer, that some swelling of the deck combined with shrinkage of the buttress must be considered as a possible, and probable, state of affairs and the designer must be governed accordingly.

The author states that the writer advised contraction joints in buttresses and arches in 1924. This is not quite correct, since the writer advised consideration of "temporary" joints[17] and suitable construction methods.

Recently, in connection with the design of two multiple-arch dams, the writer, in collaboration with other engineers, gave this question careful consideration. The consensus of opinion was, that it was better to reinforce the buttresses in an effort to prevent unsightly cracks, than to attempt to provide shrinkage joints, which would be likely to promote cracking in the general direction of the joint, unless they started at the deck and went entirely through to the foundation (see Fig. 11). Additional steel was placed near the groin line and parallel to it, in order to counteract the swelling-shrinkage effect already mentioned. In addition, it was agreed that the buttresses should be constructed as far ahead of the arches as possible, in order to give them a chance to shrink before the arches were poured.

Calvin V. Davis,[18] Assoc. M. Am. Soc. C. E. (by letter).—The author has made a valuable contribution to the art of dam design. This paper emphasizes the important principle that a dam is a series of elementary curved, inclined columns, each of which transmits part of the water pressure from the water-bearing surface through the structure to the foundation. This discussion will treat several phases of this principle, as developed by Mr. Schorer, and will also demonstrate that the same principle may be developed by the trial method of design.

In his "Synopsis", the author makes the following statement:

> "The theory is based on the conception of elementary arched column units which transmit the water pressure from their respective deck areas directly and in uniform compression to the ground, together with the accumulated dead load. The elementary column units can be combined to a monolithic buttress system in which the first principal stress is uniform compression throughout and the second principal stress is zero."

[17] *Loc. cit.*, p. 311, last paragraph.

[18] Chf. Designer, Ambursen Dam Co., New York, N. Y.

As the writer understands this, Mr. Schorer considers that if each of a series of inclined elementary columns were in equilibrium under their respective loading this same condition would apply when the columns were combined to form a monolithic buttress. In the writer's opinion the stress conditions in a buttress considered as a monolith will not be similar to the stress conditions in the elementary columns when they are considered independently. The elastic properties of each elementary column will have some relation to the elastic properties of each adjacent column and, consequently, in arriving at the stresses in the structure, the deformations in the buttress as a whole must be considered.

Buttresses are not ordinarily constructed as rectangular sections and their structural properties are materially influenced by combining haunch or monolithic deck areas with the buttress section. For instance, the monolithic deck shown in Mr. Schorer's design example (Fig. 11) will have the effect of moving the center of gravity of a horizontal buttress section in an up-stream direction. When the buttress is considered as a monolith the effect of this added up-stream area will be to increase the eccentricity of the resultant loading. If the inclined columns were designed so as to show zero second principal stress along the joints when considered independently and neglecting the monolithic action of the deck, the second principal stresses would be in tension down stream from the deck if the buttress were analyzed monolithically and the effect of the horizontal deck area were included in the computations. In the monolithic analysis the increased eccentricity would lower the vertical normal stresses in the up-stream portion of the buttress and this, in turn, would change the second principal stresses from a value of zero down stream of the deck to some value in tension. On the other hand, the second principal stress throughout the deck will be compression. The writer believes that the results obtained by considering the buttress as a monolith will be less favorable than those obtained by Mr. Schorer's method and, therefore, would be more conservative to use in buttress dam design.

The writer is in thorough agreement with Mr. Schorer in the statement that the greatest economy may be obtained through the use of a buttress dam in which the first principal stresses are of uniform intensity and approach the allowable value throughout the structure. The results of several years of research, however, have convinced the writer that the same structural properties, that is, uniform strength, zero second principal stress, etc., may be obtained in a buttress of triangular shape with approximately rectangular horizontal sections. These properties may be readily controlled through the proper selection of both the up-stream and down-stream buttress slopes and also through the use of pilasters on the down-stream face of the dam. The second principal stresses in the designs developed from the research already mentioned were relatively high values in compression and this property, in the writer's opinion, adds a substantial margin of safety to the structure. Failure to include the effect of possible second principal stress in compression or tension is perhaps the greatest objection to the use of Mr. Schorer's method, which gives results only with reservoir full. Under all other loadings the second principal stresses will be compression. The inclined joints will only be on trajectories of first principal stress with reservoir full, and with the reservoir partly filled light shearing stresses will be developed across these joints. The writer believes it is important to determine these stresses and to provide keys in the joints or other means to take care of them in order that the monolithic character of the structure as a whole may be preserved.

For the reasons outlined the writer prefers the trial method of design, even if its use is somewhat tedious and involves considerably more labor than Mr. Schorer's method. The trial method is general and may be applied to the analysis of any type of dam. It is understood, of course, that it must be carried far enough to determine completely the principal stresses and their directions and also the shearing stresses in all parts of the structure. It is no longer adequate, as Mr. Schorer points out, to base a design on the determination of vertical normal stresses alone, as the second principal stresses may have high values in tension with the trapezoid of vertical normal stress entirely in compression.

FIG. 19.

In applying the trial method the principal stresses and shearing stresses may be determined directly from the vertical normal stresses by means of successive integrations. The writer believes that this procedure was first introduced in the United States by the late William Cain, M. Am. Soc. C. E., in 1909.[19] Mr. Jakobsen first showed the necessity for taking into consideration the principal stresses in a multiple-arch dam.[3]

Figs. 18 to 23 illustrate the application of the trial method of analysis to the design of a typical high dam of the gravity type; and at the same time they illustrate the development of the inclined column principle. The computations were not carried out for the upper half of the structure, but were carried far enough to illustrate the points raised in this discussion. No uplift pressure was assumed in making these computations. It is essential, of course, to consider uplift pressure in gravity dam design. However, these pressures are more important in considering sliding and overturning than stress intensity and distribution. It is possible that uplift pressures may vary from zero to 100% of the full static head at the heel and, of course, any assumption of this kind may give fictitious values. Inasmuch as the principal stresses may have maximum values with no uplift pressures, this assumption was used.

FIG. 21.—PRINCIPAL STRESSES.

Fig. 18 shows the vertical pressures on horizontal planes as obtained by the well-known law of the trapezoid. By taking the algebraic sum of all vertical stresses acting on elementary prisms, shearing forces on these prisms may be obtained, and from these may be obtained shearing stress intensities, as shown on Fig. 19. The same procedure may be followed in determining horizontal forces on elementary prisms and from these may be obtained the horizontal normal stresses shown on Fig. 20. The necessary elements are now at hand for determining the principal stresses and their directions. These may be obtained from either the principal stress equations, or by the more convenient method of using Mohr's circle. Fig. 21 shows the intensity of the first and second principal stresses; Fig. 22 shows curves of equal principal stress intensity; and Fig. 23 shows the trajectories of the first and second principal stresses.

It will be observed that the directions of the principal stresses follow definite mathematical laws and form regular curves which are normal to the up-stream face of the dam and asymptotic to the down-stream face. This calls attention again to the fact that the dam is a series of curved, inclined columns, each transmitting part of the water pressure from the up-stream face to the foundation. The curvature, of course, represents the weight influence of the masonry. These illustrations also serve to show the uneconomical use of material in a gravity dam design. Maximum principal stresses and maximum shearing stresses are attained only at the down-stream face. In a dam of the buttress type it is possible to keep all these values uniform throughout any horizontal plane and thus make the most efficient use of the material. The difference in cost of the buttress type and the gravity type of dams represents, after all, the difference in the value of the material required for stabilizing purposes for the gravity dam. In the gravity dam dependence is placed on the weight of material in the structure alone to attain stability. This means an unsatisfactory stress distribution. In the buttress type, stability is obtained through the use of an inclined up-stream face which introduces heavy stabilizing water loads on the structure. This allows an economical use of material in the structure and makes possible the attainment of satisfactory stress distribution.

Direction of First Principal Stress
Direction of Second Principal Stress

FIG. 23.

A. A. EREMIN,[20] ASSOC. M. AM. SOC. C. E. (by letter).—The author has developed a new method of designing buttresses in which first principal stress compression is uniform and second principal stress is zero.

The present method of computing principal stresses is based on assumptions which have numerous limitations. The lines of uniform principal stresses in a buttress vary, due to changes in temperature, shrinkage of concrete, and lateral stiffness of the buttress. Professor Otto Mohr[21] has stated that in ten dams the stresses will be different regardless of the fact that they may be constructed under similar conditions.

---

[20] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.

[21] "Die Staumauern," by Dr. N. Kelen, p. 85.

Principal stresses in buttresses are commonly computed with the assumption that the normal stresses in the transverse section vary linearly. Therefore, the deformations in a buttress must obey the principle expressed by Navier, that transverse plane sections will remain plane after loading and in Hooke's law, that strain is proportioned to stress or that the modulus of elasticity of material is constant at all stresses.

The modulus of elasticity of concrete is variable. However, in sections with all compressive stresses, the error from using a constant modulus of elasticity is negligible, as was also stated by the writer in another discussion.[22]

A number of experimental tests with model walls was made in order to prove Navier's principle in the transverse sections of concrete gravity walls or buttresses. Maurice Lévy[23] investigated a wedge-shaped wall with water pressure on one side, and stated that the measured deformations are in close agreement with the Navier principle. However, a small deviation was noticed when a vertical load was applied at the crown of the wall. Later, Mr. J. H. Mitchell and Dr. Fillunger[23] confirmed the statement made by Lévy, and, furthermore, they found a departure from the Navier principle in the lower sections of a model wall (Fig. 24), if a horizontal force or a moment is applied at the crest. Karl Wolf[23] has stated that Lévy's conclusions are correct for walls well keyed into solid rock foundations. For his tests he used a model of a wall with its vertical face on the water side and the down-stream side inclined at 45°, and his investigations are based on St. Venant's theory.

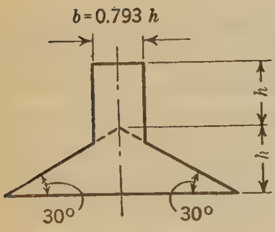

FIG. 24.

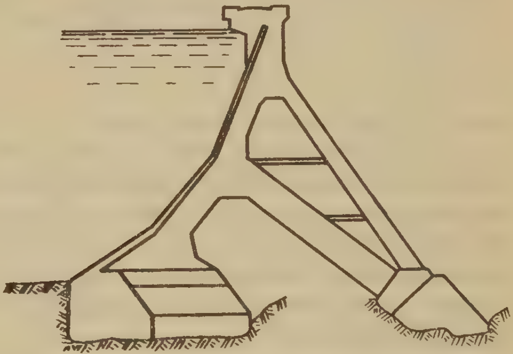

FIG. 25.—SECTION OF BUTTRESS USED BY DR. ROSSIN.

Experimental tests have proved also that shear stress in a transverse section of a buttress does not follow a linear distribution.[23] Thus far, however, all experimental tests to determine the distribution of stresses in gravity dams or buttresses have been performed with small-sized models and their results may be in error when applied to the massive sections used at the present time.

Involved mathematical analyses of buttress sections based on an uncertain distribution of stresses may be worthless unless a more precise method of stress computation is discovered.

[22] *Transactions,* Am. Soc. C. E., Vol. 95 (1931), p. 679.

[23] "Die Staumauern," by Dr. N. Kelen.

The author has properly indicated the advantages of the buttress composed of the elementary arched columns; however, the following factors should be considered in the design of the arched columns:

1.—If the deck is monolithic and separated from the arched columns by a frictionless joint, as shown in Figs. 4 and 5, secondary stresses in the deck will occur due to unequal settlement of the columns or to a variable change in the temperature of the buttress.

2.—A rock foundation is seldom homogeneous or isotropic and, therefore, a deformation of the foundation should be considered in any precise design of buttresses.

3.—If the elementary deck strips are monolithic with the arched columns there will be reaction forces along the center line of the deck strips where these strips touch each other (Figs. 5 and 6). These forces will vary with the swelling effect of the deck due to the moisture in the concrete, and with the temperature variation in the deck, and the result will be bending stresses in the arch columns, and eccentricity of pressures in the foundations.

The idea of a unit system of buttresses was used by Dr. Rossin[24] (see Fig. 25). This buttress is more economical than a monolithic buttress and the stresses in the members of the frame may be determined with reasonable precision by the method of least work or any other design method applied to the rigid frame.

The height of Dr. Rossin's buttress may be increased by using the hollow type of columns or by columns stiffened with counterforts or struts.

For the advancement of knowledge concerning buttress design, experimental tests on stress distribution on a large scale are needed. This paper is a meritorious contribution to the advancement of the theory, and the application of the author's new design methods to actual practice is highly desirable.

Eugene Kalman,[25] M. Am. Soc. C. E. (by letter).—Although the writer cannot agree with all the conclusions drawn by Mr. Schorer, he considers this paper a valuable contribution to the study of dam design. The ordinary buttress shape defined by two more or less parallel planes has been discarded and replaced by a more complicated form. The choice of that form constitutes a remarkably ingenious effort, and it proves that sometimes by making structures more complicated it is possible to simplify their analysis, due to the special shape.

Arch Column Unit.—The author's analysis is rather difficult to understand, and it will be useful, therefore, to review some of the underlying principles briefly. In Fig. 1 the two loads, P_0 and P_1, acting on the upper and lower section of the arch column, are necessarily the closing sides of the string polygon formed by the axis of the column, the intermediate forces being represented by the weights of the single elements in the column. Since all those weights are acting vertically downward, the force polygon will have the shape illustrated in Fig. 26(*b*). The vectors, $O\,B$ and $O\,D$, represent the magnitude and direction of the end loads, P_0 and P_1. The vector, $O\,C$, represents the resultant acting at a point along the axis of the column at which the tangent to the axis is parallel to $O\,C$, as shown in Fig. 26(*a*).

---

[24] "Die Staumauern," by Dr. N. Kelen, p. 264.

[25] Visiting Prof. of Civ. Eng., California Inst. of Technology, Pasadena, Calif.

First, the shape of the column axis must be known and, therefore, its equation must be determined. This may be accomplished by equating the inclinations of an arbitrary intermediate force in the funicular polygon and in the force polygon. Let ϵ and η denote the co-ordinates of the column axis. Then, the slope of the force, P, in Fig. 26(*a*), may be expressed by,

$$\tan \phi = -\frac{d\eta}{d\varepsilon} \quad \text{.......................} (38)$$

On the other hand, the inclination of $O\,C$ is expressed as follows:

$$\tan \phi = \frac{A\,C}{O\,A} = \frac{A\,B + B\,C}{O\,A} \quad \text{..................} (39)$$

Since $B\,C$ is the total weight of the column between the points of application of P_0 and P, its value will be given by the sum,

$$w = \gamma_c \int_{\varepsilon_0}^{\varepsilon} w\,t\,ds \quad \text{........................} (40)$$

in which, w, t, and ds are the width, the thickness, and the elementary arch length of the column, respectively, at an arbitrary point on the axis.

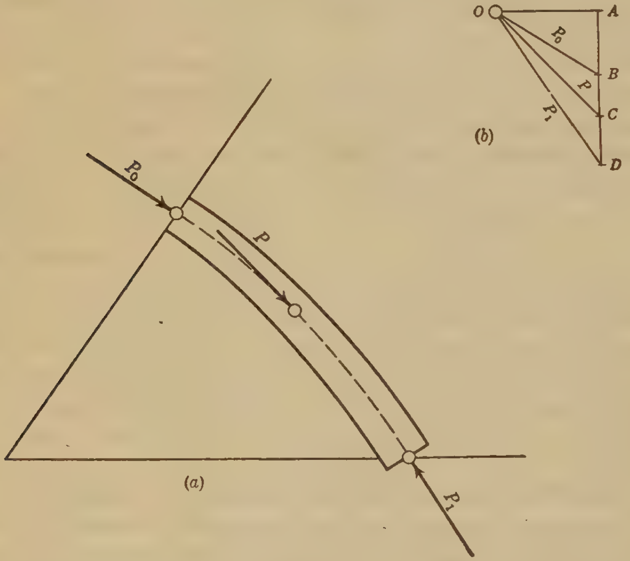

FIG. 26

The values of $O\,A$ and $A\,B$ are determined by the magnitude and direction of the upper end load, P_0, and hence from Equations (38) and (40),

$$\frac{P_0 \sin \phi_0 + \gamma_c \int_{\varepsilon_0}^{\varepsilon} w\,t\,ds}{P_0 \cos \phi_0} = -\frac{d\eta}{d\varepsilon} \quad \text{................} (41)$$

Equation (41) expresses one of the two fundamental relations of the problem.

The other follows from the specification of a constant unit compressive stress, f_c, at all sections of the column. That stress may be obtained by dividing the force, P, by the area, $w\ t$, on which it is distributed. The magnitude of P can be evaluated from Fig. 26(*b*) as follows:

$$P = O\ A \sec\phi = P_0 \cos\phi_0 \sec\phi \dots\dots\dots\dots\dots (42)$$

from which the second fundamental relation is,

$$\frac{P_0 \cos\phi_0 \sec\phi}{w\ t} = f_c \dots\dots\dots\dots\dots\dots\dots\dots (43)$$

In order to obtain the equation of the axis, both sides of Equation (41) must be differentiated. This operation may be performed after the substitution of the arch element, *ds*, by $\sec\phi\ d\epsilon$, thus deriving the equation,

$$-\frac{d^2\eta}{d\ \varepsilon^2}\ \frac{P_0 \cos\ \phi_0}{\gamma_c} = w\ t \sec\phi \dots\dots\dots\dots\dots (44)$$

The product, $w\ t$, may be evaluated from Equation (43) for use in Equation (44), with the following result:

$$-\frac{d^2\eta}{d\ \varepsilon^2}\ \frac{P_0 \cos\phi_0}{\gamma_c} = \frac{P_0 \cos\phi_0 \sec^2\phi}{f_c} \dots\dots\dots\dots\dots (45)$$

and applying the well-known formula,

$$\sec^2\phi = 1 + \tan^2\phi = 1 + \left(\frac{d\eta}{d\varepsilon}\right)^2 \dots\dots\dots\dots\dots (46)$$

the ultimate form of Equation (45) will be:

$$c\,\frac{d^2\eta}{d\varepsilon^2} + \left(\frac{d\eta}{d\varepsilon}\right)^2 + 1 = 0 \dots\dots\dots\dots\dots\dots (47)$$

This is a differential equation of the second order, for which the following general solution applies:

$$\eta = c \log\cos\frac{\varepsilon + C_1}{c} + C_2 \dots\dots\dots\dots\dots\dots (48)$$

A simple substitution will show that Equation (48) is really an integral of Equation (47), in which, C_1 and C_2 are two arbitrary constants. Equation (48), expressing the curve of the column axis, indicates that two geometrical conditions may be imposed upon it, and, since the position of the upper end is always given, as well as the slope of the up-stream face which yields the first derivative of the catenary, the curves of Equation (48) are entirely determined. With the form of the up-stream face given, there is one, and only one, catenary that passes through each point of that curve. The buttress is, then, subdivided into a certain number of independent catenaries, for which the width, w, is known at every point. Consequently, Equation (43) enables the designer to select a thickness at every section of each independent column unit, such that the unit stress at any section will remain constant.

Multiple Column Buttress of Uniform Strength.—A structure is obtained by the foregoing method that represents an ideal buttress. At every section the stress is constant, provided the columns are not in contact with each other and the proper loads, P_0 and P_1, are applied at their upper and lower ends.

Obviously, this ideal structure cannot be duplicated in actual practice. In the first place, the independent column units cannot be built; and, in the second place, the practical buttress will have to rest on the foundation and not on a system of needles, such as P_1.

In constructing the buttress one column unit must be placed upon the other; and after the construction, when the reservoir is filled, the column units will undergo certain deformations. Will they act independently of each other? In a buttress built as a monolithic structure, will the trajectories follow the ideal catenary curves? The influence of the minor principle stress has a tendency to disturb the equilibrium of the individual column units. Will the effect of this tendency be negligible?

These are the questions that are raised by a study of the author's method and there is no satisfactory answer to them in his paper. Unfortunately, Mr. Schorer makes extensive use of a refined mathematical tool to analyze the case of a buttress subdivided into column units and to explain their statical behavior (which does not interest the designer very much). On the other hand he drops the theoretical considerations entirely in treating the reconstruction of the buttress from the column units and in explaining the statical behavior of the buttress (which is the only thing that really does interest the designer).

The author merely limits himself to a few generic remarks which are absolutely not convincing. He writes, for instance:

> "Since the buttress is subject mainly to direct stresses in one direction, the internal work must approach a possible minimum. From Castigliano's principle of least work it can then be concluded that the stress distribution in the monolithic buttress is very nearly the same as that in the multiple column buttress composed of independent arched column units."

The foregoing statement is nebulous and the writer has been entirely unable to interpret it. The paper does not state whether the foundation will re-act exactly or approximately in conformity with the load system, P_1, which was selected, without any consideration of the foundation. It is assumed that the catenaries are trajectories and that the minor principle stresses are negligible everywhere; but these assumption have not been proved by the author.

Comparison with the Principle of Linear Stress Distribution.—Since the paper does not include a quantitative analysis of the stresses in the proposed buttress, the most simple check at hand might be attempted, and that is to compare it with the principle of linear stress distribution at a horizontal section of the buttress.

In the case of a plane up-stream face, all catenaries are identical curves, since $\phi_0 = 0$. The lower catenaries are obtained from the uppermost one by a simple translation. This fact follows since that portion of the upper catenary unit lying to the right of any arbitrary section may be removed and the corresponding thrust, P, at that section may be substituted for it.

The only difference between the remaining portions of the highest catenary unit and the lower column units is that the upper end-points of the first are acted upon by the constant, P_0, while the load, P_0, acting on the upper ends of the lower column units will depend on the depth. This will involve a corresponding increase in the thickness in the lower columns in proportion to the depth of their upper end points. The derivation of the curve for the lower catenaries from the higher one by means of the foregoing system of translation is illustrated in Fig. 27. The slopes of the two catenaries, R and R', are equal. Consequently, the slope of the reaction at R' is obtained by drawing the tangent to the catenary, $S\,Q$, at the point, R. In this way the direction of the reaction at any point of the horizontal section under consideration may be determined.

Information concerning the distribution of vertical normal stresses on the horizontal section is lacking. The foregoing graphic procedure permits a designer to avoid the more cumbersome algebraic operations. The directions of the reactions, P_1, are now known and since the major principal stresses are assumed to be equal to a given f_c, the magnitude of the reactions, P_1, also, is known.

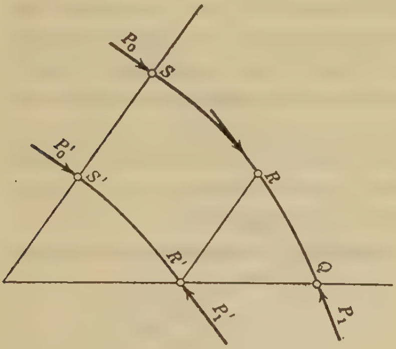

FIG. 27

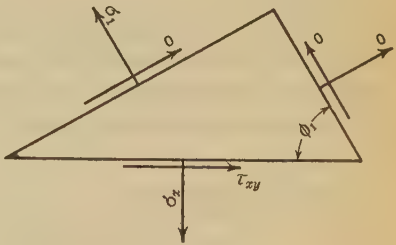

FIG. 28

The magnitudes of the vertical normal stresses at different points of the horizontal section may be evaluated with the assistance of Fig. 28, which represents the equilibrium of the stresses acting on an elementary prism. The catenaries are assumed to represent special trajectories without minor principal stresses. This means that the major principal stress is the only one acting on the two smaller sides of the prism, provided the smaller sides are parts of trajectories. In Fig. 28, note the vertical normal stress, σ_x, and the horizontal shearing stress, τ_{xy}. From the condition of equilibrium on the prism, the following equations may be written:

$$\sigma_x = f_c \sin^2 \phi_1 \quad \text{.........................(49)}$$

and,

$$\tau_{xy} = f_c \sin \phi_1 \cos \phi_1 = \frac{1}{2} f_c \sin 2\,\phi_1 \quad \text{..............(50)}$$

These values may be determined, since the angles, ϕ_1, at any point are known. They are plotted for illustration in Fig. 29(a) and Fig. 29(b).

The corresponding curves referring to the buttress with a vertical upstream face are particularly interesting. The tangent to all catenaries at the left end point of the horizontal sections will be horizontal. The value of ϕ_1 in Equations (49) and (50) is equal to 0. Consequently, both the vertical normal and the horizontal shearing stress will be equal to zero at the left end points of all horizontal sections, as indicated in the curve, Fig. 30(*a*) and Fig. 30(*b*).

It will be noticed that the stress distribution does not follow the trapezoidal rule. The diagrams are peculiar especially in the case of the vertical up-stream face. Engineers are inclined to accept the trapezoidal rule as a matter of fact, and they do not like to discard it unless its fallacy has been proved. Mr. Schorer, however, does not supply this deficiency, since he fails to prove that there is no shear and no minor principal stress along the catenaries. In fact, there are both normal and tangential loads acting on the sides of the five columns in Fig. 11. Furthermore, it is quite probable that the effect of the foundation is to create a still greater discrepancy between the actual stress distribution and that shown in Figs. 29 and 30, in which the buttress alone is considered. It is universally recognized that because of the influence of the foundation the trapezoidal rule does not hold in triangular dams. It is also known that considerable speculative and experimental effort has been directed toward an effort to determine the actual stress distribution in such a profile.[26] Nevertheless, no suggestion has yet been accepted for a change in the stress distribution different from that provided by the trapezoidal rule. The writer wonders whether the theory offered in this paper will be accepted, despite the fact that there is absolutely no proof of its validity.

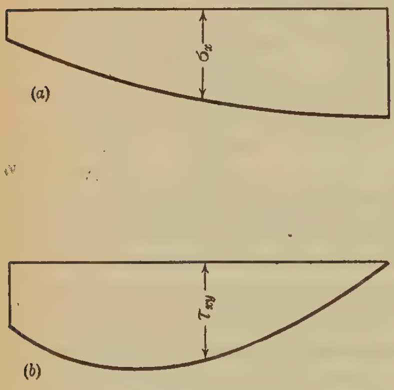

FIG. 29

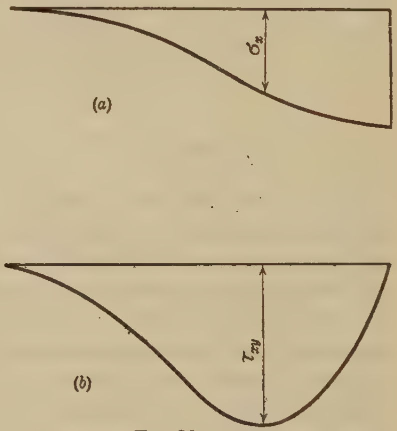

FIG. 30

The author states that his direct procedure makes it possible for a designer to proportion the entire buttress so that it will have a uniform strength; but engineers like to check the structures after they have been proportioned. How should one proceed to check the structure in this case? Should the buttress be treated as a column when it is monolithic? Decidedly, it is not a column. Should it be treated as a beam? If so, the trapezoidal rule should be applied to the individual sections, and the author is opposed to the application of this rule.

---

[26] See p. 489.

The buttress units might be treated as laminæ, approximately, but their complicated shapes introduce insurmountable difficulties to such treatment. It would be valuable if Mr. Schorer would suggest some way of checking the dimensions selected.

Design Example.—The design example illustrated in Fig. 11 contains nothing revolutionary. Its characteristic features are the subdivision of the buttress into five parts, a somewhat strange "neck", and a decrease in thickness from the up-stream face toward the down-stream face. It contains no sections of the shape indicated in Fig. 27. Of all the innovations only the back portion is new, which, by the way, is not a convincing innovation. A perfectly triangular profile of the same volume could supplant it without the least appreciable change in the statical conditions.

There are two construction features that should be discussed. The continuous plate, or slab, that covers the buttresses on the down-stream side is quite useful as a means of preventing buckling. However, its presence makes it impossible to inspect the buttresses and, in the writer's opinion, it should be removed entirely, or, at least, it should be confined to certain isolated parts of the dam. The same reasoning applies to the continuous slab at the inside face of the highest column unit. The prospect of removing these slabs directs attention to the general resisting conditions of the structure and especially to the column unit under consideration as applied to the possibility of buckling. The column unit is only 1.5 ft. thick, and its length is about 300 ft. Such a length would cause designers to worry even with stiffening cross-walls and even if the thickness were as much as 8 ft. at the bottom. By removing the cross-walls at alternate cells, the material thus saved could be used in proportioning the column unit with somewhat greater thickness. In the construction of dams, certainly, there is no room for quibbling over the addition or subtraction of every inch of concrete in place.

Another construction feature may be mentioned in connection with Section *X-X* of Fig. 11. Fig. 11(*i*) shows that the column units change abruptly in thickness from one to the other, while Fig. 11(*d*) shows that the horizontal section at the base has a uniform width. No section is given to show where the difference between Fig. 11(*d*) and Fig. 11(*i*) becomes compensated. The writer does not approve the arrangement in Fig. 11(*i*), Section *X-X*. From a purely theoretical point of view, abrupt changes are not justifiable, because any two hypothetical elementary column units in any of the five columns are subjected to different loads and, therefore, require different cross-sections. From a practical point of view, abrupt changes in thickness do more harm than good.

Conclusions.—A continuous rear slab is not a desirable feature in this kind of design. Furthermore, the shape of the "neck" at the level of 250 ft. is not essential and the abrupt change in thickness at the joints is a poor feature. The writer does not favor the introduction of joints in the design of recent dams for two reasons: First, they weaken the buttress from a structural point of view without making the statical conditions any clearer. Indeed, they make the conditions of static so complicated that they cannot be comprehended at all. The second reason for distrusting the use of joints is that they do not improve the conditions in the buttress in view of the hazards caused by shrinkage and temperature changes. A further remark may be added concerning the buttresses. They should not be made too slender near the down-stream face where the relatively great height of the column unit is most conducive to buckling.

As for the theoretical considerations in the paper, the author does not furnish any proof as to the validity of his theory for the monolithic buttress, or even for a definite number of columns resting on each other. The writer has established the fact that in monolithic buttresses the author's theory involves proving that the rule of the trapezoid is not valid. For this reason, the proposed method cannot be used for the final selection of the shape of the buttress. It is an excellent way to estimate, without much preliminary effort, an approximate shape for the buttress. It will be necessary, however, to analyze a certain number of horizontal sections by means of the trapezoidal rule. Although, admittedly, this rule is not correct it is to be preferred to any other stress distribution until the newer plan has been proved valid. Obviously, the process of analyzing horizontal sections by means of the trapezoidal rule will be extremely laborious by analytical methods, owing to the irregular change in thickness throughout the entire buttress. That is the disadvantage of this procedure in contrast to the alluring possibility of choosing, directly, the shape of the buttress by Mr. Schorer's method. A graphical method, however, can be easily found for the successive investigation of the single horizontal section by adopting and extending the well-known graphical application of the trapezoidal rule to the analysis of the single horizontal section in a gravity profile of general shape.

The author deserves considerable credit for having introduced the idea of elementary columns, even if it cannot be applied to monolithic buttresses. His method undoubtedly permits a direct selection of a primary, approximate buttress shape so that when the method is completed by means of a supplementary graphical investigation, as suggested in the foregoing remarks, it represents a positive progressive step in the design of dams.

A. FLORIS,[27] ESQ. (by letter).—It is well known that tensile stresses are produced in dams during the cooling period of the concrete. Furthermore, it is generally recognized that in triangular dam profiles near the foundation the stress distribution, due to water pressure and the weight of the dam, does not remain linear. To reduce the shrinkage in concrete dams to any considerable extent is scarcely possible at present, and the problem of determining stresses at the base of the dam produced by water pressure and the weight of the structure presents many mathematical difficulties that have not yet been overcome. For this reason attempts have been made to avoid these difficulties by introducing joints and thus allowing the concrete to contract, without cracking, along predetermined lines. The dam is then analyzed either approximately by considering these joints or by assuming that the structure is monolithic in spite of them.

---

[27] Civ. Engr., Los Angeles, Calif.

In the literature on dams the statement has been made repeatedly in recent years that inclined contraction joints should be located along the trajectories of the first principal normal stress caused by the water pressure and the load of the structure. These trajectories, on the other hand, are determined by means of the rule of the trapezoid and by assuming the dam to be monolithic. However, the introduction of such joints complicates the problem of stress distribution very much, because the boundary loads transmitted to the given column from the adjacent columns formed by the joints are not known.

One can be reasonably confident that in the near future the problem of determining the stress distribution in gravity dam profiles without joints, and which form a single unit with the foundation, will be solved. Then, the stress distribution in various types of monolithic buttresses will also be known within satisfactory limits. However, this cannot be expected in the case of dam profiles with joints.

Mr. Schorer states that from Castigliano's theorem of least work it can be concluded that the stress distribution in monolithic buttresses will be very nearly the same as that produced in the independent columns. Stresses can be found in prismatic bars (one-dimensional) by the use of Castigliano's theorem, but it cannot be applied to the stress distribution in gravity dam profiles (two-dimensional) and certainly not in the type of buttress suggested by Mr. Schorer, which varies in form even in the third dimension (three-dimensional).

The author has not proved that the catenaries of the independent arched columns will coincide with the trajectories of the first principal normal stress in a monolithic buttress. Furthermore, it is not correct to state that the first principal normal stress in a monolithic buttress will be equal to that produced in the structure with independent arched columns; nor is it correct to state that the second principal stress will vanish in a monolithic structure the same as it does in independent arched columns. It is not at all correct to maintain that the influence of shrinkage and temperature changes will be so great that the effect of the principal normal and shearing stresses, Poisson's ratio, etc., can be neglected.

The effort to discard the rule of the trapezoid in designing dams by introducing the arched column theory is not quite new. In addition to the fact that dams with inclined joints have been built in recent years, other writers before Mr. Schorer have treated the same subject. In studying failures of dams, Paul Ziegler came to the conclusion that a kind of arch action takes place in gravity and buttressed dams.[28] He points out that cracks produced in the remaining buttresses of the Gleno Dam which failed and also in other gravity dams, indicate that arches are probably formed in gravity and buttressed dams under stress. Such arches apparently have a horizontal abutment at the up-stream face while the other is resting either on rock in the lower part of the dam, or is carried in the upper parts of the profile by the lower arches as shown in Fig. 31. The author attempts to locate these arches and thus to determine the stresses in the dam graphically by using funicular polygons.

---

[28] "Volle Strebenmauer und Pfeiler-Strebenmauer," von Paul Ziegler, *Schweizerische Bauzeitung,* June 29, 1929, p. 315.

The method proposed by Fredrik Vogt, Assoc. M. Am. Soc. C. E., is exactly the same as that presented in this paper.[29] By dividing the buttress of a monolithic dam into a number of independent columns subjected to the load, p_0 (see Fig. 32), Dr. Vogt derives the following differential equation for the column axis:

$$\frac{d^2\,y}{dx^2} = q\left[1 + \left(\frac{dy}{dx}\right)^2\right] \ldots\ldots\ldots\ldots\ldots\ldots (51)$$

in which, $q = \frac{\gamma_w}{\sigma}$, γ_w = the water pressure, and σ = the allowable compressive stress. Let $y = 0$, and let $\frac{dy}{dx} = \tan \alpha$; when $x = 0$, Equation (51) becomes:

$$y = \frac{1}{q} \log \frac{\cos \alpha_0}{\cos \alpha} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (52)$$

in which, $\alpha = \alpha_0 + q\,x$.

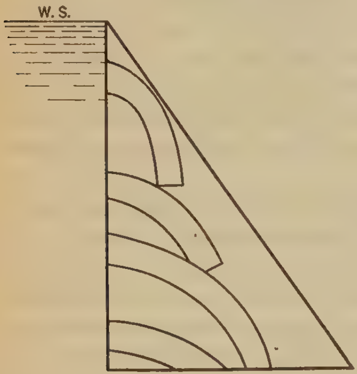

FIG. 31

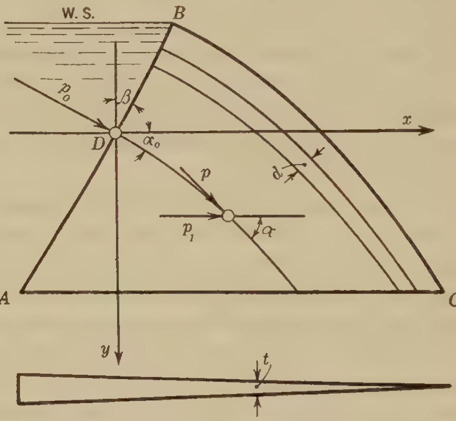

FIG. 32

The curve represented by Equation (52) is, as in the author's case, a catenary. Let the thickness equal,

$$t = \frac{A}{\alpha} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (53)$$

in which, $A = \frac{p}{\sigma} = \frac{p_1}{\sigma \cos \alpha}$, and p_1 = the constant horizontal component of p. By selecting the thickness of the columns properly, they may be designed so as to be subjected to the same compressive stress at every point. Because the width, d, of the columns decreases toward the base of the dam directly in proportion to the increasing pressure, p, to maintain uniform strength throughout, it is clear that the thickness of the column must be increased accordingly. Furthermore, by determining the minimum value for the expression of the sum of deck and buttress weights between two adjacent elevations, the following expression for the variable slope, β, of the up-stream curve, ADB, in Fig. 32, can be derived:

---

[29] Economical Design of Buttresses for High Dams and of Cellular Gravity Dams," by Fredrik Vogt, Det Kgl. Norske Videnskabers Selskab, Trondhjem, Norway, Forhandlinger, Bd. II, No. 40, p. 141.

$$c^2 F^2 z^4 + 2\,c\,(1 + c^2)\,F^2 z^3 + [(1 + 4\,c^2 + c^4)\,F^2 - 1]\,z^2 \\ + 2\,c\,F\;[(1 + c^2) - 1]\,z = (F - 1)\,(1 - c^2 F) \quad \text{..........} \; (54)$$

in which, $z = \sin\beta$, $F = e^{2qh}$, and c varies from 0 to 0.2. The constant, c, expresses the ratio of deck weight to water pressure, and in high multiple-arch dams it is approximately equal to 0.1. By solving Equation (54), with respect to z, the up-stream curve of the dam can be traced step by step.

The same procedure is followed by Mr. Schorer, and his proposed dam profile (see Fig. 10) is, therefore, necessarily the same as that presented by Dr. Vogt.

FREDRIK VOGT,[30] ASSOC. M. AM. SOC. C. E. (by letter).—The writer has studied this paper with the greatest interest, particularly because he has worked along the same line himself, and published a short paper on this subject in 1929.[29] It is gratifying to note that the general point of view is the same in both papers, and that even the formulas check each other to a great extent, except for differences in nomenclature.

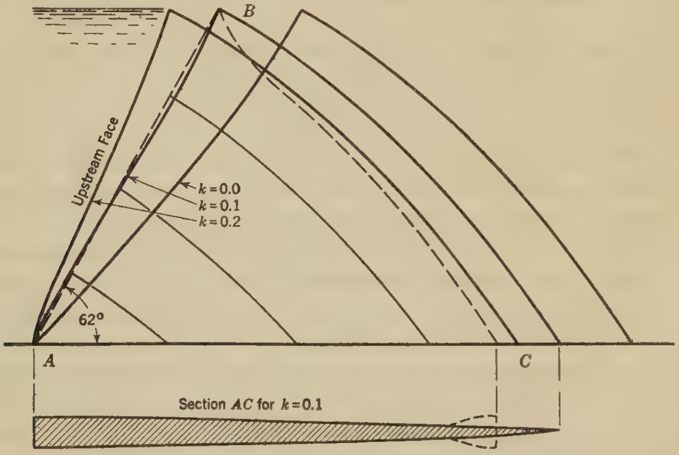

FIG. 33.—MOST ECONOMICAL SHAPE OF BUTTRESSES WITH DECK FACTORS 0, 0.1, AND 0.2, AND BUTTRESS RATIO, $\phi = 0.5$.

The writer has not much to add, therefore, except to state that theoretically the most economical shape of buttresses approaches very close to that of a straight-faced dam when the cost of the arches is included in the analysis. Fig. 10 gives this shape for a deck factor, 0, defined by Equation (22), that is, neglecting the cost of the arches. For actual dams the deck factor averages 0.1. Fig. 33, taken from the writer's paper, illustrates the shapes corresponding to deck factors 0, 0.1, and 0.2. It may be noted that a deck factor, 0.1, makes the up-stream face, determined in this way, steeper than if this factor were zero. Furthermore, the up-stream face is almost entirely straight if the deck factor is 0.1, or more. For practical design the writer, therefore, suggested a straight-faced dam as shown by the dotted lines. This shape has also been adopted by the author.

---

[30] Prof. of Mechanics, Norges Tekniske Höiskole, Trondhjem, Norway.

Dams with steep up-stream faces require a minimum amount of concrete, but the sliding factor computed for horizontal joints does not satisfy the usual standards. Therefore, the saving in concrete work can only be effected if sliding is prevented by cutting large steps in the rock foundation approximately normal to the lines of thrust for each of the columns into which the buttress is divided. Furthermore, if sliding is to be prevented in this manner, the rock foundation should be perfectly sound.

A. C. SCHWAGER,[31] ESQ. (by letter).—The strict solution of a problem, that has been sought since the beginning of modern dam design, is presented by the author. The writer proposes to analyze the mathematical parts of this paper without regard to the construction aspect described by Mr. Schorer. The method may be outlined concisely, as follows:

> (1) The design specifies that only compression stresses, constant throughout any buttress, shall exist. Therefore, each hypothetical column in a buttress may be assumed to be a unit, and its equilibrium can be investigated independently of adjacent column units in the buttress.
>
> (2) An infinitely small element is selected and the differential equation resulting from its condition of equilibrium is set up.
>
> (3) These differential equations are integrated and are made to coincide with the boundary conditions.

Some engineers regard the foregoing procedure as if it were based entirely on abstract and scientific premises. The idea of stating the problem in terms of infinitesimally small volumes seems especially impractical to them. It appears much more natural to sketch an outline of a buttress, analyzing it and dissecting it in a manner that enables the practical engineer to visualize the action and interaction of forces and their variations. Repeated trial analyses show the direction to improvement, and as such trials are duplicated the confidence of the designer in the structure grows proportionately. At the various sections the occurrence of secondary stresses will be indicated, but their magnitude can be determined and, if that is small, such stresses are considered of relatively little importance.

Which of the foregoing two methods should be given preference? From a scientific standpoint there is no doubt of the extreme superiority of the method of exact integration. In the history of technical advancement the same situation has often been repeated. Electrical engineering was the first technical science to apply the exact principles brought over from the field of pure physics in the form of the Maxwell equations. It is scarcely conceivable that a power transmission line could be designed without them. A problem encountered in mechanical engineering is especially comparable to that of the author's buttress of uniform strength. When the development of steam turbines began to increase most rapidly, speeds advanced into a range previously unknown. As a consequence, the stresses in the disk wheels produced by their own centrifugal forces represented the major design problem.

---

[31] Oil Circuit-Breaker Design Engr., Pacific Elec. Mfg. Corporation, San Francisco, Calif.

Trial methods based on successive graphical solutions were inaccurate and time-consuming. A small proportion of the total weight, placed incorrectly, caused inefficiency and resulted in designs that were dangerous to life. It was De Laval and Stodola who introduced the requirement of constant radial and tangential stresses. They integrated the differential equations and obtained the disk of uniform strength. The resulting formulas have made it possible to eliminate all guesswork. They are considered definitely correct and have been accepted for several decades as the tools of every turbine designer.

In the case of the buttressed dam of uniform strength the same arguments apply as in that of the transmission line or the turbine wheel. The scientific analysis offers the only correct solution eliminating waste of materials and time. The success of Mr. Schorer's method of solution from a technical standpoint cannot be doubted, but it is just as important from a scientific standpoint, since once more it has proved the tremendous power that is available in this use of differential and integral mathematics. It is not possible to over-emphasize the fundamental importance of stating a problem in differential equations wherever possible as set up by the exact science, and of finding the integral effects applicable to the particular condition.

PAUL BAUMAN,[32] M. AM. SOC. C. E. (by letter).—The method of designing buttressed dams as proposed by the author is well adapted to the flat-slab type, because in that case his theory holds without modification. With a multiple-arch dam, a joint between the arch barrel and the face of the buttress would be required to make it directly applicable, which is not in accordance with standard practice. The greater the span of multiple-arch dams, the greater becomes the prominence of the arch over the buttress, both as to area and moment of inertia.

In a hoof dam, for example, with spans of 200 ft., or more, between buttresses, the principle of uniform strength would scarcely prove advantageous because the greater part of the dam is in the arches, which can only be designed, safely and economically, as such. The relative load taken by the buttresses of such a dam is materially smaller than with a flat-slab dam. Even with a flat-slab dam the safe height would probably be considerably less than the one based on the author's formulas, because of stresses due to elastic deformations of the arched column which, as far as the writer is aware, are not covered by the paper.

If a dam of considerable height is designed for full load, a uniform compression of the arched columns of maximum length does not necessarily take place even though the slab during the deformation may remain practically straight, as suggested by Mr. Schorer.

---

[32] Chf. Designer, Quinton, Code & Hill-Leeds & Barnard, Engrs., Consolidated, Los Angeles, Calif.

Less work is involved in shortening these arched columns by bending than by concentric pressure. To enable this the columns must shorten their average radius of curvature by bending toward the air side of the dam and by opening up the joints. The latter will take place due to eccentricity of the line of support, primarily caused by a restraining moment at the base due to deflection of the buttress. The maximum stresses thereby produced would be materially greater than those due to uniform pressure, but would not necessarily be critical since the basic, uniform pressure could be rather low even with a strictly economical design.

A further tendency toward eccentricity in the arched columns exists during partial load, provided they are designed for full load. The resulting stresses may again be greater than those for full load, and the factor of safety may be smaller for partial load than for full load. This may sound somewhat paradoxical, but similar conclusions may be drawn from the study of structures of entirely different types, such as a continuous beam over numerous supports, etc. If designed for uniform load only, the latter may promptly fail under partial load.

To establish the principal trajectories by the author's method is more satisfactory than to determine them from the stresses (horizontal plane), assumed to be linearly distributed because, even if their distribution is nearly linear, they are more or less in error, except for a flat-slab dam with triangular buttresses. From a practical standpoint, the elimination of friction from the joints of a buttressed dam of uniform strength would probably be the outstanding task.

I. M. Nelidov,[33] Assoc. M. Am. Soc. C. E. (by letter).—The author's method of proportioning the buttress with the aid of the catenary curves is a process opposite to that ordinarily used. Instead of assuming loading and dimensions of a buttress and expressing stresses as functions of co-ordinates (ultimately principal stresses), the principal stresses and loadings are assumed and dimensions of the buttress are expressed as their functions.

This process is applicable only to the cases in which the continuity of loading is assured, that is, when the water level is at the crest of the dam or higher. It is applicable only for the particular loading assumed, because only with this loading is the direction of the first principal stresses at the base coincident with that of tangents to the catenary, and only for this case is there no difference as to whether or not the elementary columns are fixed or hinged at the base. If the base is fixed then for any other loading the afore-mentioned tangents must remain unchanged.

The writer wished to investigate the difference between the stress distribution computed by the author's method and by the ordinary method, by taking moments of weights and loads about the center of gravity of the base, computing moments of inertia of the base, etc. For this purpose a buttress was selected, with the following data given: $D = 100$ ft., $b = 20$ ft., $k = 0.1$ (constant, although in actual practice k increases with v, causing a "hump" at the upper part of the buttress), $\gamma_w = 62.5$ lb. per cu. ft., $\gamma_c = 144$ lb. per cu. ft., $f_c = 250$ lb. per sq. in., and $\phi_0 = 30$ degrees.

---

[33] Senior Engr. of Hydr. Structure Design, State Dept. of Public Works, Sacramento, Calif.

With these data and notation in Fig. 34; $\phi_k = 34.71512°$, $\alpha = 2.15286°$, and $\dfrac{h}{h_v} = 0.97564$.

Furthermore, let $\dfrac{v - v_1}{2} = q$; then,

$$t = \frac{\gamma_w b h e^{2q} \sec^2 \phi_k}{f_c [\tan \phi'_0 \tan \phi' + 1]} \qquad (55)$$

$$x' = v \tan \phi'_0 + c\,(\phi' - \phi_k) \qquad (56)$$

and,

FIG. 35.

Taking moments about Point O (Fig. 34):

$$M_{co} = \gamma_w\; b\; h\; d\; v\; [v \tan \phi'_0 (\tan \phi' - \tan \phi_k) + c \tan \phi' (\phi' - \phi_k) - (v - v_1)] \qquad (58)$$

and,

$$\tan \phi' = \sqrt{e^{2q} \sec^2 \phi_k - 1}$$

In case $v_1 = 0$, then $\phi' = \phi_1$.

The stresses as computed by the catenary method are:

Vertical normal stress:

$$\sigma_y = f_c \sin^2 \phi' \qquad (59)$$

Horizontal normal stress:

$$\sigma_x = f_c \cos^2 \phi' \qquad (60)$$

and,

Shearing stress:

$$\sigma_x = f_c \sin \phi' \cos \phi' \qquad (61)$$

Due to the fact that the face of the buttress makes an angle, $\beta = \phi_k - \phi_0 + \alpha = 6.86845°$, with a plane normal to the catenary at that point there is very slight shearing stress at the face, $\tau = f_c \sin \beta \cos \beta = 29.7$ lb. per sq. in., the compressive normal stress being $\sigma = f_c \cos^2 \beta = 246.4$ lb. per sq. in.

Vertical normal stresses by the ordinary method were computed by the formula:

$$\sigma_y = \frac{\Sigma V}{A} \pm \frac{\Sigma M}{S} \quad \ldots\ldots (62)$$

The stresses at the up-stream face are:

$$\sigma_y = \frac{\Sigma V}{A} - \frac{\Sigma M}{S} \quad \ldots\ldots (63)$$

$$\tau_x = \tau - (\sigma_y - \sigma)\, n \quad \ldots\ldots (64)$$

$$\sigma_x = (\sigma_y - \sigma)\, n^2 - 2\, n\, \tau + \sigma \quad \ldots\ldots (65)$$

$$\sigma_1 = \frac{\sigma_x + \sigma_y}{2} + \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau^2_x} \quad \ldots\ldots (66)$$

$$\sigma_2 = \frac{\sigma_x + \sigma_y}{2} - \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau^2_x} \quad \ldots\ldots (67)$$

$$\tau_{\text{max.}} = \sqrt{\left(\frac{\sigma_x - \sigma_y}{2}\right)^2 + \tau^2_x} \quad \ldots\ldots (68)$$

and,

$$\tan \theta = \frac{\tau_y}{\sigma_1 - \sigma_y} \quad \ldots\ldots (69)$$

in which, $n = \tan \phi'_0 = 0.52828$.

The stresses at the down-stream face are:

$$\sigma_y = \frac{\Sigma V}{A} + \frac{\Sigma M}{S} \quad \ldots\ldots (70)$$

$$\tau_x = m\, \sigma_y \quad \ldots\ldots (71)$$

$$\sigma_x = m\, \tau_x \quad \ldots\ldots (72)$$

$$\sigma_1 = \sigma_y (1 + m^2) \quad \ldots\ldots (73)$$

$$\sigma_2 = 0 \quad \ldots\ldots (74)$$

and,

$$\tau_{\text{max.}} = \frac{1}{2}\, \sigma_1$$

in which, $m = \cot \phi'$.

Analytical stress computations were checked by Mohr's circle as adapted by the writer to the general condition of stress as shown on Fig. 35. Table 1 shows that the two methods give essentially the same results, at least for the

FIG. 37.—DIAGRAM OF MAXIMUM SHEARING STRESSES, τ_{max}.

In conclusion, the writer wishes to mention that joints should not enter the problem until shrinkage and other structural items have been discussed because if the buttress is treated as an inelastic body the separate catenary columns will be in equilibrium regardless of whether or not they are joined together.

HERMAN SCHORER,[34] ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Girand properly calls attention to the factor of safety against overturning and suggests that two-thirds of the actual weight of the concrete be used for design purposes. This assumption evidently is identical in effect with that of using a normal unit weight for concrete, but a unit weight of water and a design stress, which are both 50% larger than the usual values.

Since the unit weight of concrete is not subject to changes, the latter assumptions would perhaps be somewhat more logical, because the unit weight of the impounded fluid may actually increase, due to gradual or sudden silting of the reservoir, depending on the character of the drainage area. According to Charles Terzaghi,[35] M. Am. Soc. C. E., the consolidation of mud deposits is an extremely slow process, so that the full fluid pressure may be exerted over a considerable period of time.

The French Commission, which reported on the third failure of the La Habra Dam,[36] which was of the gravity type, has estimated a fluid weight of 81 lb. per cu. ft. for the impounded mud and water caused by a sudden torrential flood.

Under such conditions, a higher compressive stress would be entirely justified on account of the increase in the compressive strength of concrete with age. It is much more important to avoid tensile stresses in the concrete and sliding of the buttresses under such extreme, but not impossible, load conditions. As pointed out by Mr. Girand, this large factor of safety can be obtained with comparatively small additional quantities, probably not exceeding 10% in most cases.

A conservative building code for dams, specifying a fluid weight of 90 lb. per cu. ft., a weight of concrete of 140 lb. per cu. ft., a principal compressive stress of 600 lb. per sq. in., no tension, and a maximum sliding factor of 0.70, would lead to an adequate design, consistent with the importance of such structures. Of course, the same specifications should apply to gravity dams.

The question, whether or not expansion joints are advisable, is mostly a matter of convenience and economy, a decision which also depends on the foundation conditions at each particular site. The fact that concrete is subject to volumetric changes due to shrinkage and temperature stresses must be recognized in the design. The joints may be omitted for dams of moderate height, supported throughout on solid bed-rock of uniform elastic properties, provided a liberal amount of reinforcing steel is used and the concrete is cured wet for at least 30 days. For higher dams, and in case of non-uniform foundation conditions, the provision of permanent joints has decided advantages, because large masses of concrete are thereby subdivided into convenient construction units, and the amount of reinforcing steel may be considerably reduced.

---

[34] Chf. Engr., Thebo, Starr & Anderton, Inc., San Francisco, Calif.

[35] "The Science of Foundations—Its Present and Future," by Charles Terzaghi, *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 278.

[36] "La Rupture du Barrage de L'Habra," *Le Génie Civil*, March 24, 1928, p. 283.

Mr. Girand suggests locating expansion joints, if any, in the direction of the second principal stress. Evidently, a joint so placed could not act as intended, because the first principal stress would prevent movement on account of friction. His proposed method of placing concrete would certainly be the ideal way. In case of a monolithic buttress most of the reinforcing steel should be placed in the direction of the second principal stress, as pointed out by Mr. Girand in Fig. 14.

Mr. Noetzli has evidently worked along similar lines in the design and, therefore, has come to fairly identical conclusions. The writer is aware of the fact that inclined joints have been used in several dams before this paper was published; but not, however, before the time of his original conception and formal presentation. This feature is inherent with the principle of self-supporting arched column units, where the columns may be built integral or adjacent to each other, and therefore, the writer does not hesitate to claim priority in this matter.

The joints shown by Mr. Noetzli in Fig. 15 and Fig. 16 stop a short distance below the deck, causing a local stress concentration, which could be eliminated by extending the joint through the deck. Mr. Noetzli mentions that in some cases the stress analysis indicated tension in the direction of the second principal stress which undoubtedly made it necessary to stop the joint below the deck and to provide extra steel reinforcement in the deck zone.

It is not sufficient that only the shearing stresses be zero along the plane of the joint; it is still more important that the normal stresses (second principal stress) should not be tension. Steel reinforcement cannot generally be relied upon to transmit tensile stresses to the foundation and a slight amount of compression in the direction of the second principal stress is, therefore, desirable.

With the ordinary buttress shape of rectangular horizontal cross-section and other arbitrary dimensions the elimination of tension is a rather difficult problem. This is especially true in case of a steep down-stream face combined with a steep up-stream face, as in the case of the Gleno Dam, analyzed by A. Stucky.[37]

Mr. Noetzli's Fig. 16 is very instructive because it indicates a fairly close agreement between the σ_x stresses, as derived from the arched columns and those computed for the monolithic buttress by means of the trapezoidal rule.

His comparison of the round-head buttress with the cantilever type of deck is interesting, but not convincing. The stresses in a disk-shaped member, such as Fig. 17(*a*), cannot be computed by the ordinary beam theory. The tests by E. Moersch[38] have shown conclusively the beneficial influence of the haunches on the reduction of the shearing stresses. For a more exact analysis, supported by photo-elastic stress measurements, the reader is referred to the work of Akira Miura.[39]

---

[37] "Der Talsperrenbruch im Val Gleno," by A. Stucky, *Schweizerische Bauzeitung*, Vol. 83 (1924), p. 74.

[38] "Der Eisenbetonbau," by E. Moersch, Vol. I, Second Half, Fifth Edition, pub. by Konrad Wittwer, Stuttgart, 1922, p. 197.

[39] "Spannungskurven in rechteckigen und keilförmigen Trägern," by Akira Miura, pub. by Julius Springer, Berlin, 1928.

The rounding of the up-stream face may have a favorable influence on the stress distribution, but the total saving in concrete, if any, will be small, because the yardage in the deck is a small percentage of the total yardage in the dam. Since the deck is a very vital part of the structure the writer would not advocate the omission of reinforcing steel in a deck of this type. It should be pointed out that the dead load stresses are not radial and the possibility of shrinkage and temperature cracks, as well as earthquake stresses, may lead to serious consequences in the case of a plain concrete deck. Since reinforcing steel should be provided in either case, the advantages of a straight cantilever deck in the ease of placing steel and form work are evident.

On account of his pioneer work in the analysis of principal stresses in multiple-arch dams,[40] Mr. Jakobsen is well qualified to appreciate the possible advantages of a direct design method. The result of his comparison in a practical case is gratifying and demonstrates the usefulness of the proposed principle.

As pointed out by Mr. Jakobsen, the arrangement shown in Fig. 5 introduces the possibility of an upward thrust on the deck. This uplift force should be combined with the other forces acting on the monolithic column head, as mentioned by the writer under the heading, "Design Example."

The writer thoroughly agrees with Mr. Jakobsen that inclined joints, if used at all, should be continuous through deck and buttress down to the foundation.

Mr. Davis prefers the use of a more laborious method, because in his opinion the results obtained by considering the buttress as a monolith will be less favorable than those obtained from the independent arch columns. If the adjacent arched columns were not designed for the same compressive stress throughout, then, the monolithic and independent stress system could not be identical. By computing an actual design example, Mr. Davis will convince himself that the results are almost identical with those obtained by the trapezoidal rule. In order to be consistent, the same assumption regarding the action between deck and buttress, either according to Fig. 4 or Fig. 5, must be made in both stress computations.

Mr. Davis correctly states that the method can only be applied for "reservoir full." For lower reservoir levels the principal stress system must necessarily be different. Perhaps he overlooks the fact that the proposed principle is not a stress analysis method, but only a means to dimension the structure directly for the most dangerous case of loading under given design assumptions. If several possible load conditions could produce maximum or minimum stresses of the same order, then, such a direct method could not give the desired result.

In the design of dams there are generally only two important cases of loading, namely "reservoir full" and "reservoir empty." In gravity dams, both these load conditions produce maximum and minimum stresses of the same order. In arch dams and buttressed dams, however, the most dangerous load condition is found with reservoir full, so that a structure dimensioned for this case will generally be safe under all other load conditions. In no case, however, should the designer neglect to investigate other conditions of loading, even if they are apparently safe. The analysis by means of the trapezoidal rule will be sufficient for such cases.

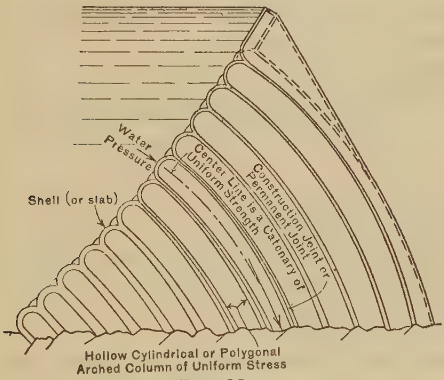
---

[40] "Stresses in Multiple-Arch Dams," by B. F. Jakobsen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 276.

Mr. Eremin points out the possibility of secondary deck stresses due to unequal column deformations. If the deck is separated from the monolithic buttress by means of a continuous joint, as shown in Fig. 4, then the buttress can only deform as a whole. Since the deck is comparatively much more flexible than the stiff buttress, it is evident that the secondary deck stresses are small, but their magnitude may be determined from the buttress deformation.

The writer agrees with Mr. Eremin that the arrangement of Fig. 4 (independent deck) should not be combined with independent column units because the relative deformation of the individual column units may introduce high local deck stresses near the column corners. With the arrangement of Fig. 5 the possible interaction between individual deck strips can practically be eliminated by providing a plastic filler in the deck joint area.

Mr. Eremin points out that the foundation deformations should be considered in an exact design of the buttress. These deformations may be estimated according to the methods proposed[41] by Fredrik Vogt, Assoc. M. Am. Soc. C. E.



Water Pressure
Shell (or slab)
Center Line is a Catenary of Uniform Strength
Construction Joint or Permanent Joint
Hollow Cylindrical or Polygonal Arched Column of Uniform Stress

FIG. 38.

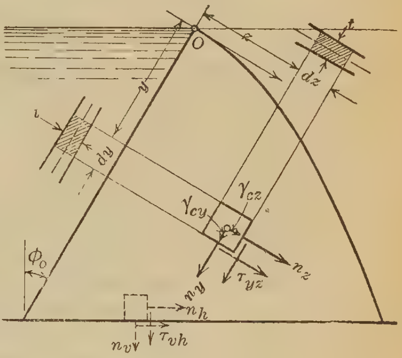


FIG. 39.

Mr. Eremin's suggestion to increase the possible height of Dr. Rossin's buttress type by the use of hollow columns, is interesting. Fig. 38 shows the adaptation of the arched column principle to a tentative design with reinforced hollow column sections. The construction of Dr. Rossin's type, or a type similar to that of Fig. 38, is economical in locations where cheap skilled labor is available in connection with comparatively expensive material.

Professor Kalman's able discussion is based mostly on theoretical considerations and, therefore, can be answered only on that basis. For this purpose it will be necessary to introduce the fundamental relations of the theory of elasticity, as applied to structures of this type, with the usual assumptions made for the elastic properties of the material.

---

[41] *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 554.

Under the heading "Comparison with the Principle of Linear Stress Distribution," Professor Kalman states:

> "Should the buttress be treated as a column when it is monolithic? Decidedly, it is not a column. Should it be treated as a beam? If so, the trapezoidal rule should be applied to the individual sections, and the author is opposed to the application of this rule."

The buttress is neither a column nor a beam, but it is a three-dimensional elastic body. Since one dimension is small compared to the other dimensions it may be defined as a disk of variable thickness, symmetrical about its middle plane. This disk, in contrast to a plate or slab, is assumed to be loaded by forces acting in the direction of the middle plane only. If the thickness is comparatively small, then the stresses in the direction normal to the middle plane can be neglected, resulting in a two-dimensional, or plane (not necessarily straight-line) stress system, as defined by Föppl.[42]

With reference to Fig. 39, the following definitions are introduced:

O = origin of co-ordinate system.
y, z = co-ordinates of a small element, dy, dz.
t = thickness of buttress, given as a function of y and z.
n_y = normal unit stress on small element, acting in the direction, y (tension positive).
n_z = normal unit stress on small element, acting in the direction, z (tension positive).
τ_{yz} = unit shearing stress acting on disk element, in the direction, y and z, respectively (positive as shown).
n_v = vertical, normal unit stress.
n_h = horizontal, normal unit stress.
τ_{vh} = unit shearing stress in a vertical and horizontal plane, respectively.
n_1 = first principal stress.
n_2 = second principal stress.
s_y = normal stress component in the direction, y.
s_z = normal stress component in the direction, z.
q = shearing stress component, in the direction, y and z, respectively.
γ_{cy} = unit weight component, in the direction, y.
γ_{cz} = unit weight component, in the direction, z.
$\nabla^2 () = \frac{\partial^2()}{\partial y^2} + \frac{\partial^2()}{\partial z^2}$, the Laplace operator in the two-dimensional system, y, z.

For the purpose of the following analysis it will be most convenient to consider the stress components, instead of the unit stresses, acting on a small element. The stress components are:

$$s_y = t\, n_y \qquad (75)$$

$$s_z = t\, n_z \qquad (76)$$

$$q = t\, \tau_{yz} \qquad (77)$$

---

[42] "Drang und Zwang," by August Föppl and Ludwig Föppl, Vol. I, Second Edition, pub. by R. Oldenbourg, Munich and Berlin, 1924, p. 244.

In order to maintain equilibrium on a small element the following well-known fundamental equations apply,

$$\frac{\partial s_y}{\partial y} + \frac{\partial q}{\partial z} + t\,\gamma_{cy} = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(78)$$

and,

$$\frac{\partial s_z}{\partial z} + \frac{\partial q}{\partial y} + t\,\gamma_{cz} = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(79)$$

As shown by Föppl,[43] the compatibility between stresses and deformations also requires compliance with the following equation,

$$\nabla^2 (n_y + n_z) = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(80)$$

or, expressed by the stress components,

$$\nabla^2 \left(\frac{s_y}{t} + \frac{s_z}{t} \right) = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots(81)$$

For a given load system and given buttress dimensions, the three unknowns, s_y, s_z, and q, must be determined by integration of the three simultaneous, differential Equations (78), (79), and (81).

Since t is expressed as a given function of y and z, a function, $T\ (y, z)$, may be determined by partial integration of t with respect to y and z, so that,

$$t = \frac{\partial^2 T}{\partial y\,\partial z} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(82)$$

The stress components can now be expressed as the second partial derivatives of a common stress function, $F\ (y, z)$, defined as follows:

$$s_y = \frac{\partial^2 F}{\partial z^2} - \frac{\partial T}{\partial z}\gamma_{cy} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(83)$$

$$s_z = \frac{\partial^2 F}{\partial y^2} - \frac{\partial T}{\partial y}\gamma_{cz} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(84)$$

and,

$$q = - \frac{\partial^2 F}{\partial y\,\partial z} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(85)$$

By substituting Equations (82), (83), (84), and (85) for s_y, s_z, q, and t, in Equations (78) and (79), it may be seen that the equilibrium equations are satisfied.

The compatibility Equation (81) then becomes, by substituting s_y and s_z from Equations (83) and (84),

$$\nabla^2 \left(\frac{1}{t}\frac{\partial^2 F}{\partial y^2} + \frac{1}{t}\frac{\partial^2 F}{\partial z^2} - \frac{1}{t}\frac{\partial T}{\partial y}\gamma_{cz} - \frac{1}{t}\frac{\partial T}{\partial z}\gamma_{cy} \right) = 0 \ldots\ldots(86)$$

Equation (86) represents the general differential equation of the desired stress-function in the most general case of a buttress of variable thickness, subject to any external loads acting in the middle plane, and gravity action.

---

[43] "Drang und Zwang," by August and Ludwig Föppl, Vol. 1, Second Edition, 1924, pp. 247 and 326.

If the gravity action is neglected, then Equation (86) becomes,

$$\nabla^2\left(\frac{1}{t}\frac{\partial^2 F}{\partial y^2}+\frac{1}{t}\frac{\partial^2 F}{\partial z^2}\right)=0 \ldots\ldots\ldots\ldots\ldots(87)$$

Equation (87) is given by Föppl,[44] but the general integral is not known and, therefore, neither is that of Equation (86). For a disk of constant thickness (t constant), Equation (87) is reduced to the well-known differential equation for Airy's stress function,

$$\nabla^2\left(\frac{\partial^2 F}{\partial y^2}+\frac{\partial^2 F}{\partial z^2}\right)=0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots(88)$$

or, written in the more common form,

$$\frac{\partial^4 F}{\partial y^4}+2\frac{\partial^4 F}{\partial y^2\,\partial z^2}+\frac{\partial^4 F}{\partial z^4}=0 \ldots\ldots\ldots\ldots\ldots(89)$$

The general integral of Equation (89) is a complex function, as given by Föppl,[45] but such a solution only applies to a buttress of constant thickness, or a slice of a gravity dam section, contained between two parallel vertical planes, normal to the up-stream face.

Any exact solution of the most general case must be based on Equation (86). For a given load system and given buttress dimensions there can exist only one stress function, which satisfies this differential equation and such a stress function then defines the exact stress system.

As pointed out by Professor Kalman, the proposed method of dimensioning a buttress of uniform strength results in a deviation from the trapezoidal rule, especially in the case of a vertical up-stream face. The following analysis, therefore, will be derived for a vertical up-stream face, in which case the maximum discrepancy from the exact solution can be expected. With $\phi_0 = 0$, and the designations of Fig. 39, from Equations (2), (4), and (10), in the case of a weightless deck, the thickness of the buttress at any point is defined by the equation,

$$t=\frac{b\,\gamma_w}{c\,\gamma_c}\left(y+c\log\cos\frac{z}{c}\right)\sec^2\frac{z}{c} \ldots\ldots\ldots\ldots\ldots(90)$$

The function, T, defined by Equation (82), is found by partial integration of Equation (90) with respect to y and z, which gives,

$$T=\frac{b\,c\,\gamma_w}{\gamma_c}\left[\tan\frac{z}{c}\left(1+\frac{y}{2\,c}+\log\cos\frac{z}{c}\right)-\frac{z}{c}\right]y \ldots\ldots(91)$$

For $\phi_0 = 0$, $\gamma_{cy} = \gamma_c$ and $\gamma_{cz} = 0$, therefore,

$$\frac{\partial T}{\partial y}\,\gamma_{cz} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(92)$$

and,

$$\frac{\partial T}{\partial z}\,\gamma_{cy}=b\,\gamma_w\left(\frac{y}{2\,c}+\log\cos\frac{z}{c}\right)y\sec^2\frac{z}{c} \ldots\ldots\ldots\ldots(93)$$

---

[44] "Drang und Zwang," Vol. I, Second Edition, 1924, p. 326.

[45] *Loc. cit.*, p. 252.

The desired stress function, F, as given by the following equation has been found by trial:

$$F = -b\,\gamma_w\left[\frac{y^3}{6} + \frac{c\,y}{2}\left(y + c\log\cos\frac{z}{c}\right)\log\,\cos\frac{z}{c} + c\int\!\!\int \tan^2\frac{z}{c}\log\cos\frac{z}{c}\,dz\,dz\right] \quad\ldots\ldots\ldots\ldots\ldots\ldots(94)$$

With reference to Equations (83), (84), (85), (92), and (93), the following values of the stress components are obtained from Equation (94),

$$s_y = -\,b\,\gamma_w\left(y + c\log\cos\frac{z}{c}\right)\tan^2\frac{z}{c} \quad\ldots\ldots\ldots\ldots\ldots(95)$$

$$s_z = -\,b\,\gamma_w\left(y + c\log\cos\frac{z}{c}\right) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(96)$$

and,

$$q = -\,b\,\gamma_w\left(y + c\log\cos\frac{z}{c}\right)\tan\,\frac{z}{c} \quad\ldots\ldots\ldots\ldots\ldots(97)$$

At the up-stream face, with $z = 0$, the stress components give the following values,

$$s_y = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(98)$$

$$s_z = -\,b\,\gamma_w y \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(99)$$

$$q = 0 \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(100)$$

These boundary conditions evidently correspond to a buttress of unlimited height, with the water level at the origin, O, of the co-ordinate system, as shown in Fig. 39, and a weightless deck of the width, b.

With reference to Equations (75), (76), (77), (90), and c from Equation (1), the unit stresses at any point of the buttress become,

$$n_y = \frac{s_y}{t} = -\,f_c\sin^2\frac{z}{c} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(101)$$

$$n_z = \frac{s_z}{t} = -\,f_c\cos^2\frac{z}{c} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(102)$$

and,

$$\tau_{yz} = \frac{q}{t} = -\,f_c\sin\frac{z}{c}\,\cos\frac{z}{c} \quad\ldots\ldots\ldots\ldots\ldots(103)$$

The sum of the normal stresses at any point becomes, therefore,

$$n_y + n_z = -\,f_c\left(\sin^2\frac{z}{c} + \cos^2\frac{z}{c}\right) = -\,f_c \quad\ldots\ldots\ldots\ldots(104)$$

Substituting Equation (104) in the compatibility Equation (80), and considering that f_c is a constant,

$$\nabla^2(n_y + n_z) = \frac{\partial^2(-f_c)}{\partial y^2} + \frac{\partial^2(-f_c)}{\partial z^2} = 0 \quad\ldots\ldots\ldots\ldots(105)$$

Since the stress function, Equation (94), complies with the compatibility Equation (80), it also satisfies the differential Equation (86), as well as the equilibrium Equations (78) and (79) and, therefore, defines the actual stress system for the given buttress shape and the aforementioned boundary conditions.

From Equations (101), (102), and (103), the principal stresses, n_1 and n_2, at any point, are found from the well-known equations;

$$n_1 = \frac{n_y + n_z}{2} - \frac{1}{2}\sqrt{4\,\tau^2_{yz} + (n_y - n_z)^2} = -f_c \;\ldots\ldots\ldots (106)$$

and,

$$n_2 = \frac{n_y + n_z}{2} + \frac{1}{2}\sqrt{4\,\tau^2_{yz} + (n_y - n_z)^2} = 0 \;\ldots\ldots\ldots (107)$$

Designating the direction of the first principal stress by the angle, β, with the direction, z, then,

$$\beta = \frac{1}{2}\tan^{-1}\frac{2\,\tau_{yz}}{n_z - n_y} = \frac{z}{c} \;\ldots\ldots\ldots (108)$$

For a vertical up-stream face, from Equation (4),

$$\frac{z}{c} = \phi_1 \;\ldots\ldots\ldots (109)$$

Equation (109) indicates that the direction of the first principal stress at any point coincides with the direction of the tangent of the catenary of uniform strength through that point. Equation (106) shows that the first principal stress at any point is constant, compression, and equal to the design stress, f_c. Equation (107) shows that the second principal stress is zero at any point.

From the foregoing derivations it must be concluded, therefore, that the buttress dimensioned according to Equation (90) actually gives the exact solution for the buttress of uniform strength in the case of unlimited height, vertical up-stream face, weightless deck, and full reservoir.

A similar solution also can be derived in case of a buttress of unlimited height, the up-stream face of which is inclined at the angle, ϕ_0, to the vertical, and the thickness at any point defined by the equation,

$$t = \frac{b\,\gamma_w \cos\phi_0\, y}{f_c} \;\ldots\ldots\ldots (110)$$

The shape of such a buttress is similar to that of the upper part of Fig. 2, consisting of a triangular up-stream face, triangular horizontal cross-sections, and a straight down-stream face, normal to the plane of the up-stream face. The proposed method gives such a shape in case the unit weight of the concrete is assumed to be zero and the corresponding stress function is,

$$F = -\,b\,\gamma_w \cos\phi_0 \frac{y^3}{6} \;\ldots\ldots\ldots (111)$$

The unit stresses, by similar derivations as the preceding, are:

$$n_y = 0 \;\ldots\ldots\ldots (112)$$

$$n_z = -f_c \;\ldots\ldots\ldots (113)$$

$$\tau_{yz} = 0 \;\ldots\ldots\ldots (114)$$

Since the shearing stress is zero, the co-ordinate system, in this case, also defines the principal stress system, the first principal stress being constant at any point, and again equal to the design stress, f_c, the second principal stress being zero. Such a buttress, therefore, can be conceived as built up of straight, weightless columns, the axes of which are normal to the up-stream face. The vertical stresses in a horizontal section are also uniform and, in this case only, are identical with those obtained from the trapezoidal rule.

Since the proposed design principle represents the exact solution for the two most extreme cases it is logical to conclude that the same theory also applies to intermediate cases and, therefore, Professor Kalman's sweeping statement, to the effect that there is absolutely no proof of its validity, must be completely rejected.

With the designations of Fig. 39, the stresses in a horizontal section, from Equations (98), (99), (103), and (109), become,

$$n_v = -f_c \sin^2 \phi_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

$$n_h = -f_c \cos^2 \phi_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (116)$$

and,

$$\tau_{vh} = -f_c \sin \phi_1 \cos \phi_1 \ldots\ldots\ldots\ldots\ldots (117)$$

Equations (115) and (117) are identical with Professor Kalman's Equations (49) and (50). However, the writer is unable to check Professor Kalman's stress diagrams, Fig. 29 (*b*) and Fig. 30 (*b*), because the angle, ϕ_1, (see Fig. 1), can never assume a value of 90° and for this reason the shearing stresses, as computed from Equation (50), or Equation (117), can never become zero at the down-stream face.

Professor Kalman's general conclusions, based on these diagrams, are therefore misleading, especially also due to the fact that the assumptions of Figs. 29 and 30 are not clearly stated.

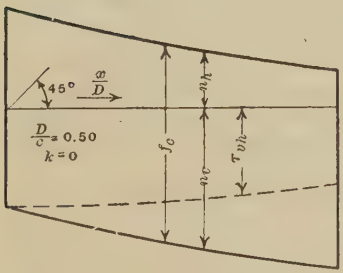

FIG. 40.

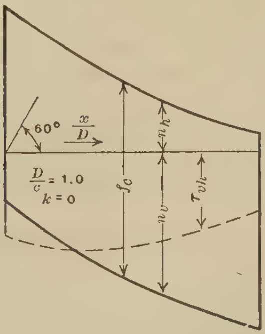

FIG. 41.

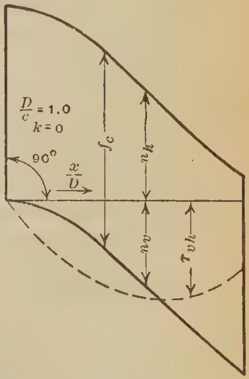

FIG. 42.

Fig. 40 shows the normal and shearing stresses in a horizontal section, based on a buttress with $\frac{D}{c} = 0.50$, $\phi_0 = 45°$, and $k = 0$. These conditions, except for the weightless deck, are typical within the ordinary practical range. The stress diagram indicates that, in this case, the assumption of the trapezoidal rule for the n_v stresses would give a satisfactory agreement with the actual stress conditions.

Fig. 41 is based on a buttress with $\frac{D}{c} = 1.0$, $\phi_c = 30°$, and $k = 0$, and represents approximately the conditions at the upper practical range, because an even steeper up-stream slope would generally give sliding factors that are too high. It will be noted that the deviation from the trapezoidal has increased. Although the discrepancy is not large, the shape of the n_v-stress diagram indicates that the trapezoidal rule would not necessarily give stresses on the safe side.

Fig. 42 illustrates the conditions in the case of a vertical up-stream face which is only of theoretical interest due to excessively high sliding factors combined with a waste of material. The trapezoidal rule would indicate a triangular n_v-stress diagram, which, in this case, is a rather poor approximation to the actual stress conditions.

Of course, the foregoing comparisons with the trapezoidal rule only apply to a buttress of uniform strength and do not permit any general conclusions for other buttress shapes, especially if such shapes deviate greatly from those obtained with the proposed design method.

However, these typical examples sufficiently demonstrate that in a reasonably economical design a fairly close agreement with the actual conditions can be expected from a principal stress system derived by means of the trapezoidal rule, provided the up-stream slope is not too steep. The satisfactory results obtained by Mr. Noetzli and Mr. Jakobsen seem to support this point. There is absolutely no objection to a comparison of the findings in this manner as long as the designer keeps in mind the fact that the trapezoidal rule is an assumption and that the actual stress system can only be determined by integration of the differential Equation (86).

Regarding the design example, Professor Kalman evidently overlooks the fact that Fig. 2 is based on zero deck weight, whereas Fig. 11 is not. Since he doubts the stability of the thin walls he is referred to the analytical treatments by G. H. Bryan,[46] S. Timoshenko,[47] H. M. Westergaard,[48] M. Am. Soc. C. E., and the tests by the U. S. Bureau of Standards.[49] For convenience of the designer the results of these investigations are shown diagrammatically in Fig. 43. The short sides are hinges in all these cases, except No. I, which is Euler's case. In Case III, the coefficient, $k = 2$, applies to the longitudinal stress, and T and $\frac{T}{2}$ are uniform loads, measured per unit length of the respective sides.

FIG. 43.—BUCKLING STRESS OF THIN PLATES: $F_{cr} = k \frac{\pi^2 E}{12} \left(\frac{t}{d}\right)^2$

Mr. Floris doubts that Castigliano's theorem can be applied to the stress distribution in gravity dam profiles and still less to a buttress type, as suggested in this paper, which is three-dimensional. Föppl[50] has shown conclusively also that in a three-dimensional elastic body the actual stress system will produce the least amount of work. In fact, every elastic body has, of course, three dimensions and the definition of one-dimensional, or two-dimensional stress systems only serves to introduce permissible simplifications in the analysis when certain dimensions are comparatively small.

Since the general Equation (86) defines the actual stress system, it also conforms to the principle of least work and so do Equations (94) and (111) in the special case of a buttress of uniform strength.

The writer is aware of the fact that other authors have treated the same subject before this paper was published. In connection with Paul Ziegler's work, however, it should be noted that the writer's paper was first submitted March 12, 1929. The arched columns proposed by Mr. Ziegler, as illustrated by Fig. 31, appear to be a rather crude solution of the problem, because they intersect each other, a condition which gives an entirely impossible principal stress system, as shown for instance by Mr. Davis in Fig. 23.

The writer is very gratified to find that Professor Vogt, in treating the same subject quite independently, has evidently arrived at the same equations in the case of the buttress of absolute minimum weight. Since the conclusions reached by Professor Vogt are almost identical in every respect there remains nothing to be added.

Mr. Schwager points out the progress made in mechanical and electrical engineering by the application of exact mathematical analysis. With concrete as a construction material and a foundation with more or less irregular elastic properties even a theoretically correct solution becomes necessarily an approximation. However, the stress system obtained from exact analytical methods under ideal elastic conditions must always serve as the most reliable guide in a practical design.

---

[50] "Drang und Zwang," by August Föppl and Ludwig Föppl, Vol. I, Second Edition, 1924, p. 99.

The writer agrees with Mr. Bauman that the method requires some modifications when applied to the design of multiple-arch dams. A joint between the arch barrel and the face of the buttress in case of a monolithic buttress, similar to Fig. 4, has actually been advocated by N. Kelen.[51] Although such construction is not in accordance with standard practice, there are certain advantages to be gained, but the total yardage in the dam will generally be larger than in the case of a monolithic connection between deck and buttress, as shown in the comparison of Figs. 4 and 5.

FIG. 44.

In order to apply the proposed method to a monolithically connected arch barrel it will be consistent to consider self-supporting arch elements of uniform strength, which are curved in two directions, as shown in Fig. 44.

---

[51] "Die Staumauern," by N. Kelen pub. by Julius Springer, Berlin, 1926, p. 171.

It follows then that in the case of long span arches a large proportion of the water pressure and the arch weight in the lower part of the deck will be transmitted directly to the foundation, similar to the arch ring action suggested by Professor Vogt.[52] Nevertheless, the yardage in the buttress proper will still exceed that of short span construction, on account of the additional dead load in the upper parts of the deck structure, which is transmitted through the buttress.

However, the exact solution of the multiple-arch dam is truly a three-dimensional problem, which, at present, can only be approximated by considering the arch barrel and the buttress as two separate, symmetrical, two-dimensional systems. In order to obtain coincidence of the deformations at the up-stream face of the buttress, it will then be necessary to apply equal and opposite, corrective reactions along this face, whereby a secondary stress system can be superimposed to the main stress systems in the arch-end buttress, respectively. The proposed method enables the designer to determine the main buttress deformation due to the shortening effect of the arched columns, as indicated in Fig. 1, Line FT'. In a more exact analysis the foundation deformations should also be taken into consideration in similar manner.

Mr. Bauman's statement that less work is required in shortening the arched columns by bending rather than concentric pressure, is not confirmed by the exact analysis, as derived in answer to Professor Kalman's discussion in case of a monolithic buttress. However, the writer agrees with Mr. Bauman regarding the possibility of eccentric column pressures due to partial loads in case of inclined joint construction. For this reason, a normal joint has been provided near the foundation in Fig. 11, containing a sheet-lead filler to allow slight plastic deformations and a redistribution of secondary stresses.

The elimination of friction in the inclined joints does not present any serious problem. With reservoir full there are no normal forces acting across the joint, and the columns can deform freely. With partial loads and reservoir empty there will be a normal component acting across the joint. However, with the usual up-stream slopes, the friction coefficient will seldom be less than 1.0, so that movement could still take place, even with reservoir empty.

Mr. Nelidov contributes a very desirable and instructive comparison of the buttress stresses as given by the proposed catenary method and those obtained by analyzing the same buttress by the ordinary method. According to Mr. Nelidov's Equation (62), the latter method is identical with the trapezoidal rule, commonly assumed to be valid for the vertical normal stress distribution in horizontal sections.

For the buttress investigated, with $\frac{D}{c} = 0.40$, $\phi_0 = 30°$, and $k = 0.10$, the agreement between the two methods is quite satisfactory, whereby the conclusions regarding the possible accuracy of the trapezoidal rule, in answer to

---

[52] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1288.

Professor Kalman's discussion, are further confirmed by Mr. Nelidov's careful analysis for the given case.

In conclusion, the writer wishes to express his sincere thanks to all those who have so freely discussed this paper. It is gratifying to note that the discussions have been constructive throughout, thereby contributing many important points not treated in the original paper.

RELOCATING LAND SURVEYS IN TEXAS[1]

By B. F. Williams,[2] M. Am. Soc. C. E.

With Discussion by Messrs. J. M. Howe, Arthur D. Kidder, and W. J. Powell.

Synopsis

This paper describes the problems encountered by engineers in Texas who are engaged in relocating old survey lines. The conflicting influence of Spain and England on the land laws are discussed, and the modern equivalents of old and obsolete units of measurement are given. The paper includes also an interesting anecdote concerning the monumenting of the 100th meridian.

The principal emphasis, however, is directed toward outlining some practical rules to govern the engineer on relocation surveys. Of what use to the surveyor is the evidence pertaining to annual rings of old trees? How is it possible to obtain direct evidence of the location of a timber line? How was the land cleared? The answers to these and other important questions are given in this paper.

Original Marks

It is a well fixed principle of law that in relocating surveys it is the duty of the surveyor to follow the boundary lines as laid on the ground in the original survey. "Move not the ancient land marks" is an old legal maxim given by Moses in Deuteronomy. Land boundary litigation has burdened the Civil Court dockets since the beginning of private ownership of the soil, and many wars between kings, princes, barons, and lords have been fought over disputed boundaries.

Indefiniteness in description and inaccuracy in laying down the original boundaries cause most of such litigation. As an example the following is cited from the archives of the Texas General Land Office:

> "In the same Town on the same day, month, and year that precedes, Don Juan de la Garza and Don Pedro de Salvana, the Surveyors, the former on the part of His Majesty and the latter on that of the Town, came into our presence and said: That in conformity with the Act made known to them on

[1] Presented at the meeting of the Surveying and Mapping Division, Dallas, Tex., April 25, 1929.

[2] State Reclamation Engr., Austin, Tex.

the third, they proceeded to mark out the boundaries assigned to the Town on the south, and using the cord composed of fifty Mexican varas recognised by the Commissioners present, they stretched the same one hundred times (beginning at the center of the Town) which make five thousand Mexican varas or one complete league, with which they arrived at the point known as La Cantera, which they marked out; with as many more they reached a vale with woods which are transitable and which is named the stopping place called Senor San Jose; with as many more to the gully at the foot of the hills of Los Quatitos and they dedicated it to our Senor of San Juan; with as many more to the stopping place called Agua-pas and dedicated it to our Lady of La Sotemano; with as many more to a hollow in front of Abra del Quemado which they dedicated to our Lady of Dolores; with as many more to the margin of the River Blanco which they dedicated to our Lady of Loreto, and they are the six leagues which in accordance with the order communicated to them they have surveyed and marked out, each league for itself on said course. And from said plain they returned to the Town and directing themselves to the North from its center they stretched the cord one hundred times and arrived at the Palitos Blancos and dedicated it to our Lady of Santa Ana; and with another hundred cords commencing on the other bank of the Rio Grande del Norte (for the reason that but a few varas remained between the said league and the river) they arrived at a hill which they dedicated to San Joachin and marked out the second league; with as many more to an opening in the hills (Abra) called El Yachupin which they dedicated to San Francisco de Borja; with as many more to the end of the said opening in the hills to the place called San Lorenzo; with as many more to the opening in the hills of San Yldepfonso which they dedicated to Santa Theresa de Jesus; and with as many more to a hill which is on one side of the stopping place called San Yldepfonso which they dedicated to La Santissima Trinidad, which six leagues they surveyed and marked out in the same manner as those above specified, always following the said course North. And this is what they did in compliance with their duties, and without having any thing to add, they signed with us and those of our assistance.=Palacio.=Lizos Ossino.=Juan Jph de la Garza Falcon.=Pedro Joseph Ygnacio de Salvana.=of Assistance, Duran.= of Assistance Federico Losada."

Such deficiencies as these are the causes of the greatest difficulties to the surveyor in making a relocation. The boundaries of a survey are usually a series of connected straight lines having given lengths and bearings, and designated natural or artificial objects, marks, and monuments; or they follow the meanderings of streams or divides of water-sheds. The natural marks are streams, mounds, hills, rocks, trees, etc. The artificial marks are crosses, blazes, hacks, drill holes, stakes, letters, figures, mounds, pits, a pile of buffalo bones, a cow's head, or other conventional signs and characters on standing timber, rocks, ledges, or on the ground. In order to retrace the lines of a survey it is necessary to have the description of the original boundaries made by the surveyor who laid them down. This description, called the field notes, is usually found in the archives of the General Land Office or in the records of deeds in the county where the property is situated. It is also necessary to know the laws, rules, regulations, and conditions under which the survey was made.

TEXAS LAWS

All early surveys in Texas were made under Spanish and Mexican laws and regulations. The territory within the present boundaries of the State—

under the discoveries of Columbus, the conquests of Cortez, and the explorations of Coronado, De Soto, and others—was claimed by Spain until the successful Mexican Revolution of 1821. This claim, however, was disputed by the French on the basis of La Salle's explorations in 1684. Therefore, the land laws of this State have been influenced by the Spanish and French laws, which have a common origin in the Roman Civil Law. After the Texas Revolution of 1836 the principles of the English Common Law took precedence over the Spanish and French influences, but the land titles granted by Spain and Mexico were recognized and ratified by the Republic and the State of Texas. Prior to the Texas Revolution, title to about 35 000 000 acres had been granted.[3] Texas was attached to and administered as part of the Mexican States of Coahuila and Tamaulipas from 1821 to 1836, when it became an independent republic. In 1845, it was admitted into the American Union of States. By a provision of the act of admission, Texas retained title to all her public vacant land, and the State has administered these lands chiefly for the benefit of railroad development and the endowment of a public educational system. The United States has never owned or administered the public lands of the State and, therefore, the Federal system of land surveys has never been adopted.

The Arabs and Moors who helped to develop the Spanish laws and customs, having established governments in the arid and semi-arid territories of Arabia, Northern Africa, and the Iberian Peninsula, impressed upon the Spanish law rules for laying out surveys of land, giving each tract or grant a front on a stream of permanent water wherever possible. The Spaniards followed this policy in North America.

The streams of the State of Texas all have a general southeasterly course; therefore, all Spanish and Mexican surveys make an angle with the meridian and seldom does the width northwest and southeast exceed one-half the length northeast and southwest; and the statutes now provide that in laying surveys along a stream they shall have a stream front of not more than one-half the square. Stephen F. Austin, impresario of one of the earliest colonies, in a letter of instruction to Elias Wightman, a surveyor, directs that surveys shall be laid along the streams, giving each a water-front, and if any land could not be covered, but should be left vacant, it would be on the prairies where the land had no value.

MEASURING UNITS

The Spanish and Mexican laws prescribed the units of land measurement and the methods of laying out surveys and of marking the lines and corners. The linear unit is the "vara" (in the Austin collection of documents frequently called "bar"), which is equal to 33⅓ in. and is defined as 3 "geometrical" ft.[4] or "pie". The term, "pie", is a Spanish unit of length, corresponding roughly to 1 ft. In Castile it compares with the Old Roman foot, as 923 is to 1 000.[5] The vara had different values at different dates and in different countries. For example, in Peru, it equals 33 in.; in Spain, 33.384 in.; in

---

[4] "Lamar Papers," edited by Harriet Smither, Vol. V, p. 129.

[5] See, Velazquez Spanish Dictionary.

Argentina, 34.092 in.; and in Portugal, 43.7007 in.[6] When the Americans began to make surveys in Texas, each surveyor had his own idea of the length of the vara. Stephen F. Austin[7] prescribed the length as 33⅓ English in. and this value has become the standard.[8] The geometric foot was generally used in the Sixteenth Century. DeMorgan[9] gives its value as 9.8 in. and Locke[9] as 10 in. The units of area are the square "pie", square vara, "labor", and "league" or "sitio". An English acre is equivalent to 5 645.376 sq. varas. A labor contains 1 000 000 sq. varas, or 177.13 acres. It is 1 000 varas square. The league is 5 000 varas square and contains 25 labors, or 4 428 acres. Many of the Spanish surveys contain a league and labor, or 26 labors, which is equal to 4 605 acres. Five leagues or sitios is a hacienda. In the theory of the Spanish laws and customs the labor is a farm, or an area upon which to labor and to produce crops. In contradistinction to the labor, a league is land upon which to conduct ranching and stock-raising operations.

It is also interesting to note a peculiar custom of ancient origin practiced in Latin countries in connection with granting and delivering land. The patent contains a certificate over the signature of the administrative officer that upon a certain date he took the grantee by the hand and led him around the land and pointed it out, and the grantee went upon the land and pulled herbs and threw stones and proclaimed in a loud voice that he was the owner of the said land. However, a similar custom was practiced by many ancient peoples.

In the Spanish laws, natural objects received preferential importance over artificial marks as monuments and witnesses to the boundaries in the specifications for laying out surveys, and, in numerous opinions, the State Courts have uniformly held that natural objects, other elements of the proof of the locations of the survey being equally certain, shall be given superior importance. In relocating surveys the Courts consider four elements in the following descending order of importance: Natural objects, such as rivers, creeks, mountains, etc.; artificial objects, such as marks on trees, marked lines, stakes, etc.; course and distance; and quantity. These rules are founded on reason, experience, and observation, and the surveyor must approach the problem of relocation with them well in mind, because he may be, and frequently is, required to defend the accuracy of his work before the Courts. While the surveyor must know the law, he has done his duty when he has found all the facts relating to the original boundary, relocated it upon the ground, and reported his findings of fact to his principal, or to the Court. In many cases he will be unable to harmonize the description of the original boundaries with the facts he finds on the ground.

Two cases will illustrate the point. A surveyor returned field notes to the General Land Office for 116 sections of land along the right bank of the Canadian River. His certificates state that the work was done on the ground, that the boundaries were marked by natural and artificial objects, and that he began at a definite point, and progressed toward the west giving each survey a river front of ½ mile. Each succeeding survey begins at the northwest corner of the preceding survey on the right bank of the Canadian River. In making a relocation on the ground it was found that one of these sections would cross the river twice, and a part of it, at its northwest corner, would lie on the left bank of the stream and all succeeding surveys in the series would lie on the left bank if joined to the northwest corner of the preceding survey.

[8] "Lamar Papers," edited by Harriet Smither, Vol. V, p. 129.

[9] Century Dictionary, under "Geometrical Foot."

During a lawsuit involving the location of some of the surveys in this series the surveyor testified that the only field work done was the taking of the few bearings on the course of the river, while an assistant kept watch at the top of the cliff to give warning of Indians. After taking these bearings on the course of the river and assuming that it continued indefinitely on the same course, he went into the safety of his office and wrote out the field notes. When asked why he did not make the surveys on the ground as certified, he said, "It would have taken a company of United States soldiers to have kept the Indians off of me while making these surveys, and the land was not worth it." In Fig. 1 the solid lines show the location as called for in the field notes; the dotted lines show the actual river with the surveyed tracts as they would lie in relation to it.[10]

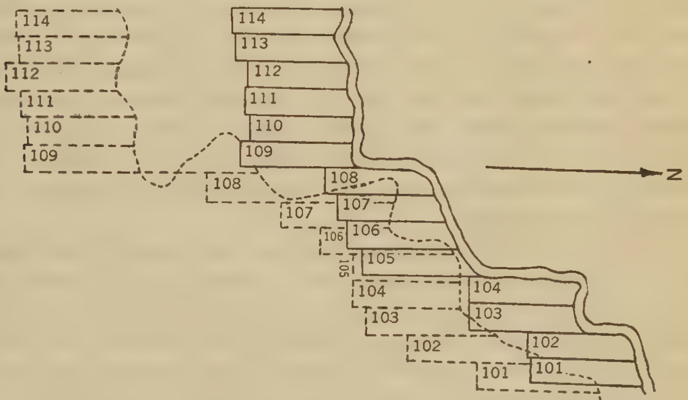

FIG. 1.—SECTION OF THE CANADIAN RIVER IN THE TEXAS PANHANDLE, SHOWING EFFECT OF INACCURACY IN OLD SURVEYS.

In 1886 or 1887, a district or county surveyor, in order to locate tracts of school land in the Panhandle, sold by the State, ran a connecting line from a monument on the 100th meridian west (at right angles to that meridian at the initial point) for 50 or 60 miles to the school surveys, and located the tracts in that manner. It is plain that he did not cross the next meridian at right angles, and his corners were located several hundred feet too far south. These corners conflicted with the adjoining alternate sections previously located and patented to a railroad company for constructing its lines, and the owners had the surveyor enjoined by Court proceedings. The result was that a settlement of various conflicting claims became necessary and by co-operation with the State a re-survey of all the railroad and alternate school sections in that part of the State was made.

[10] Sanborn *et al.* *v.* Gunter *et al.*, Southwestern Reporter, Vol. 20, p. 72.

It is interesting to note that the position of the initial monument on the 100th meridian, located by Jones and Brown in 1859, by observations of lunar culminations, when checked in 1892 by Messrs. H. S. and H. C. Pritchett and T. U. Taylor, M. Am. Soc. C. E., for C. A. Culberson, Attorney General of Texas, to secure evidence in the trial of a suit brought by the United States against Texas to recover the territory in Greer County, was found to be 3 797.3 ft. west of the 100th meridian. In 1929 a new monument was set in correct geodetic position by Mr. S. S. Gannett under the directions of a United States Supreme Court decision, and the true 100th meridian was run and monumented.[11] This adds a strip of territory about 134 miles long, about 880 ft. wide at its north end and 4 040 ft. wide at its south end, to the eastern edge of the Texas Panhandle, over which Oklahoma had theretofore exercised sovereignty. The Legislatures of the two States are now (1929) adjusting the civil affairs of this strip.

QUALIFICATIONS OF SURVEYOR

In making investigations of natural objects called for in a description of a boundary, the surveyor is confronted with problems in physiography, geology, and ecology. Stream channels change location by erosion, avulsion, and accretion. The Courts have laid down rules of law governing titles to lands affected by such changes, but the surveyor is not concerned with titles. It is his duty to lay down the lines on the identical location of the original boundaries. He must locate and identify ancient stream channels and terraces and determine their ages by strata formations, timber growth, and collateral facts. The writer has found river channels ¾ mile from their locations as recorded fifty years before.

The beds of all navigable streams in the State belong to the public. A statute of 1837 defines a navigable stream as being one with a mean width of 30 ft. or more, from its mouth throughout.[12] The statutes prescribing methods of laying out surveys prohibit crossing navigable streams. The effect is to leave such streams beds in the public domain. Many streams in Texas are dry throughout a great part of the year, but in wet seasons the wetted perimeters are several hundred feet long and the width between the cut banks of the freshet flows makes them navigable under this statutory definition. It appears that surveyors understood the definition of a navigable stream to mean a 30-ft. width of water and gave no importance to the width between the cut banks of the flush flow. These flashy streams are located in the arid or semi-arid regions, which at the time the surveys were made, were sparsely settled. The work was done under great difficulty of transportation and accessibility of supplies, and with great dangers from savage marauding Indians. It was usually done in the warm, dry season, and the surveyors in many instances found these streams dry. They located the surveys across the streams in violation of the statute, if it is assumed that the Congress of the Republic meant to prescribe a width between cut banks and without regard to the width of water. The Supreme Court of the United States, however, in the Texas-Oklahoma Boundary Case laid the common boundary between these States on the south cut bank of the Red River as located under the treaty of 1819 and as subsequently changed by erosion and accretion.[13] The surveyor is frequently called upon to locate the public lands in the stream beds of the State, and the work requires highly technical knowledge and skill. It is necessary to locate the original boundaries of the adjoining surveys and determine the changes made by the forces of the stream.

---

[11] See, Rept. of Samuel S. Gannett, Boundary Commr., Washington, D. C.

[12] Article 5302, Texas Rev. Civ. Statutes, 1925.

An investigation of artificial objects requires no less skill and experience. A fair knowledge of botany, plant anatomy and physiology, and ecology is required. Many efficient, capable, and skillful surveyors have no definite or organized knowledge of these sciences and probably have never heard or seen the names of some of them; they are students in them nevertheless. A little native wit and common sense, that is, sense about common things, supplies a great deficiency in knowledge of organized science. There is probably no technical branch of work that requires more common sense and self-reliance than surveying. Species, genera, habits, and methods of growth of trees must be known and ages of marks must be determined in many cases by inspection.

Identifying Survey Lines on Timber

Consider, for example, the importance of knowledge concerning annual rings on trees. The exogenæ, as the name of this great division of plants indicates, enlarge outwardly, each year's growth showing in cross-section as a ring. The cambium layer, which is next under the bark, is the only growing part. Since the inner wood does not change by growth, a mark put on it remains until destroyed by decay. Scar tissue is deposited in the matrix; the wound heals, but a scar will show on the bark for many years. Neither the character nor the age of the mark can always be determined by the scar on the bark, and it may be necessary to cut away the wood and count the annual rings back to that on which the mark was made. Marks sixty-five or seventy years old have been positively identified in this way. Often it is difficult to determine definitely the presence of a mark on a tree; the lateral enlargement of the trunk distorts it, and on an exposed side it may be more or less obliterated by disintegration of the bark; therefore, it may happen, and frequently does, that two competent and credible witnesses will disagree as to the presence of a mark.

The field notes describing a boundary usually give the sizes and genera of the trees called for, and sometimes they will include descriptions of timber lines and character of flora. While magnitude of size varies directly with magnitude of age, the surveyor must not assume that all large trees are very old or that all small trees are very young and, therefore, refuse to examine small trees for old marks. In 1920, in making a relocation, the writer found a cedar elm which was marked in 1842 as a witness to a corner. The locating surveyor gave the size as 6 in. in diameter. In 1920, the diameter was 8 in. On another occasion, a post oak, 3½ in. in diameter, was compared with a sweet gum, 18 in. in diameter. The oak had 52 annual rings, while the larger sweet gum had only 60 annual rings.

---

[13] State of Oklahoma *v.* State of Texas, U. S. Intervenor, U. S. Repts., Vol. 256, p. 70.

Often it becomes highly important to determine the locations of old timber lines on some of the early surveys. If the notes call for a timber line at a given distance from a corner, or for timber at the corners, and these locations are found in fields or on prairies, it is necessary to determine whether the conditions called for existed at these locations when the survey was made. To make the investigation pits are dug 2 or 3 ft. in the ground. By careful examination of the vertical banks of these pits the forms of tree roots can be traced by the presence of root bark or coloration of the earth long after all trace of the wood fiber of the roots has perished. Most hardwood trees have large tap roots, penetrating deep into the substratum of clay. These roots persist long after all surface traces of the trees are gone, and even after the roots have decayed completely, their forms can be easily traced by the residual humus and the surface soil washed and settled into their clay moulds.

The writer's experience indicates that the pioneer surveyors ran most of their lines long, and that the bearings vary on the ground considerably from those given in the field notes; but in making a relocation of an old survey, if the surveyor will use a light, open-sight compass with an ordinary Jacob staff he will have little difficulty in following the marked line.

DUTIES TO CLIENTS

A proper approach to a difficult relocation is very important. The surveyor is usually called in after a controversy has arisen to which his client is a party. The client expects the surveyor to find the facts in his favor, but the only interest the surveyor should have is in finding the facts. He should make his position clear to the contending parties and with the record before him approach the problem very much as a detective investigates the mysteries of a great crime. He should run down clues and test out theories until some one or more facts have been established. Then by applying the descriptive matter of the record, he should find corroborative facts and make out the complete case. He should observe the rules of legal evidence, because they are the results of experience from time so remote that the memory of Man "runneth not to the contrary." Hearsay testimony without corroborative facts cannot be accepted, except as clues.

When the investigation is finished, the surveyor must be certain of the results beyond a reasonable doubt. If he has found sufficient facts to justify it, he should relay the boundary on the location of the old one regardless of interests or conflicts. On the other hand, if the facts are not sufficient, he should not make a relocation, but should report to his client the conflicting evidence, giving the client the benefit of all clues, theories, and facts found during the investigation. Doubtful relocations and conflicting interests can be settled by agreements or adjudicated by the Courts.

CONCLUSION

In making relocations the surveyor must have a definite conception of his duty. If the field notes state that the original surveyor began at a definite point and ran the lines on given bearings for given distances; that he marked certain objects and monuments at the initial, terminal, and intermediate points; and if those objects can be found on the ground and can be identified by the marks, the lines joining them fix the original boundary regardless of course, distance, or quantity of land. Therefore, it is the duty of the surveyor to find and identify the objects called for and lay the relocated boundary on the ground accordingly. The surveyor is employed to find and report the facts. His duties do not require him to become an advocate of his principal, but it is his privilege and duty to defend the facts set out in his report.

DISCUSSION

J. M. Howe,[14] M. Am. Soc. C. E.—Texas land-line location is so interwoven with Texas land law that the surveyor or engineer who depends upon the rules of the U. S. General Land Office will soon be completely lost. Some one has said that "land surveying is an art and not a science", and if this applies anywhere, it certainly does in Texas.

The earliest surveys were so placed as to give riparian rights and formed a border along the principal streams with their back lines serrated so as to be roughly parallel to the course of the stream. The later surveys, to fill the unappropriated areas, tie into the riparian grants and make the land map look like an old-fashioned crazy quilt. As the early work was poorly done, with corners and lines inadequately marked, or frequently not marked at all, the fill-in work often laps over or fails to reach the earlier lines. When the first surveys were made the land had values of less than $1 per acre, and scarcely more than that for the later fill-in tracts. In consequence, chaining was carelessly done and courses were only approximate.

The Texas law requires that precedence be given to senior surveys, and many of the conflicts in title are due to failure or inability of the later surveyors to identify the earlier lines. Theoretically, the surveyor should be able to re-locate them by giving the senior surveys their distances and thus retrace the entire map structure on the ground; but original monuments, when identified, hold precedence over both course and distance. Therefore, regardless of the recorded length of lines, when junior surveys are in conflict, the junior must give way. When one appreciates that the early surveyors were working for the grantee and not for the sovereignty of the soil, he can readily understand that many of the early grants have lines on the ground considerably longer than the distances called for in the patent, and it is these lines that hold and not the ones called for in the field notes.

Unfortunately, one has to contend not only with uncertainty of distance, but also with uncertainty of course. North in Texas is seldom true north. The early surveyors, or at least most of them, knew that the magnetic needle had a declination, but their ideas were at considerable variance as to what allowance to make. Not infrequently one will find well identified original lines of surveys in the same county, each calling for the same course, but put in by different surveyors and varying by as much as 5° from each other. When the work of different surveyors comes together, the result is what a facetious judge once termed the "Texas rectangle", which he defined as a "rectangular parallelogram, no two sides of which are the same length and no angle of which is a right angle". As far as the speaker knows, no attempt was ever made to allow for earth curvature, and the change in length between meridians due to curvature has to be absorbed in errors in course or distance. This, however, is a minor matter, as the errors in execution of the work are sufficient to make curvature corrections negligible.

---

[14] Cons. Engr. (Howe & Wise), Houston, Tex.

In his closing paragraph the author states that the duty of the surveyor is to find and report the facts, and that his duties do not require him to become an advocate. This is true if he is working for the State or qualifying as a witness, but when he is employed by a land owner, his employer expects to be shown the outline of his property and the surveyor is supposed to have sufficient skill to determine these lines. The land owner wants to know the number of acres to which he has title, and what lines he can sustain on the ground.

The surveyor, therefore, must have a working knowledge of the essentials of Texas land law. He must decide in the field, without legal advice, whether he should follow a well marked, and apparently well recognized, crooked line or connect the two corners with a straight line. When calls are inconsistent with measurements on the ground, he must know which calls he should change. Where fencing is found, he must know what weight to give to it as fixing the line, and this involves an acquaintanceship with the 3, 5, and 10-year limitation laws and the decisions interpreting them. His success as a surveyor depends upon his ability to place the lines so that they will be sustained in Court.

ARTHUR D. KIDDER,[15] M. AM. SOC. C. E. (by letter).—The important observations to be noted in this paper are the great need for durable survey monuments, for a complete field-note record of the surveys, and for experience in the work. The need is present both with reference to the establishment of the original boundaries and sub-divisions, and in making retracements of lines for restoration of lost corners and other purposes.

It is made plain that the official survey and plat are the means constituted by law for the identification and description of the public lands of the State of Texas as well as within the Federal domain. The locations are controlled by the established original monuments, and the difficulties of the surveying procedure greatly increase when the monuments disappear. The difficulties become complicated in the event of unexpected discrepancies between the field-note record and the evidence of the survey to be found upon the ground.

The author has not overstressed the need for extended experience in meeting the practical questions which are to be dealt with, the scope of which could only be outlined, and it is presumed to be obvious that a good technical training is requisite, as well as broad field experience. The specialized character of the surveyed work described, may well be emphasized; similar conditions, with their attendant problems in making restorations, are encountered in other localities.

W. J. POWELL,[16] M. AM. SOC. C. E. (by letter).—Little has been written, outside of transcripts of Court proceedings, concerning the surveying of land in Texas. Therefore, this paper is of great value to engineers in this State. When it was admitted to the Union the State of Texas retained all its public domain, and the Federal system of surveys has never been established. Probably this is due to the difficulty of co-ordinating that system, or, for that matter, any other system of surveys, with the old Spanish, Mexican, and Republic of Texas land grants which are discussed by Mr. Williams. Nor is it easy to determine to what extent, if any, the Federal Land Laws affect surveys in Texas. In fact, it is difficult to learn the laws governing such surveys because published information on the subject is difficult to obtain.

---

[15] Assoc. Superv. of Surveys, Gen. Land Office, Interior Dept., Washington, D. C.
[16] Cons. and City Planning Engr. (Wood & Powell), Dallas, Tex.

The principles stated by Mr. Williams, of course, have general application in all parts of the State, but some of the methods discussed in the paper have no such general application. For example, it would be quite difficult to retrace an old survey line by the marking of the timber, or to determine the age of a witness tree by counting its rings, in vast areas in the western part of the State where the trees are scarcely large enough to afford shade to a jack-rabbit. Furthermore, in that region the usual problem is not solved when the original survey lines have been retraced because there still remains the important and sometimes very difficult work of reconstructing the surveys based on the original survey lines, which are often only random lines run across a large group of surveys.

The author has shown, in a most interesting manner, the vagueness in the descriptions of many of the old land grants of former Governments. In such cases it is frequently impossible to retrace or determine the original boundaries of the grants, and the only way of settling disputes in regard to them is by agreement and compromise or by lawsuit. By far the greatest portion of the public domain of Texas, however, was disposed of and surveyed during a later period, when education and transportation were the crying needs of the State. During the three decades following the Civil War large grants of land were made to the public schools and also to railroad companies to encourage the building of railroads in the State.

The school lands were usually granted in solid blocks varying in size and shape. Many of them were not surveyed at all, but were delineated by "paper field notes," filed in the General Land Office of the State. In the case of the railroads the State issued certificates or scrip to the railroad company on the basis of 16 sections, containing 640 acres each, for each mile of track built in the State, and to provide for such grants "reservations" were set aside within which the railroad company could locate its lands and apply the certificates. Under the laws in force at that time the railroad companies were required to survey the lands. For fear the companies would take up all the good land, all the water, and all the mineral prospects, the State required that they take alternate surveys and, in surveying the land, to return field notes for two sections; the odd numbered ones for the railroad company and the even numbered ones for the State. This resulted in a checker-board arrangement.

In one of these large grants it is interesting to note the manner in which the regulations were met. When the work was started a number of surveying parties were put in the field and for a time all section lines were actually run out on the ground. Somewhat later a system of surveys consisting of blocks, 6 miles wide and 8 miles long, was developed, and the surveyors ran out the block lines. Later, and farther West, they ran out every other block line, and, finally, contented themselves with running a line across a large group of blocks; in some cases, no lines were run at all.

The methods used by these early surveyors were crude and the difficulties under which they worked, were severe. The land was beyond the frontier and the survey parties were usually accompanied by small military escorts to protect them from Indians. There were no roads and transportation was by wagon and team. Water and forage were scarce, and the country was sometimes a sandy, barren plain and at others rugged mountain topography. A light compass (without vernier), a Jacob staff, and a 10-vara chain sometimes constituted the surveying equipment. Under such circumstances it is surprising that they got as good results as they did; but, at best, the work was inaccurate, and many conflicts and vacancies have developed. Excess is almost universally found in these old surveys. The lines were not run straight, and the brush was not cut; and it is said that it was the practice of many of the old surveyors to add a chain at every "out" to allow for the shortcomings of the chaining.

The law requires that a re-survey shall follow as nearly as possible in the footsteps of the original surveyor. If the original surveyor left marks on the ground that can be found and identified by bearings or witnesses, this requirement can be complied with; and if he actually ran all the boundaries of a survey and set corners that can be re-established beyond reasonable doubt, the problem of the re-survey is solved at once. If, however, he ran only one boundary line, or only a random line across a group of surveys, and protracted the other lines, where are his footsteps on the lines that he did not run on the ground?

Many surveyors hold to the theory that the variation actually used by the original surveyor should be determined and, with that variation, the other lines of the survey should be run on the bearings called for in the original field notes. This theory is all right for small tracts, but in surveys covering large areas where the curvature of the earth becomes a considerable factor it is likely to produce incorrect results.

In a specific case, the original surveyor started at the northeast corner of a group of surveys which is two blocks (16 miles) wide north and south, and ten blocks (60 miles) long east and west. The north lines of these blocks are supposed to lie in the Thirty-Second Parallel of Latitude. The surveyor ran a zigzag line, following the valley of a stream from east to west through this group of surveys. His field notes call for the lines to be north and south and east and west. His corners, as found on the ground, are sometimes north, sometimes south, of their correct positions, so that no two corners could be accepted as determining his actual east-west lines, and since he apparently neglected to correct his variation from time to time, a general average of his corners does not give a true east-west line. The approved construction in this case is as follows: Where two or more corners are found on a line they determine that line between them; all other lines are meridians and parallels passing through the controlling corners. This sounds simple, but working it out on the ground is no small job.

Such problems as this are frequently encountered in the western part of the State. Many surveyors still apparently believe that the earth is square, and some weird results have been obtained.

FLOW OF WATER IN TIDAL CANALS[1]

By Earl I. Brown,[2] M. Am. Soc. C. E.

With Discussion by Messrs. R. L. Faris, G. T. Rude, Eugene E. Halmos, W. M. Black, H. F. Flynn, Ralph G. Davis, and Earl I. Brown.

Synopsis

The passage of the ocean tidal wave before the mouth of an estuary, river, or inlet sets up therein a derived wave, which is propagated into the mouth in accordance with certain laws not yet clearly understood by engineers. The simplest example of a channel in which a derived wave may be propagated is a canal of uniform width and depth. This paper is devoted to a consideration and further study of the phenomena resulting from the propagation of derived waves in inland channels.

The derived wave is considered to be a wave of translation with successive alternating positive and negative phases, propagated in accordance with known laws. Proper allowances are made for the effects of friction on the bottom and sides of the channel. The problem is treated from the standpoint of the expenditure of the energy imparted to the derived wave by the generating wave in overcoming this friction.

The length, width, and depth of the canal have an effect in determining the rate at which this energy is expended. The conditions under which the derived wave is propagated are also modified by the character of the body of water with which the canal communicates at its farther end. Three cases are considered, namely, (*a*) a body of water at constant level; (*b*) a body of water with varying level, but with no proper tide of its own; that is, one that depends for its variation on the wave propagated through the canal; and (*c*) a body with varying level, but having a tide of its own derived from some source independent of the tide propagated through the canal.

Theoretical considerations are discussed, first, in order to enable fundamental conceptions to be established as to the mechanism of propagation, and as to the influence of width, depth, and canal outlet on propagation. These fundamental conceptions lead to the proposal of what may be termed the "Reflected Wave Theory" to account for the effect on the derived wave of the characteristics of the body of water at the outlet of the canal. This theory is believed

to be new; the writer has not heretofore encountered it in his researches in literature on tidal subjects.

As they usually exist, no canals are so long that friction will absorb all the energy of the derived wave. Therefore, the presence of the unexpended energy of the wave, when it arrives at the end, or the outlet, must be explained. According to the reflected wave theory this remaining energy is propagated back into the canal in the form of a reflected wave the energy of which is also subject to frictional losses; if the remaining energy is not entirely consumed in the course of the transit of the reflected wave, a second reflected wave is set up, and so on indefinitely until practically all the energy of the derived wave shall have been absorbed by friction within the limits of the canal.

If the canal outlet is restricted or closed, the reflected wave will be of the same sign with respect to height as the derived wave. If the outlet is wider than the width of the canal, it will be of the opposite sign.

These various waves, derived and reflected, exist simultaneously in the canal, and accordingly they will interfere at all points in accordance with the laws of the interference of simultaneous waves. The derived wave as actually observed in the channel is the resultant formed from this interference.

Wave energy is manifested both in the height of the wave above or below mean sea level and in the velocity of the water set up by the wave propagation. In the simple wave of translation, the height of the wave and the accompanying velocity of the water are roughly proportional. When two simple waves of translation interfere while being propagated in opposite directions, the heights will be added to form the resultant height, and the velocities will be subtracted to form the resultant velocity, since the two component velocities are traveling in opposite directions. Hence, in the resultant, the height and velocity are no longer proportional to each other.

While the longitudinal profile of the generating wave is not usually truly sinusoidal, it may be so considered without appreciable error; hence, the derived wave, including the resultant and all reflected waves, may be considered as sinusoidal. This approximation makes it unnecessary to compute the effect of friction in reducing each element of the derived wave, but only of the summit of the wave. All other elements follow from that by an application of the cosine law.

To apply this theory, an equation is first deduced by which the height of the wave summit, as reduced by friction, may be found for any point in the canal. An extension of this computation by the same formula gives the height at the selected point of as many reflected waves as have sufficient magnitude to warrant their consideration. The cosine law is applied to each of these with proper allowances for phase differences resulting from the various times required for each wave to be propagated from the entrance to the selected point, and the summation of these results gives the resulting wave height. A similar process gives the resulting velocity at the same point.

The method of applying the theory to canals of various characteristics is shown, and methods of determining the coefficient of friction for each case are indicated.

Lastly, the theory is tested by making the computations in accordance with it for certain known canals and then comparing the computed results with the results of observation.

DEFINITIONS

The term, "tide," relates to the rise and fall of the water due to the propagation of a derived wave.

The movement of a "simple wave of translation" causes a particle of water to remain permanently displaced in one direction or the other. This wave is usually referred to under the same "wave of translation", in which the height of the surface and the velocity of the water at a given point are approximately proportional.

A "compound" or "resultant wave of translation" is formed by the interference of two or more simultaneous simple waves of translation.

The "speed" of a wave is the rate at which its form is propagated. It is not to be confused with the velocity of the water.

"Mean sea level" is that at which the body of water in which the generating tide is propagated would stand if there were no tidal action in it. It is the plane of reference used herein.

"Mean canal", or "mean river level", is the mean of the high and low-water levels at any point.

The "depth" of the channel referred to herein is the reduced depth. It is the ratio of the area of cross-section referred to mean sea level to the mean width at the same level.

"High-water stand," or "low-water stand" refers to the instant at which the vertical tidal variation changes from rising to falling, or *vice versa.*

The "summit" of a wave is that element at its greatest rise or fall.

The "velocity" is the rate of motion of a particle of water acted on by a wave of translation. Velocity due to other causes is neglected in this study.

The "strength of the tide" is its maximum mean velocity.

"Slack water" refers to the instant at which the mean velocity in any cross-section is zero.

The "turn of the current" is the instant at which the current at any point changes direction. It usually occurs at or near the instant of slack water.

The "local tidal curve" expresses the relation between height of tide and time at any point in the canal.

The "instantaneous tidal curve" indicates the height of the tide at all points in the canal at a given instant.

The "geometric loci of high and low water" are the curves enveloping the local tidal curves.

The "local velocity curve" expresses the relation between the velocity and time at any point in the canal.

The "instantaneous velocity curve" indicates the velocity at all points in the canal at a given time.

The "geometric loci of slack waters" are the curves indicating the height of tide at which high or low-water slack occurs.

NOTATION

C = speed at which the wave is propagated; C' denotes the rate at which a wave is propagated between two given points.
c = time before the instant, $t = 0$, when the tide was at mean sea level; that is, when $t + c = 0$.
D = reduced depth of the canal.
d = difference in times between the arrival of high water at the ends of the canal.
E = energy of any unit length of a wave.
e = elevation of mean sea level corresponding to the staff reading, R.
F' = work done by frictional resistance.
F = friction per square foot of the water on the wetted surface of the bed of the canal.
f_0 = coefficient of friction depending on the nature of the bottom, the water depth, and the velocity of flow.
g = acceleration due to gravity.
h = height of the tide referred to mean sea level at any point, x, corresponding to any time, t.
H = height of the tide at the summit of the wave (Point x), at the time, t_m.
H_0 = maximum height of the generating wave (and, consequently, of the derived wave) at the canal entrance; H_1, H_2, H_3, etc., denote the value to which H_0 becomes reduced by friction in the first, second, third, etc., passages of the simple derived wave of translation. They each have different values for each value of x.
h_v = velocity height, or the height of a simple wave of translation which, by itself, would create a velocity, V.
K = a constant.
l = width of the canal at sea level.
L = length of a wave.
M = surface area of a reservoir.
p = wetted perimeter of any cross-section at mean sea level.
Q = the discharge.
R = a staff reading.
t = time, in seconds, counted from the instant of high water at the canal entrance.
t_m = time at which maximum high water occurs at the point, x. It is, therefore, the time required for the resultant wave to be propagated from the entrance of the canal to the point, x. t_1, t_2, t_3, etc., denote the time required for the wave of translation and the second, third, etc., reflected waves to reach the point, x, counted from the instant, $t = 0$.
t_{mv} = time of occurrence of the maximum velocity at a point, x. It is, therefore, the time required for the maximum resultant velocity to be propagated from the entrance of the canal to the point, x.
T = total tidal period from one high water to the next (44 715 sec.).
t_x = time required for the crest of the wave to travel from the entrance of the canal to the point, x, in question.
t_y = time required for the propagation of a reflected negative wave from the reservoir toward the sea to a point, x.
t_L = time required for the positive wave to be transmitted from the sea to the reservoir.
u = velocity of any current of water not of tidal origin.
U = horizontal displacement of the water molecules.
v = actual velocity of the water at any time, t, and at any point, x.
V_m = maximum velocity at any point corresponding to the time, t_{mv}.

V_0 = velocity at the entrance to the canal corresponding to the height, H_0. V_1, V_2, V_3, etc., equal the velocities at any point, x, due to the passage of a wave of translation, or the second, third, etc., reflected simple waves of translation, with heights equal to H_1, H_2, H_3, etc.

V_h = velocity due to height, h, in an infinitely long canal.

x = abscissa on the sine curve, or the distance required for wave propagation in the canal.

y = ordinate on the sine curve.

Y = height of water above the mean level of the canal, due to the propagation of a wave of translation at any instant, t, counted from the time of high water in the tidal sea.

ρ = density of the water.

WAVES

To treat of this subject, it is first necessary to determine the character of the flow through canals subject to tidal influences. Most textbooks treat only of the flow of water under the influence of a surface slope, without much reference to tidal influences and the manner in which their effects are manifested. Tidal currents are sometimes attributed to the effects of the surface slope of the tidal wave, but both theory and observation disprove that explanation. Omitting from consideration for the present all questions of fresh-water flow or discharge, and taking into consideration only the flow directly attributable to tidal influences, consider the manner in which such influences are manifested.

All tidal action in coastal waters is clearly generated by the great ocean tidal wave formed directly under the combined attraction of the moon and the sun. This great wave gives rise to other waves which are propagated in greater or less degree to all waters connected with the sea at a suitable level. This paper is not concerned with any of the theories of the action of the ocean tide, except as it is manifested along the coast line, usually in a semi-diurnal rise and fall, during which the graph of the surface variations is approximately a cosine curve.

The only waves of importance affecting tidal canals besides the tidal waves are wind waves, or secondary waves generated by wind waves, and these are too irregular and variable to be considered herein.

Waves of Oscillation.—Every force which acts upon a liquid mass develops waves in it, among which waves of oscillation and waves of translation may be distinguished.

Waves of oscillation occur whenever the water is subjected to a vertical force which causes a momentary depression or elevation upon a relatively extensive area of the surface. They may be ordinary or periodical. Periodical waves follow each other like ordinary waves, but each has its own particular cause; their periodicity is inherent in the force which acts upon the water, and which produces a wave each time it acts. The undulations of the water oscillate above and below the level of equilibrium, and are of the same height or semi-amplitude in both directions.

The agitation produced by waves of oscillation makes itself manifest below the surface of the water. Undulations of the same length as those upon the surface occur in the body of the water, but their amplitude diminishes from the surface. Waves of oscillation, therefore, cause motion in the water only for a limited depth.

Two different undulatory motions, which occur together in a liquid mass, are propagated independently of each other, without coalescing. The resultant wave has a different form from that of the two components; the variation of the level of the water at any given point is the algebraic sum of the superelevations and depressions due to the two waves. The heights are added together or subtracted according as they are above or below the mean level.

Waves of Translation.—A wave of translation will originate in the waters of a canal, at the extremity of which there has been introduced suddenly a given mass of liquid, or when there has been impressed upon a transverse section an instantaneous effect of compression. Thus, a laden boat in motion, on entering into a narrow section of the canal, of sufficient length, carries before it a certain quantity of water, and should the boat stop abruptly, the intumescence thus formed above the surface of the water detaches itself, becomes an undulation, and continues its progress in the direction of the motion of the boat.

The wave of translation is single for each effort imposed upon the liquid mass; for this reason it is also called the solitary wave. It has the characteristic of being contained entirely above the surface of the water.

The most notable experiments which have been made upon the solitary wave date from 1837 and are due to Sir Scott Russell;[3] the results which he obtained have been confirmed by Bazin.[4] The works of these two scholars have disclosed the different properties of waves of translation.

Although the horizontal force which creates such a wave may act upon only a portion of the water, the wave spreads over the entire width of the surface, and puts the entire mass of liquid in motion from top to bottom.

When the wave is propagated in a canal of variable cross-section, it takes a greater height at the narrow points, while it becomes lower in the places where the canal is wider; but it always occupies the entire section of the canal.

In still water of sufficient depth each wave produced by a force exercising pressure on the liquid mass in the horizontal direction gradually takes a certain form which is distinguished by its great stability; this is influenced only by the attrition resulting from friction, which is quite slow.

The speed or velocity of propagation of the wave of translation, observed under these conditions, has for its expression,

$$C = \sqrt{g\,(D + h)} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

If the depth is variable in the same cross-section, the wave takes a single velocity of propagation corresponding to the mean depth of the section. In a wide rectangular canal, the waters of which are endowed with uniform motion, any wave of translation, when propagated in the direction of the current, takes a regular form, of remarkable longevity, which tends to approach that of the solitary wave traversing still water of constant depth. Its speed is given by the formula,

---

[3] Rept., Fourteenth Meeting, British Assoc. for the Advancement of Science, September, 1844, Lond., 1845.

[4] "Recherches Expérimentales sur la Propagation des Ondes," *Mémoires* des Savants Etrangers, Tome XIX.

$$C = \sqrt{g\,(D + h)} + u \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

For a wave which is propagated in a direction opposed to that of the current the formula becomes,

$$C = \sqrt{g\,(D + h)} - u \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

In this case the wave soon departs from the original regular form, differing more as the current is swifter, and when the speed has diminished to the point of approaching the velocity of the current, it loses its vitality rapidly, the mass of water composing it being gradually dissipated in the current.

Boussinesq has determined by analysis a general theoretical formula which permits the computation of the speed of each layer, $d\,x$, of a wave of translation, when the wave has not acquired the permanent form which is assumed in the case of the experimental formulas, Equations (1), (2), and (3), which assume the same speed for all layers. Boussinesq's formula[5] is,

$$C^2 = g\left(D + \frac{3\,h}{2} + \frac{1}{h}\,\frac{D^3}{3}\,\frac{d^2\,h}{d\,x^2}\right) \ldots\ldots\ldots\ldots\ldots\ldots(4)$$

Among all the intumescences of various forms the propagation of which may be imagined, there is one for which the heights, h, and the curvatures, $\frac{d^2\,h}{d\,x^2}$, are so distributed that the speed of propagation is the same for all its elements. That is the solitary wave—the wave of translation—studied by Sir Scott Russell.

Tidal Waves in the Sea.—Tidal waves in the open sea take the form of waves of oscillation. The propagation of the wave sets up currents due to the displacements of the liquid involved in the motion. Tidal currents have no relation to the surface slope of the water; they are exclusively undulatory phenomena.

Tidal currents in shallow waters near the shore line are mass currents, acting for the entire depth of the sea; they are directed successively in the direction of travel of the undulation, and then in the opposite direction. They are called flood currents in the former case and ebb currents in the latter. They are alternating currents; barely perceptible in the deep sea, they increase in intensity as the depth of water diminishes. The currents sometimes become gyratory because of the combination of longitudinal currents with lateral currents which come and go, corresponding to the alternate rise and fall of the water on shore, or of the crossing of two co-existent waves the directions of which intersect at an angle.

The stage of the tide that corresponds to the moment when flood and ebb currents cease to run (and when they are about to be replaced by currents in the opposite direction) has received the name "flood slack", or "ebb slack", as the case may be. Under normal conditions the tidal wave is periodical and its curve takes a regular sinusoidal form; the currents which it generates turn at mean tide level, reaching their maximum velocity or strength at high or low water. These phenomena are completely modified when the depth decreases rapidly, and the propagation of the wave is hindered or checked in its travel, as in approaching the coast line, in estuaries, and especially in tidal rivers.

---

[5] "Essai sur la Théorie des Eaux Courantes," par J. Boussinesq; see, also, "Hydraulique," par A. Flamant, Paris, 1923, pp. 433–435 and pp. 438-440.

In general, near the coast line, the situation is intermediate between the state of free propagation of the tidal wave, and that of filling a basin of small dimensions; the regimen of the tide becomes changed. The reversal or turn of the tide is then no longer effected at mid-tide, but approaches closer to the times of high and low water, and the maximum velocity approaches mid-tide. The velocities then differ from their theoretical value and, in order to interpret the phenomena observed, one is tempted at times to have recourse to considerations based upon the hydraulics of running water and the influence of surface slope. Under these conditions the tidal wave loses its usual characteristics, entirely or in part, and in order to account for observed facts, it must be considered as formed by a series of small waves of translation each of which is propagated according to its own proper law.

Waves in Tidal Channels.—In the propagation of a wave there is only a simple transmission of motion, during which the molecules of water are successively raised and lowered on the passage of a wave, without participating in any way in its velocity of propagation. These transmissions of motion cannot take place without being accompanied by transportation of liquid molecules occurring step by step in the horizontal direction, which gives rise to currents in the direction of propagation.

For waves in tidal channels, the horizontal force which produces them resides in the rise of the tide at the mouth. The derived wave in tidal channels is not a tidal wave in the sense in which that term is used in connection with the ocean tidal wave; it is not a periodic wave of oscillation, a chop, or a seiche. It exhibits the traits of a simple wave of translation, resembling it notably in the means of its formation, but differing from it as soon as the conditions of propagation are considered. The velocity of propagation of the derived wave is generally less than is indicated by the usual theoretical formulas. Furthermore, in the true simple wave of translation, all the velocities are in the same direction, whatever point of the wave is considered, while in the derived wave the currents flow alternately in one direction and then in the other, and the velocities may be greater or less than for a simple wave of translation.

The various discrepancies, however, are more apparent than real, and arise from the fact that formulas for the speed and velocity of the wave of translation, such as Equations (1) to (4), inclusive, are applicable to small waves which are propagated in relatively wide and deep channels. In cases of this kind the influences of resistances and of reflections are inappreciable. The equations are not applicable to waves of which the height is comparable to the depth of the channel and which are propagated in short, crooked channels with irregular banks. These conditions offer very great resistance to the propagation of the wave. It is to these resistances and to reflections within the channel that the discrepancies observed between the behavior of the derived wave and that of small simple waves of translation, must be attributed.

Effect of the Canal on Waves in It.—Accepting these conclusions as to the identity of the canal wave with the wave of translation, such a wave entering into a canal from another body of water will be confronted by a set of conditions differing from those prevailing when it enters a tidal river or estuary from the sea. Its character is changed by the expenditure of energy necessary to overcome each resistance to its progress, and this expenditure must then cause either a diminution of the volume of the wave, a reduction of its height, or both simultaneously.

A tidal river or estuary will always be found closed at its upper end. This limits the distance in which the wave may be propagated and it limits the volume of the wave that may be propagated past any given point. In such cases the wave may also be opposed by a large fresh-water discharge. In addition to friction losses, the usual funnel shape of the river or estuary causes a continual decrease in the volume of the wave. Such lost volume, together with friction losses and any fresh-water discharge, is ejected down stream.

These conditions, however, are not usually encountered in a canal. The canal is not ordinarily of a funnel shape; it is usually of constant depth and cross-section. There is seldom any fresh-water discharge to be considered.

The physical characteristics of a canal have a preponderating influence upon the propagation of the tide within it. Assuming a horizontal canal of constant width and depth, communicating at one end with a body of tidal water, the character of the tide within the canal will be further controlled by the length of the canal and the character of the body of water with which it communicates. In this study it will be assumed that the canal communicates at its far end with some body of water, and is not merely a closed channel.

Regardless of the length of the canal, three cases will arise with respect to the body of water with which it communicates:

(1) The body of water may be at a constant level;
(2) It may vary in level due to tidal flow through the canal; and
(3) It may vary in level due to a proper tide of its own.

Case (1), as stated, implies a non-tidal reservoir sufficiently large in area so as not to be affected appreciably by any tidal flow it may receive through the canal. Case (2) may be a rather small reservoir which will be partly filled and emptied through the canal at each tide. In Case (3) the canal will be the meeting place of two opposed independent waves, the phases and amplitudes of which may differ widely.

These three comprise practically all cases of tidal flow in canals. The flow in tidal rivers and estuaries will not be included in this study. However, before beginning these practical studies, it is necessary to consider the theory of tidal action in a canal of infinite length, in order that the theory may be of assistance.

The Theoretical Canal, Infinitely Long

An infinitely long canal is a fiction that has been invented to meet the necessities of theory. Except in rare instances, such as the Amazon River, the St. Lawrence River, or Chesapeake Bay, the length of channel influenced by the tide does not exceed that of an entire wave. It is nevertheless of interest to follow scientists into the hypothetical domain and to examine the theoretical regimen of the tide in such a canal assuming that its bottom is horizontal and that its cross-section remains constant for its entire length. Under these restrictions the question has been treated by several investigators, and it is of interest to review the results at which they have arrived.

Theory of Airy.—Airy has devoted an important work[6] to the general study of the tides and of waves of different kinds, in which he has discussed in the greatest detail the circumstances of the propagation of the tidal wave in tidal rivers and estuaries. The results which he obtained may be summed up in the following equations:

$$h = H_0 \sin \frac{2\pi}{T}\left(1 - \frac{x}{\sqrt{g H_0}}\right) + \frac{3}{4}\,\frac{2\pi H_0^2}{T D} \sin \frac{4\pi}{T}\left(t - \frac{x}{\sqrt{g H_0}}\right) \ldots (5)$$

The speed or velocity of propagation of the wave equals, at high-water stand,

$$C = \sqrt{g\,(D + 3\,H_0)} \ldots\ldots\ldots\ldots (6)$$

and at low-water stand,

$$C = \sqrt{g\,(D - 3\,H_0)} \ldots\ldots\ldots\ldots (7)$$

The horizontal displacements of the molecules, which are the same from the bottom to the surface, are:

At high-water stand,

$$v = \left(1 - \frac{5\,H_0}{8\,D}\right) \frac{H_0}{D} \sqrt{g\,D} \ldots\ldots\ldots\ldots (8)$$

and at low-water stand,

$$v = \left(1 + \frac{5\,H_0}{8\,D}\right) \frac{H_0}{D} \sqrt{g\,D} \ldots\ldots\ldots\ldots (9)$$

Airy gave the changes to be made in these formulas when the water has a seaward current and when its depth is variable. He recognized that a bore should occur in such a case unless an additional horizontal force should intervene to combine its action with that of gravity, and he suggested that friction might supply such a force. He attempted to evaluate the influence of friction of the liquid on the bottom of the canal, assuming it to be proportional to the velocity, but he found that an evaluation thus made, did not possess the desired reliability for use in practice; nor was it capable of explaining the phenomena noted by observation.

Theory of Saint-Venant.—Saint-Venant has treated the same question[7] based upon a hypothesis previously proposed by Bremontier and confirmed by Bazin and Partiot. It consists in considering the tidal wave (which is of the class termed "periodical") as the result of the superposition of a series of very small waves of translation being propagated according to the laws established by Scott Russell and developed by Bazin. During the flood wave, these elementary waves would be formed by intumescences or fluxes, and during the ebb by depressions or refluxes.

---

[6] "Tides and Waves," Encyclopedia Metropolitana, Vol. V, 1845, p. 241.

[7] *Comptes Rendus* de l'Academie des Sciences, Vol. LXXIII, 1871, pp. 147 and 189.

Under this hypothesis, and neglecting the influence of friction upon the walls of the canal (assumed to be rectangular), he obtained the following results:

$$v = 2\sqrt{g(D+h)} - 2\sqrt{g(D-h)} \quad \ldots\ldots\ldots\ldots (10)$$

$$C = 3\sqrt{g(D+h)} - 2\sqrt{g(D-h)} = v + \sqrt{g(D+h)} \quad \ldots\ldots (11)$$

and,

$$x = C\left(t - \frac{T}{\pi}\, \text{arć sin} \sqrt{\frac{2h}{D}}\right) \quad \ldots\ldots\ldots\ldots (12)$$

Theory of Maurice Lévy.—The theory of Saint-Venant was verified and confirmed by Maurice Lévy[8] who also treated the general question of the regimen of the tide in canals both of constant and of variable width. He made an application of the theory to river tides in the case in which the width is constant or slowly variable, due regard being given to the friction exerted upon the tidal wave.

He established the principles that:

1.—The wave is propagated with a decreasing height according to a definite coefficient of extinction.

2.—The velocity of propagation is given by a simple expression as a function of the height of the tide and of the depth of the water in the canal at half-tide.

3.—The strength of the current occurs before the high and the low waters, and its value diminishes as the point considered is farther from the mouth.

His results are more in accord with the results of observation than those of the others. The superiority of his theory arises principally from the fact that Lévy has succeeded in taking into account the effects of friction which Saint-Venant had neglected and which Airy thought inadequate to explain the discrepancies between facts and the results of his analysis. This influence of friction upon the phenomena of the tide, formerly regarded rather vaguely, is now an established fact. It can be computed in a fairly precise manner, under simple circumstances, it is true, but nevertheless in such a way as to permit rational inductions to be made for the most complicated cases.

In attempting to apply his equations to the Suez Canal, Lévy found that the computed values of the velocity were far less than the actual velocities, particularly at the end next to the Bitter Lakes. He attempted to remedy this discrepancy by the use of equations to a second approximation, but still without a complete agreement with observation.

The theory of Lévy is quite fully set forth and explained in an article[9] on the Cape Cod Canal by the late William Barclay Parsons, Hon. M. Am. Soc. C. E. This paper gives the deduction of Lévy's equations and makes a practical application of them to the Cape Cod Canal. Recognizing that the frictional coefficient is not a constant quantity, but varies slightly in an inverse ratio with the velocity, Mr. Parsons proposed a frictional coefficient which, as a linear function of the mean velocity, will absorb the same total energy in the interval during which the velocity changes from zero to maximum.

[9] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), pp. 1–157.

Writings of Bourdelles.—In a remarkable series of memoirs,[10] M. Bourdelles, Inspector-Général des Ponts et Chaussées, has fully and clearly set forth the theory of the propagation of waves of translation in canals, and has pointed out how closely observed facts confirm that theory. Bourdelles' exposé of the theory is so clear and vigorous that much of what follows has been adapted from his writings. However, Bourdelles, as well as Lévy, was unable to explain satisfactorily certain anomalies of velocities observed at points where canals empty into tideless seas. In such cases, where the observed velocities exceeded the computed velocities, those authors explained the anomaly by attributing it to the influence of flow due to surface slope in the undulatory motion of the tide. The writer advances the theory of a reflected negative wave to explain it.

Tidal Rivers.—M. Bonnet, Chief Engineer and Director of the Ponts et Chaussées of Belgium, has made a most valuable contribution[11] to the theoretical study of tidal rivers. He treats the propagation of the tidal wave as a wave of translation continually modified by friction (which he evaluates) and by the shape of the bed. These causes which act to reduce the energy of the wave give rise to a current directed down stream the volume of discharge of which represents at each instant the volume of water lost in a unit of time by the portion of the wave which has passed into the river. This he terms counter-current. He also shows that the propagation of the wave of translation and the action of the counter-current permit an explanation of all the characteristics of the river tide. Bonnet's method of showing how the energy of the wave is reduced by friction has been adopted in this paper, with necessary modifications.

Propagation of Elementary Waves of Translation in an Infinitely Long Canal.—Assuming that the tidal wave entering a canal is a wave of translation, it is necessary to consider some of the properties of the latter. To do so intelligently, the first step is to study the propagation of such a wave in a canal of constant depth and cross-section, but of infinite length.

Suppose the water is without motion at the moment of the introduction of the first flux emitted by the tidal wave on the flood. In Fig. 1, which represents a longitudinal profile of the canal, $A\,B$ is the mouth with a mean depth, D; $A\,M$, the horizontal level of the water in the canal at low water; and $h = A\,a$, the height of the first flux the propagation of which is being studied.

By virtue of the properties of the wave of translation, after a time which will be assumed as unity, this flux, propagating itself with a speed of $C = A\,M$, will have arrived at $M\;N$, introducing into the canal a volume, $A\;a\;m\;N = C \times h$ per unit of width, and in impressing upon all the vertical filaments of the canal a horizontal displacement of translation the velocity of which will be designated by v. This displacement will have the effect of moving the molecules of water of the section of the mouth, BA, to $B'A'$, and of introducing into the canal a volume, $Baa'B' = v(D+h)$. Since this volume is necessarily equal to that of the flux, $Ch = v(D+h)$, or,

$$v = C\frac{h}{D+h} \qquad (13)$$

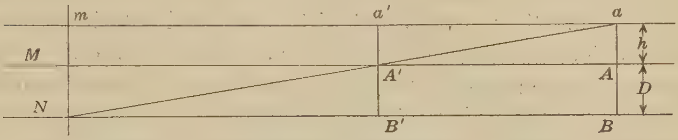

FIG. 1.—LONGITUDINAL PROFILE OF A CANAL.

Thus, a known relation is found between the velocity of displacement common to all the molecules and the speed of the undulatory motion which causes this displacement. Furthermore (see Fig. 1), the velocity is represented by the right line, AA', since $\frac{h}{D+h} = \frac{AA'}{BN} = \frac{A'A}{C}$. The effect of the undulatory motion thus becomes quite clear. The impetus is propagated successively to all the vertical filaments of the canal with a rapidity equal to the speed, giving to each of these filaments the same velocity, so that the compression of the water comprised between two neighboring filaments produces the height of the flux corresponding to it. Hence, the total compression, equal to the volume of the flux, provokes an equivalent supply of water through the mouth.

Fig. 1 also demonstrates that, for the same depth, D, the supply of water to the canal and the horizontal displacements increase with the height of the flux. The same is true when (the height of the flux and the mean depth remaining constant) the speed is nevertheless increased by extraneous circumstances.

It is to be noted finally that, in the infinitely long canal, the first flux will continue to be propagated during the entire period of the flood until the moment when the ebb, beginning to be formed at the mouth, will be opposed to the introduction of the necessary water for the supply of the flux. In spite of this obstacle, it will be able, however, to continue its propagation to some degree; but then the action of friction will result in the gradual diminution of its height and its final extinguishment.

It is needless to add that all that precedes is also applicable to the refluxes on the ebb. There is no difference except in the lesser speed of the propagation and also in the mode of supplying the wave volume. This is effected by expelling water from the canal, creating a current which is opposite in direction to that of propagation.

Friction has the effect of diminishing the height, the speed, and the velocity of a flux or of a reflux, by an amount proportional to the velocity and to the duration of the undulatory motion.

The first flux will be propagated during the entire flood tide, under the conditions just indicated. The second flux will be propagated in the same manner as the first, with the difference, however, that it will flow in the current created by the preceding flux, which will increase its normal speed by a quantity equal to the velocity of that current. It is the same for the other fluxes which follow, up to the moment of high water, so that the velocity of the flood current will continue to increase in all parts of the canal during the rising tide.

Beginning with the moment when the tide begins to fall, the refluxes will travel from the mouth into the canal with speeds and velocities almost equal to those of the fluxes corresponding to the same height of the tide. When the fluxes cease to be propagated during the ebb, they will be extinguished successively by the corresponding refluxes, the summation of the effects of which will accordingly be to evacuate to the sea, almost completely, a quantity equivalent to the water introduced by the flood. The fluxes continue their propagation, however, when the length of the canal allows it, and they will escape entirely from the action of the refluxes if the length of the canal is infinite. Under the hypothesis as defined, therefore, it is apparent how a portion, or even all, of the volume, introduced by the fluxes, may remain in the canal after the end of the ebb, without being evacuated by the succeeding refluxes. Then the surface of the canal becomes a succession of positive and negative waves of translation, both being propagated in the same direction. The positive waves leave each particle of water moved forward a distance dependent upon the volume of the wave, and each succeeding negative wave, if it is of equal volume, returns the particle to its original location. If for any reason, such as increased frictional resistances, the negative wave should not equal the positive wave in volume, the particle will suffer a permanent displacement in the direction of propagation after the passage of each positive wave and its succeeding negative wave.

Friction.—The sum of all friction losses in the water flowing in an open canal—whether flowing under the influence of a surface slope or under the impulse of the propagation of a wave of translation—may be reduced to the friction on the sides and the bottom of the canal, which is to say, on the wetted perimeter.

Observation has resulted in the formulation of general laws as to friction losses. For example, they are proportional to the length of the channel; they increase with the roughness of the walls; they decrease as the mean depth increases; they increase nearly as the square of the velocity; and they are independent of the pressure of the water.

It is usually assumed that the friction per unit of wetted surface may be represented by,

$$F = f_0 \, v^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

In this study, F will be considered as a constant for any canal, and will be given such value as shall have been found experimentally sufficient to reduce the summit of each wave to its observed value.

The reason for this is that the coefficient of friction is applied only to the value of the maximum height or summit of the wave to determine its value at a given point in the canal, and the remaining heights are assumed to be found from this maximum height by the cosine curve. As this maximum height varies quite slowly from point to point under the influence of friction, the corresponding maximum velocities do not vary rapidly. Accordingly, the value of the frictional coefficient varies slowly enough to be considered as constant without any great error.

The influence of friction is manifestly of more importance as the depth of the channel becomes smaller. In a narrow strait, several hundred feet deep, it might be negligible, but in artificial canals and the more prevalent tidal channels, it has a great effect.

Effect of Friction in Reducing Height of Wave in an Infinitely Long Canal.—It has been established experimentally that, in the case of a long flat wave of translation, with little curvature (as in the case of a tidal wave of translation), the speed of propagation, C, may be found from the so-called Scott-Russell formula (Equation (1)). The current velocity, v, may be represented by,

$$v = C \frac{H}{D + H} \quad \text{(15)}$$

When the velocity of propagation is not very great, and when only the interior frictional resistances of liquids are considered as a main cause, the resistance due to friction per unit length of wave is equal to $F\,p\,v$.

The theoretical value of v is expressed by,

$$v = \sqrt{g\,(D + H)} \times \frac{H}{D + H} = \frac{\sqrt{g}\,H}{\sqrt{D + H}} \quad \text{(16)}$$

Hence,

$$F\,p\,v = \frac{F\,p\,\sqrt{g}\,H}{\sqrt{D + H}} \quad \text{(17)}$$

The elementary work of frictional resistances during the time, dt, represented by dF', is,
